Stability. Despite one report[1] that fluorouracil had limited stability when dissolved in glucose 5% at room temperature (10% loss from solution in 43 hours when stored in PVC and in only 7 hours when stored in glass), others[2] found such a solution to be stable for at least 16 weeks when stored in PVC at 5 degrees. When stored at room temperature in PVC, solutions of fluorouracil may lose water by evaporation, which slowly increases their concentration.[2,3] Results of a study of fluorouracil and methotrexate admixtures in sodium chloride 0.9% suggest that extended stability (up to 13 weeks) is possible in this diluent at 5 degrees in PVC bags.[3] Commercial solutions of fluorouracil for injection have been reported to be stable for 7 days at 37 degrees in a portable infusion pump, although at 25 degrees one brand showed evidence of precipitation.[4] Fluorouracil solutions may be incompatible with synthetic elastomers: microscopic precipitation has been reported as soon as 4 hours after placement into polyisoprene reservoirs of elastomeric infusers and in polypropylene syringes with an elastomeric joint.[5] Some have questioned the validity of this finding.[6,7]

Uses and Administration

Fluorouracil, an analogue of the pyrimidine uracil, is an antineoplastic that acts as an antimetabolite. After intracellular conversion to the active deoxynucleotide it interferes with the synthesis of DNA by blocking the conversion of deoxyuridylic acid to thymidylic acid by the cellular enzyme thymidylate synthetase. It can also interfere with RNA synthesis.

Fluorouracil is used alone or in combination in the adjuvant and palliative treatment of gastrointestinal cancer. In this setting it may be combined with folinic acid (see Administration, p. 796.1). Fluorouracil is often given with cyclophosphamide and methotrexate or doxorubicin in the adjuvant treatment of breast cancer. It may also be used in the palliation of other malignant neoplasms such as those of the head and neck, liver, and pancreas. In addition, it may be used topically for treating malignant or premalignant lesions of the skin. Its use in these malignancies is further discussed under Choice of Antineoplastic as indicated by the cross-references given below.

Many dosage regimens have been used. Although it is most often given in combination regimens for the treatment of malignancy, many of the licensed dosage regimens relate to single-agent use. Such licensed regimens include:

- by *intravenous injection*, usual doses of 12 mg/kg daily (to a maximum of 0.8 to 1 g daily) for 3 or 4 days. If there is

no evidence of toxicity, this may be followed after 1 day by 6 mg/kg on alternate days for 3 or 4 further doses. An alternative schedule is to give 15 mg/kg intravenously once a week throughout the course. The course may be repeated after 4 to 6 weeks or maintenance doses of 5 to 15 mg/kg to a maximum of 1 g may be given weekly.

- by *intravenous infusion*, usual doses of 15 mg/kg daily (to a maximum of 1 g daily) being infused in 500 mL of sodium chloride 0.9% or glucose 5% over 4 hours and repeated on successive days until toxicity occurs or a total of 12 to 15 g has been given. *Continuous infusion* may also be used. The course may be repeated after 4 to 6 weeks.
- by continuous *intra-arterial infusion*, in doses of 5 to 7.5 mg/kg daily (regional perfusion).
- by *mouth*, although the parenteral route is generally preferred, a dose of 15 mg/kg, to a maximum of 1 g in one day, has been given once weekly for maintenance. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Suggested regimens with folinic acid include:

- 200 mg/m^2 of folinic acid (as calcium folinate) by slow intravenous injection followed immediately by an intravenous bolus of fluorouracil 370 mg/m^2; the treatment is given daily for 5 consecutive days, and may be repeated every 4 to 5 weeks
- lower doses of folinic acid (20 mg/m^2) followed by fluorouracil 425 mg/m^2 for 5 consecutive days, repeated every 4 to 5 weeks (the Mayo regimen)
- an initial dose of 200 mg/m^2 of folinic acid, followed by fluorouracil 400 mg/m^2 as an initial intravenous bolus injection and then 600 mg/m^2 by continuous intravenous infusion. This dosage is given for 2 consecutive days every 2 weeks (the de Gramont regimen)

The white cell count should be determined frequently during treatment with fluorouracil and therapy stopped immediately if the count falls rapidly or if the white cell or platelet count falls below acceptable levels (see also Bone-marrow Depression, p. 730.3) or if severe adverse effects occur. Doses should be reduced by up to half in patients with poor nutritional status, impaired bone-marrow, hepatic, or renal function, and within 30 days of major surgery.

Fluorouracil is used *topically* in the treatment of solar (actinic) keratoses and other superficial tumours and premalignant conditions of the skin including Bowen's disease and superficial basal cell carcinomas. For actinic keratosis it is usually applied as a 0.5 to 5% cream or as a 1 to 5% solution in propylene glycol once or twice daily for 2 to 4 weeks; the higher strength may be applied for at least 3 to 6 weeks for superficial basal cell carcinomas.

Administration. For reference to sequence-specific toxicity when fluorouracil and folinic acid were given before capecitabine, see Administration, under Capecitabine, p. 758.1.

MODULATION. Modulation of fluorouracil by other drugs has been tried in an effort to enhance its effects, particularly in the treatment of colorectal cancer (p. 706.3).

Folinic acid has been extensively used to modulate the effects of fluorouracil, and has become the agent of choice. Various regimens have been used, modifying the fluorouracil schedule (continuous infusion versus bolus), folinic acid dose (low-dose versus high-dose) and the regimen frequency (monthly, bimonthly, or weekly). Despite many studies, the optimum regimen in terms of efficacy and tolerability has yet to be determined.

In the adjuvant setting, a large-scale randomised study[1] found low-dose folinic acid was as effective as high-dose when added to fluorouracil given either once weekly for 30 doses, or for 5 consecutive days per month over 6 months.

In the palliation of advanced disease, meta-analyses have revealed the value of the addition of folinic acid to fluorouracil,[2] and the use of infusions rather than bolus fluorouracil,[3] in terms of response rates. An updated meta-analysis confirmed the benefit of addition of folinic acid to fluorouracil in terms of response rate, and found a small but statistically significant advantage in terms of overall survival. Survival benefit was restricted to studies using the same dose of fluorouracil in the treatment arms (fluorouracil alone versus fluorouracil and folinic acid), suggesting that the benefit of modulation with folinic acid could be compensated by an increase of fluorouracil dose in the fluorouracil alone arm. However, increased toxicity from high-dose fluorouracil might occur.[4] The data for low-dose folinic acid versus high-dose are less clear.[5] In 1 randomised study,[6] a bimonthly infusion regimen of fluorouracil plus high-dose folinic acid (the de Gramont regimen[7]) was more effective than a monthly bolus regimen of fluorouracil plus low-dose folinic acid. Further studies comparing the effect of high- and low-dose folinic acid added to the same schedule of continuous infusion fluorouracil are required.

10. Advanced Colorectal Cancer Meta-analysis Project. Meta-analysis of randomized trials testing the biochemical modulation of fluorouracil by methotrexate in metastatic colorectal cancer. *J Clin Oncol* 1994; 12: 960–9.

Interferon alfa also appears to modify[8] the actions of fluorouracil (see also under Interactions, p. 797.3), and has been investigated with fluorouracil and folinic acid. Although some early results were promising, later randomised controlled studies failed to show any benefit for the addition of interferon alfa to fluorouracil or fluorouracil plus folinic acid.[8] It is not clear whether interferon beta will prove of any greater benefit.

Based on the results of early adjuvant studies, *levamisole* was used as standard therapy to modulate fluorouracil, particularly in the USA. However, more recent studies indicate that levamisole is no more effective than placebo when added to fluorouracil,[1] or to fluorouracil plus folinic acid.[9]

Methotrexate has also been used to modulate fluorouracil. Meta-analysis of several studies of fluorouracil preceded by methotrexate found that the combination doubled the response rate to fluorouracil in metastatic colorectal cancer and produced some survival benefits.[10] (Combination in the reverse order, i.e. methotrexate preceded by fluorouracil, may reduce methotrexate toxicity—see Other Drugs, under Treatment of Adverse Effects, p. 827.1.)

ROUTE. Fluorouracil can be given orally, parenterally, or topically (see Uses and Administration, p. 795.3); it has also been used intralesionally and intraurethrally in the treatment of condyloma acuminata, see Warts, below.

Administration in the elderly. A review[1] concluded that there is no pharmacokinetic basis for dose modification of fluorouracil based on age alone; data are conflicting as to whether toxicity is likely to be increased in elderly patients.

Darier's disease. Two patients with resistant Darier's disease (p. 1683.2) receiving long-term oral retinoid therapy responded to treatment with topical fluorouracil applied as a 1% cream once daily.[1] There was complete clearance of skin lesions after 3 weeks of treatment. In another case,[2] topical fluorouracil 1% cream applied every second day, alternating with clobetasol ointment, dramatically improved hyperkeratosis after 1 month; improvement persisted for 2 months after the end of treatment. Fluorouracil 1% cream has also been used as monotherapy,[3,4] leading to marked improvement or complete remission after about 4 weeks of therapy.

Eye disorders. Aside from its use in glaucoma surgery (below), fluorouracil has been used adjunctively in other ocular surgery. It has also shown promising results in the treatment of ocular surface malignancies.[1]

1. Abraham LM, *et al.* The clinical applications of fluorouracil in ophthalmic practice. *Drugs* 2007; 67: 237–55.

Glaucoma. A regimen of subconjunctival injections of fluorouracil is effective in improving the outcome of glaucoma filtering surgery[1-3] in selected patients when used as an adjunct to prevent the formation of scar tissue (see p. 1999.1). However, in view of the increased risk of late-onset conjunctival wound leaks caution has been suggested in its use in eyes with a good prognosis.[3] Although one study[4] found that fluorouracil improved the success of combined glaucoma filtering surgery and cataract surgery earlier studies had failed to find any advantage.[5,6] A systematic review[7] of these and 2 other studies concluded that fluorouracil reduced the risk of surgical failure of trabeculectomy in eyes at high risk of failure, and in those undergoing surgery for the first time, but noted that the methodological quality of the studies was not high, and that this practice has largely been superseded by the use of intra-operative mitomycin. However, a later survey[8] in the UK found that the use of antimetabolites in glaucoma surgery was much less common than in the USA or Japan, and that fluorouracil was strongly preferred to mitomycin.

Intra-operative topical application of fluorouracil has been tried as an alternative to subconjunctival injection with conflicting results.[9-11]

Malignant neoplasms. Fluorouracil plays an important role in the adjuvant treatment of gastrointestinal cancer, as discussed on p. 705.2, and has been widely used in adjuvant regimens for early breast cancer (p. 702.1). It may also be employed in the management of several other malignancies including pancreatic endocrine tumours (p. 716.3), cancers of the cervix (p. 704.2) and head and neck (p. 708.1), liver metastases (p. 709.3), and tumours of the exocrine pancreas (p. 712.1). It is reported to have only modest activity in neoplasms of the kidney (p. 708.3). In addition, it is sometimes applied topically as part of the management of malignant or pre-malignant lesions of the skin (see Basal Cell and Squamous Cell Carcinoma, p. 714.2), or surface neoplasia of the eye (p. 705.1).

The role of fluorouracil in chemoradiotherapy of various malignancies has been reviewed.[1]

Toxoplasmosis. For mention of the use of fluorouracil with clindamycin to treat cerebral toxoplasmosis, see p. 271.1.

Warts. Fluorouracil has been used, as a 1% or, more usually, a 5% cream or solution in the treatment of genital warts (condylomata acuminata).[1-3] It has been tried as an adjuvant to laser therapy in severe papilloma virus-associated vulvar disease,[4] with variable results, and in men with subclinical or clinically apparent penile lesions.[5] A preparation of fluorouracil 3% in a collagen gel basis, with adrenaline as a local vasoconstrictor, has been tried by injection into genital warts.[6] Fluorouracil has also been used intraurethrally to treat intraurethral warts; preparations have included instillation of a 1% solution, 5% cream, or a 5% suppository; urethral instillation of 250 mg fluorouracil injection mixed with 0.18% lidocaine hydrochloride gel has been reported to reduce the size and number of intraurethral condyloma acuminata in 1 patient, and no new growth was seen after 6 months of follow-up.[7] A combination of fluorouracil 0.5% and salicylic acid 10% has also been stated to be effective in the topical treatment of common and plantar warts.[8] Although the evidence was weak, a systematic review found fluorouracil to be better at curing genital warts than placebo, no treatment, or podophyllum resin; use with interferon alfa-2a, or with interferon alfa-2a and carbon dioxide laser

treatment may have a better outcome.[9] For a discussion of the various agents, including cytotoxics such as fluorouracil, used to destroy warts, see p. 1689.3.

Adverse Effects and Treatment

For general discussions see Antineoplastics, p. 726.1 and p. 730.2. The main adverse effects of fluorouracil are on the bone marrow and the gastrointestinal tract, and may be dose-limiting. Toxicity is also schedule dependent: a 5-day regimen is commonly associated with bone marrow suppression, diarrhoea, and mucositis, a weekly schedule with neutropenia. With protracted continuous infusion or high-dose boluses, the palmar-plantar erythrodysesthesia syndrome (erythema and painful desquamation of the hands and feet) may occur. Gastrointestinal toxicity may be exacerbated if fluorouracil is given with folinic acid.

Treatment should be stopped at the first sign of oral ulceration or if there is evidence of stomatitis, gastrointestinal ulceration and bleeding, diarrhoea, or haemorrhage from any site. Leucopenia is common; the nadir of the white cell count may occur from 7 to 20 days after a dose, and counts usually return to normal after about 30 days. Thrombocytopenia is usually at a maximum 7 to 17 days after a dose. It is recommended that treatment should also be stopped if falling blood counts go below 100 000 cells/mm^3 for platelets or below 3500 cells/mm^3 for white cells, but see also Bone Marrow Depression, p. 730.3. Anaemia may also occur. Nausea and vomiting are common, and may be treated with an antiemetic. Alopecia may be seen especially in females, but is generally reversible. Other adverse effects include dermatitis, changes in pigmentation, changes in the nails, ataxia, and fever. Thrombophlebitis has been reported. Ocular toxicity, including excessive lachrymation, dacryostenosis, visual changes, and photophobia can occur. A transient reversible cerebellar syndrome has been reported, and a reversible confusional state can occur rarely. Cases of leukoencephalopathy have also been reported. There have been reports of chest pain, tachycardia, breathlessness, and ECG changes after use of fluorouracil. Anaphylaxis has also occurred.

Local inflammatory reactions such as erythema, pain, pruritus, burning, irritation, and photosensitivity reactions have occurred after topical use. Telangiectasia, hyperpigmentation, and scarring have also been reported. Dermatitis and, rarely, erythema multiforme have occurred. Ocular irritation has also been reported after topical use.

Effects on the eyes. Systemic fluorouracil therapy has been associated with various types of ocular toxicity including several cases of excessive lachrymation and watering of the eyes.[1] In one patient this was associated with symptoms suggesting fibrosis of the tear duct,[1] and possibly representing local irritation due to the presence of fluorouracil in tear fluid,[2] although symptoms have not always resolved on stopping the drug.[1] More seriously a case of bilateral total corneal epithelial erosion has been described.[3] Optic neuropathy, culminating in near blindness, has also occurred in a patient given fluorouracil as part of a combination regimen.[4] Severe ulceration and corneal abscess with hypopyon has followed local injection of fluorouracil into the eye in a diabetic patient with idiopathic band keratopathy.[5]

5. Hickey-Dwyer M, Wishart PK. Serious corneal complication of 5-fluorouracil. *Br J Ophthalmol* 1993; 77: 250–1.

Effects on the heart. Life-threatening cardiotoxicity (arrhythmias, ventricular tachycardia, and cardiac arrest, secondary to transmural ischaemia) has been reported to occur in 0.55% of patients given fluorouracil,[1] although the incidence of angina and less severe cardiotoxicity associated with coronary artery spasm may be higher.[1-3] Possible risk factors include pre-existing heart disease or mediastinal radiotherapy, and prolonged infusion of the drug, but symptoms can also occur in patients without these risk factors.[2-5] Therefore, at present, it is not possible to reliably predict patients at risk.[6] Some suggest that the use of a trometamol buffer in the fluorouracil formulation may contribute to the formation of cardiotoxic degradation products.[7]

Effects on the nervous system. Central neurotoxicity, including cerebellar ataxia, confusion, disorientation, and emotional lability is reported to occur rarely in patients receiving fluorouracil, although the incidence may be increased with high-dose or intensive regimens. The dihydropyrimidine dehydrogenase gene may exist in variant forms[1] and patients with polymorphisms of this or other disorders of pyrimidine metabolism may be at increased risk of neurotoxicity.[2-4] It has also been suggested that fluorouracil may produce neurotoxicity by causing thiamine deficiency.[5] (Wernicke's encephalopathy has been reported[6]) and that thiamine may be used to treat it.[5,6]

Effects on the skin. In addition to reports of fluorouracil-associated dermatitis and photosensitivity a syndrome of erythema, pain, and desquamation of the skin of palms and soles has been reported[1-6] (the palmar-plantar erythrodysesthesia syndrome, p. 730.1). Although particularly associated with continuous infusion[1,2] the syndrome can also occur after bolus doses.[3,4] Symptoms generally respond to stopping the drug, but addition of oral pyridoxine to chemotherapy regimens has been reported to prevent or resolve symptoms,[5] as has application of a nicotine patch in one patient.[6]

Rash and confusion developing in an elderly man with malabsorption and poor nutritional intake who received fluorouracil for a biliary-tract tumour were diagnosed as pellagra.[7] Symptoms responded to nicotinic acid therapy.

Hypersensitivity. Although local hypersensitivity reactions are included in licensed product information as potential adverse effects of topical fluorouracil, hypersensitivity reactions to systemic fluorouracil have been reported very rarely.[1-6] For a report of the successful use of fluorouracil in a patient allergic to capecitabine, suggesting that cross-sensitivity does not occur between the two, see p. 758.2.

Precautions

For general discussions see Antineoplastics, p. 732.2. Fluorouracil should be given with care to weak or malnourished patients, to those with a history of heart disease, or to those with hepatic or renal insufficiency. Patients with a history of high-dose pelvic irradiation or treatment with alkylating agents, and those with widespread metastases to the bone marrow should also be treated with extreme caution. Blood cell counts should be determined frequently during therapy. Fluorouracil should not be used in patients with dihydropyrimidine dehydrogenase (DPD) enzyme deficiency as this can lead to increased toxicity.

Topical fluorouracil should not be used on mucous membranes. There is a possibility of increased absorption if used excessively or on ulcerated or inflamed skin. Occlusive dressings may increase inflammatory actions. Exposure to UV light during treatment should be avoided. Creams are preferably applied using a nonmetal applicator or gloved hand; if bare fingertips are used the hands must be washed immediately afterwards.

Handling and disposal. Fluorouracil is irritant; avoid contact with skin and mucous membranes.

Urine and faeces produced for up to 48 hours and 5 days respectively after an oral dose of fluorouracil should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Metabolic disorders. For reference to increased risk of neurotoxicity in patients with a defect of pyrimidine metabolism given fluorouracil, see under Effects on the Nervous System, above.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies fluorouracil as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

For a general discussion of antineoplastic drug interactions, see p. 733.3. The actions of fluorouracil may be modified by other drugs including allopurinol, cimetidine, folinic acid, methotrexate, and metronidazole (see also under Administration, p. 796.1). Fluorouracil and fluorouracil prodrugs should not be given with brivudine, sorivudine, and analogues as these are potent inhibitors of the enzyme dihydropyrimidine dehydrogenase (DPD) which degrades fluorouracil, and increased fluoropyrimidine toxicity can occur (see also Precautions, above, and Antivirals, below).

References.

1. Jansman FGA. *et al.* Assessing the clinical significance of drug interactions with fluorouracil in patients with colorectal cancer. *Am J Health-Syst Pharm* 2005; 62: 1788–93.

Antineoplastics. *Oxaliplatin*, which is given with fluorouracil and folinic acid in the treatment of colorectal cancer, reduced fluorouracil clearance in a study[1] of 29 patients with colorectal cancer. The effect was delayed and prolonged, lasting about 15 days, and an increase in toxicity correlated with raised fluorouracil concentrations. The mechanism of this interaction is unclear. In contrast, however, another study[2] found no effect of oxaliplatin on fluorouracil pharmacokinetics; the study was not designed to investigate a delayed effect and the dose of oxaliplatin was lower than that used in the first study.

Sorafenib has been reported to have variable effects on fluorouracil exposure.

For reference to the effect of fluorouracil on the action of *paclitaxel*, see Antineoplastics, p. 842.2. For the increased risk of haemolytic-uraemic syndrome that may be seen if fluorouracil is used with *mitomycin*, see Effects on the Kidneys, p. 831.3.

2. Joel SP. *et al.* Lack of pharmacokinetic interaction between 5-fluorouracil and oxaliplatin. *Clin Pharmacol Ther* 2004; 76: 45–54.

Antiprotozoals. *Metronidazole* increased the toxicity of fluorouracil in patients with colorectal cancer, apparently by reducing the clearance of the antineoplastic. No enhanced antineoplastic effect was seen with the combination *in vitro*.[1]

1. Bardakji Z. *et al.* 5-Fluorouracil–metronidazole combination therapy in metastatic colorectal cancer. *Cancer Chemother Pharmacol* 1986; 18: 140–4.

Antivirals. Giving *interferon alfa-2b* with fluorouracil has produced a marked increase in the initial plasma concentration of fluorouracil and a decrease in fluorouracil clearance.[1]

Severe leucopenia, fatal in some cases, has been reported in patients given fluorouracil or fluorouracil prodrugs (such as tegafur) with *sorivudine*.[2,3] A metabolite of sorivudine appears to inhibit dihydropyrimidine dehydrogenase, the primary enzyme responsible for the inactivation of fluorouracil.[3] A fatality has also been reported in a patient treated with the oral prodrug capecitabine who was also given *brivudine*.[4]

4. Rätz Bravo AE, *et al.* Fatal drug-drug interaction of brivudine and capecitabine. *Acta Oncol* 2009; **48**: 631–3.

Gastrointestinal drugs. Pretreatment with *cimetidine* for 4 weeks increased plasma concentrations of fluorouracil after intravenous and oral doses in 6 patients.[1] The effect was probably due to a combination of hepatic enzyme inhibition and reduced hepatic blood flow. No such effect was seen after single doses of cimetidine in 5 patients or pretreatment for just 1 week in 6. Care is required in patients given both drugs together.

1. Harvey VJ, *et al.* The influence of cimetidine on the pharmacokinetics of 5-fluorouracil. *Br J Clin Pharmacol* 1984; **18**: 421–30.

Pharmacokinetics

Absorption of fluorouracil from the gastrointestinal tract is unpredictable and fluorouracil is usually given intravenously. Little is absorbed when fluorouracil is applied to healthy skin.

After intravenous injection fluorouracil is cleared rapidly from plasma with a mean half-life of about 16 minutes. It is distributed throughout body tissues and fluids (including crossing the blood-brain barrier to appear in the CSF), and disappears from the plasma within about 3 hours. Within the target cell fluorouracil is converted to 5-fluorouridine monophosphate and floxuridine monophosphate (5-fluorodeoxyuridine monophosphate), the former undergoing conversion to the triphosphate which can be incorporated into RNA while the latter inhibits thymidylate synthetase. About 15% of an intravenous dose is excreted unchanged in the urine within 6 hours. The remainder is inactivated mainly in the liver and is catabolised via dihydropyrimidine dehydrogenase (DPD) similarly to endogenous uracil. A large amount is excreted as respiratory carbon dioxide; urea and other metabolites are also produced.

Chronopharmacology. Plasma concentrations of fluorouracil during continuous intravenous infusion are reported to undergo circadian variations of as much as 50% of the mean, peak concentrations occurring in the middle of the night.[1] The variation may be due to a circadian variation in the activity of the enzyme dihydropyrimidine dehydrogenase in blood,[2] but striking interpatient variations in peak concentrations of fluorouracil and peak enzyme activity suggest that any adjustment of infusion times would need to be individualised.[2] It has been suggested that pharmacokinetic monitoring should be investigated as a means of individualising fluorouracil doses with the aim of improving efficacy and reducing toxicity.[3]

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Flutamide). A pale yellow, crystalline powder. Practically insoluble in water; freely soluble in alcohol and in acetone; practically insoluble in heptane. Protect from light.

USP 36: (Flutamide). A pale yellow, crystalline powder. Practically insoluble in water, in liquid paraffin, and in petroleum spirit; freely soluble in acetone, in ethyl acetate, and in methyl alcohol; soluble in chloroform and in ether. Store in airtight containers. Protect from light.

Uses and Administration

Flutamide is a nonsteroidal compound with anti-androgenic properties which appears to act by inhibiting the uptake and/or binding of androgens in target tissues. It is used, usually with gonadorelin analogues, in the palliative treatment of prostatic carcinoma (p. 712.3). The usual oral dose is 250 mg three times daily. When used in combination therapy UK licensed product information recommends that flutamide treatment should be started at least 3 days before the gonadorelin analogue to suppress any 'flare' reaction; however, in some other countries it is recommended that treatment with both agents be begun simultaneously for optimum effect.

Congenital adrenal hyperplasia. For mention of the use of flutamide with testolactone to block androgenic effects in congenital adrenal hyperplasia, see p. 1603.2.

Hirsutism and alopecia. Anti-androgens (usually cyproterone or spironolactone) are widely used for the drug treatment of hirsutism (p. 2262.1). Flutamide has no particular advantage in this context;[1,2] one study has found flutamide to be more effective than spironolactone in inhibiting hirsutism,[3] but others found them to be of similar efficacy,[4,5] and the risk of hepatotoxicity with flutamide is a problem.[2] Nonetheless, flutamide has continued to be investigated.[6-10]

Flutamide has also been investigated[11] in women with female-pattern hair loss (female androgenetic alopecia).

Adverse Effects and Precautions

The most frequently reported adverse effects with flutamide are hot flushes and reversible gynaecomastia or breast tenderness, sometimes accompanied by galactorrhoea. Nausea, vomiting, diarrhoea, increased appetite, anorexia, and sleep disturbances may occur. There have been reports of skin reactions, including epidermal necrolysis, and of liver damage, sometimes fatal. Other adverse effects reported in patients receiving flutamide include anaemias, haemolysis, headache, dizziness, malaise, blurred vision, anxiety, depression, decreased libido, impotence, and hypertension. Abdominal pain, chest pain, dyspnoea, and cough have been reported rarely. Discoloration of the urine to amber or yellow-green can be caused by the presence of flutamide and/or its metabolites.

Flutamide should be used with care in patients with cardiovascular disease because of the possibility of fluid retention. It should also be used with caution in patients with hepatic impairment and is contra-indicated in those with severe impairment. Regular liver function testing is recommended in all patients: therapy should be stopped or dosage reduced if there is evidence of hepatotoxicity.

Effects on the blood. A report[1] of methaemoglobinaemia in an elderly man was attributed to flutamide. A study[2] of 45 patients given flutamide found no cases of methaemoglobinaemia, but the authors noted a further 3 published case reports.

1. Schott AM, *et al.* Flutamide-induced methemoglobinemia. *DICP Ann Pharmacother* 1991; **25**: 600–1.
2. Schulz M, *et al.* Lack of methemoglobinemia with flutamide. *Ann Pharmacother* 2001; **35**: 21–5.

Effects on the liver. Hepatitis occurred in a 79-year old man taking flutamide 750 mg daily as sole therapy after a prostatectomy,[1] but a subsequent study[2] in 1091 patients given flutamide 250 mg three times daily as part of a regimen for prostate cancer found marked signs of liver damage only in 4, of whom only 2 had clinical evidence of hepatotoxicity. In the USA, the FDA had 46 reports of patients with hepatotoxicity associated with flutamide up to December 1994. Of these patients, 20 died from progressive liver disease.[3] Further cases have continued to be reported,[4-7] including in women receiving low doses for hirsutism.[7,8] Early tapering of the dose, stopping therapy, or switching to another anti-androgen may resolve hepatotoxic effects.[9] Patients with chronic viral hepatitis may be at higher risk of developing hepatotoxicity with anti-androgen therapy.[10]

Effects on the lungs. In a review[1] of 78 cases of pneumonitis reported to the FDA between 1998 and 2000 that were associated with bicalutamide, flutamide, or nilutamide, it was found that 14 patients had died of respiratory failure. It was estimated that the incidence of pneumonitis

was highest for nilutamide (0.77%), but lower for flutamide (0.04%) and bicalutamide (0.01%).

1. Bennett CL, *et al.* Pneumonitis associated with nonsteroidal antiandrogens: presumptive evidence of a class effect. *Ann Intern Med* 2002; 137: 625.

Effects on the skin. Photosensitivity reactions have been reported in patients receiving flutamide.[1,2] Some consider it to be an early manifestation of SLE.[2]

1. Fujimoto M, *et al.* Photosensitive dermatitis induced by flutamide. *Br J Dermatol* 1996; 135: 496–7.
2. Kaur C, Thami GP. Flutamide-induced photosensitivity: is it a forme fruste of lupus? *Br J Dermatol* 2003; 148: 603–4.

Gynaecomastia. Gynaecomastia (p. 2264.3) and breast pain are frequent adverse effects of nonsteroidal anti-androgens used to treat prostate cancer. Nearly 90% of patients treated with bicalutamide in the Early Prostate Cancer programme had breast pain, gynaecomastia, or both.[1] Some patients will accept gynaecomastia as a tolerable adverse effect of therapy but others will require specific treatment. The risk of breast changes can be reduced by the use of prophylactic low-dose irradiation of the breast area before nonsteroidal anti-androgen therapy is started. However, skin irritation can occur, and the long-term risk for development of breast cancer is unknown. Irradiation is unlikely to be effective once breast enlargement has occurred but it can help to reduce pain. Empirical use of oral analgesics or topical local anaesthetics may be considered for breast pain. Specific surgical treatment to reduce breast tissue includes liposuction and breast tissue excision.[2,3]

Hormonal therapy using tamoxifen or anastrozole has been suggested, largely based on reports of benefit in various patient groups with gynaecomastia.[1,2] Two randomised controlled studies[4,5] of men who were treated with bicalutamide for prostate cancer found that prophylactic tamoxifen was effective for the prevention of gynaecomastia and breast pain, but that anastrozole was no better than placebo. One of these studies[5] also assessed the use of these drugs as treatment and found that gynaecomastia and breast pain resolved in at least 65% of patients treated with tamoxifen, but only in about 18% of those treated with anastrozole. Tamoxifen is considered to be more effective than radiotherapy for prevention of gynaecomastia.[3]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies flutamide as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Interactions

Flutamide may increase the effect of warfarin, see Antineoplastics, p. 1532.2.

Pharmacokinetics

Flutamide is reported to be rapidly and completely absorbed from the gastrointestinal tract and peak plasma concentrations occur 1 hour after a dose. It is rapidly and extensively metabolised; the major metabolite (2-hydroxyflutamide) possesses anti-androgenic properties. The half-life of the metabolite is about 6 hours. Both flutamide and 2-hydroxyflutamide are more than 90% bound to plasma proteins. Excretion is mainly in the urine with only minor amounts appearing in the faeces.

Formestane *(BAN, rINN)* ⊗

CGP-32349; Formestaani; Formestan; Formestano; Formestanum; 4-Hydroxyandrostenedione; 4-OHA; 4-OHAD; Форместан.

4-Hydroxyandrost-4-ene-3,17-dione.

$C_{19}H_{26}O_3$=302.4

CAS — 566-48-3.

ATC — L02BG02.

ATC Vet — QL02BG02.

UNII — PUB9T8T355.

Profile

Formestane, like exemestane (p. 792.2), is a steroidal inhibitor of the aromatase (oestrogen synthetase) system responsible for the production of oestrogens from androgens. It has been used for its anti-oestrogenic properties in the endocrine treatment of advanced breast cancer in postmenopausal women.

Irritation and pain at the site of intramuscular injection have been reported; injection into or near the sciatic nerve has resulted in pain and nerve trauma. Hypersensitivity reactions have occurred.

Reviews.

2. Anonymous. Formestane for advanced breast cancer in postmenopausal women. *Drug Ther Bull* 1993; 31: 85–7.
3. Carlini P, *et al.* Formestane, a steroidal aromatase inhibitor after failure of non-steroidal aromatase inhibitors (anastrozole and letrozole): is a clinical benefit still achievable? *Ann Oncol* 2001; 12: 1539–43.

Effects on carbohydrate metabolism. Recurrent hypoglycaemic episodes developed in a diabetic patient previously well maintained on gliclazide after addition of formestane to treatment for metastatic breast cancer.[1] Episodic hypoglycaemia continued after dosage reduction, and eventually withdrawal, of gliclazide, suggesting that the effect was not simply an interaction with the sulfonylurea.

Forodesine Hydrochloride *(USAN, rINNM)*

BCX-1777 (forodesine or forodesine hydrochloride); Forodésine, Chlorhydrate de; Forodesini Hydrochloridum; Hidrocloruro de forodesina; Фородезина Гидрохлорид.

(-)-7-[(2*S*,3*S*,4*R*,5*R*)-3,4-Dihydroxy-5-(hydroxymethyl)pyrrolidin-2-yl]-1,5-dihydro-4*H*-pyrrolo[3,2-*d*]pyrimidin-4-one hydrochloride.

$C_{11}H_{14}N_4O_4$,HCl=302.7

CAS — 209799-67-7 (forodesine); 284490-13-7 (forodesine hydrochloride).

UNII — 65N82Y9U73.

Profile

Forodesine is an inhibitor of purine nucleoside phosphorylase. It is under investigation in the treatment of T-cell lymphomas, chronic lymphocytic leukaemia, and acute lymphoblastic leukaemia.

Fosbretabulin *(rINN)*

CA4P; Combretastatin A4 Phosphate; CS-A4 (combretastatin A4); Fosbretabulina; Fosbrétabuline; Fosbretabulinum; NSC-348103 (combretastatin); Фосбретабулин.

2-Methoxy-5-[(1*Z*)-2-(3,4,5-trimethoxyphenyl)ethenyl]-phenyl dihydrogen phosphate.

$C_{18}H_{21}O_8P$=396.3

CAS — 82855-09-2 (combretastatin); 117048-59-6 (combretastatin A4); 222030-63-9 (combretastatin A4 phosphate); 168555-66-6 (combretastatin A4 disodium phosphate).

UNII — I5590ES2QZ.

NOTE. The name Zybrestat has been used as a trade mark for fosbretabulin.

Profile

Fosbretabulin is a synthetic derivative of combretastatin compounds originally isolated from the African bush-willow tree (Cape bush-willow; *Combretum caffrum*). It is described as a vascular targeting agent that reduces blood flow to tumours by disrupting the endothelial cells of newly formed blood vessels, and is under investigation for the treatment of thyroid, ovarian, and non-small cell lung cancer. It is also being investigated topically for ophthalmological disease, particularly age-related macular degeneration.

Fotemustine *(BAN, rINN)*

Fotemustin; Fotemustina; Fotémustine; Fotemustinum; S-10036; Фотемустин.

(±)-Diethyl {1-[3-(2-chloroethyl)-3-nitrosoureido]ethyl}phosphonate.

$C_9H_{19}ClN_3O_5P$=315.7

CAS — 92118-27-9.

ATC — L01AD05.

ATC Vet — QL01AD05.

UNII — GQ7JL9P5I2.

Profile

Fotemustine is a nitrosourea derivative and alkylating agent with actions similar to those of carmustine (p. 761.2). It is used in the treatment of disseminated malignant melanoma (p. 714.3), particularly where cerebral metastases are present, and has been tried in primary malignancies of the brain (p. 701.2). When used as a single agent it is licensed for intravenous or intra-arterial infusion in usual doses of 100 mg/m² weekly for 3 weeks to induce remission, followed after 4 to 5 weeks, if blood counts permit, by maintenance dosage with 100 mg/m² every 3 weeks. Intravenous infusions are given over 1 hour and intra-arterial infusions over 4 hours. Liver function should be monitored regularly during induction treatment. Regular blood counts should be taken and dosage should be reduced or withheld if white cell or platelet counts are below acceptable levels (see also Bone-marrow Depression, p. 730.3). Bone-marrow suppression may be delayed, with the nadir of the white cell counts 5 or 6 weeks after dosing. Solutions for infusion must be freshly prepared and protected from light.

UNII — 22X328QOC4.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Fulvestrant). A white or almost white powder. Practically insoluble in water; freely soluble in alcohol and in dichloromethane. Store at a temperature of 2 degrees to 8 degrees. Protect from light. If the substance is sterile, store in airtight containers.

USP 36: (Fulvestrant). A mixture of the diastereoisomers A and B. A white powder. Freely soluble in alcohol. Store at a temperature of 2 degrees to 8 degrees. Protect from light.

Uses and Administration

Fulvestrant is an oestrogen antagonist that downregulates the oestrogen receptor and is used for the treatment of oestrogen-receptor positive, locally advanced or metastatic breast cancer in postmenopausal women (p. 702.1); it is given when disease has relapsed or progressed during or after treatment with anti-oestrogens. Fulvestrant is given intramuscularly in a dose of 500 mg every 2 weeks for the first 3 doses, then every month thereafter. Half the dose (250 mg) is injected into each buttock concurrently. For doses in hepatic impairment, see Administration in Hepatic Impairment, below.

Administration in hepatic impairment. Exposure to fulvestrant is increased in patients with moderate hepatic impairment (Child-Pugh class B), and so in the USA a reduced dose of 250 mg as a single intramuscular injection into one buttock is given every 2 weeks for the first 3 doses and monthly thereafter; however, such dose adjustment is not recommended in the UK. Fulvestrant has not been studied in those with severe hepatic impairment (Child-Pugh class C).

Adverse Effects and Precautions

The most commonly reported adverse effects of fulvestrant are gastrointestinal disturbances, headache, musculoskeletal and abdominal pain, hot flushes, cough, dyspnoea, asthenia, and increases in liver enzymes. Injection site reactions can occur. Other common adverse effects include rash, urinary-tract infections, and thromboembolic events. Hypersensitivity reactions, including angioedema and urticaria, can occur. Vaginal bleeding or infection, vertigo and leucopenia have been reported rarely.

There is a lack of data on the use of fulvestrant in those with severe hepatic impairment (Child-Pugh class C), and use in these patients is not recommended in some countries. It should be used with caution in those with lesser degrees of hepatic impairment; a reduction in dose may be required (see Administration in Hepatic Impairment, above). Fulvestrant should also be used with caution in those with severe renal impairment (creatinine clearance less than 30 mL/minute). Because it must be given by intramuscular injection, fulvestrant should be used with caution in patients with bleeding tendencies, thrombocytopenia, or who are taking anticoagulants.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies fulvestrant as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Pharmacokinetics

Fulvestrant is slowly absorbed after intramuscular injection and peak plasma concentrations occur after about 7 days. Steady-state concentrations are reached after about 3 to 6 doses (given monthly). Fulvestrant is highly bound to plasma proteins. It is metabolised mainly in the liver to several metabolites, some of which have oestrogen antagonist activity, and is excreted in the faeces. After intramuscular injection fulvestrant has a half-life of about 40 to 50 days.

Gefitinib *(BAN, USAN, rINN)*

Gefitinib; Gefitinibum; ZD-1839; Гефитиниб.

N-(3-Chloro-4-fluorophenyl)-7-methoxy-6-[3-(morpholin-4-yl)propoxy]quinazolin-4-amine.

$C_{22}H_{24}ClFN_4O_3$=446.9

CAS — 184475-35-2.

ATC — L01XE02.

ATC Vet — QL01XE02.

UNII — S65743JHBS.

Uses and Administration

Gefitinib is a selective inhibitor of the tyrosine kinase activity of the epidermal growth factor receptor (EGFR). EGFR is expressed on the surface of cells and is implicated in the process of cell growth and proliferation. Gefitinib is used for the management of locally advanced or metastatic non-small cell lung cancer (NSCLC; p. 710.2) in adults. In the UK and EU, gefitinib is indicated for those patients with tumours with activating mutations of the EGFR tyrosine kinase. In the USA, use is restricted to those patients who are currently receiving and benefiting from gefitinib, or to those who have previously benefited from therapy; it is only used after failure of both platinum-based and docetaxel chemotherapy regimens.

The recommended dose of gefitinib is 250 mg orally once daily. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

For patients with diarrhoea or cutaneous adverse reactions, gefitinib therapy may be interrupted for up to 14 days, after which it may be re-instated at the same dose; if therapy is not tolerated after such an interruption, gefitinib should be stopped, and alternative treatment considered.

In patients who are given a potent CYP3A4 inducer, a dose increase of gefitinib to 500 mg orally once daily should be considered; clinical response and adverse effects should be carefully monitored.

Caution is advised in some patients with hepatic or renal impairment (see below).

9. Maruyama R, *et al.* Phase III study, V-15-32, of gefitinib versus docetaxel in previously treated Japanese patients with non-small-cell lung cancer. *J Clin Oncol* 2008; **26**: 4244–52.
10. Kim ES, *et al.* Gefitinib versus docetaxel in previously treated non-small-cell lung cancer (INTEREST): a randomised phase III trial. *Lancet* 2008; **372**: 1809–18.
11. Sanford M, Scott LJ. Gefitinib: a review of its use in the treatment of locally advanced/metastatic non-small cell lung cancer. *Drugs* 2009; **69**: 2303–28.

Administration. Gefitinib tablets may be taken with or without food, and are preferably swallowed whole. However, for those patients who have difficulty swallowing a whole tablet may be dispersed in half a glass of non-carbonated water; the tablet should not be crushed, and the glass of water should be swirled or stirred until the tablet is fully dispersed (this may take 10 to 20 minutes). The dispersion should be consumed immediately (UK licensed product information specifies this as being within 1 hour), and the glass rinsed with some more water, which should also be consumed.

This dispersion is also suitable for use through a nasogastric or gastrostomy tube.

Administration in children. For reference to the use of gefitinib with irinotecan in the treatment of children with refractory solid tumours, see Administration, under Irinotecan, p. 813.1.

Administration in hepatic impairment. UK licensed product information states that, compared with healthy control subjects, exposure to gefitinib was tripled in patients with moderate or severe hepatic impairment (classified according to Child-Pugh criteria) due to cirrhosis. In patients with tumours, gefitinib pharmacokinetics in those with hepatic impairment were similar to those patients with normal hepatic function.

US licensed product information states that no dosage adjustment is needed in patients with moderate to severe hepatic impairment due to liver metastases: in the UK, patients with moderate to severe impairment (Child-Pugh B or C) due to cirrhosis should be closely monitored for adverse effects.

Administration in renal impairment. UK licensed product information states that no dose adjustment of gefitinib is needed in patients with a creatinine clearance (CC) greater than 20 mL/minute. Caution is advised in those patients with a CC of 20 mL/minute or less, due to limited data in these patients.

US licensed product information states that, while no studies have been conducted in patients with severe renal impairment, gefitinib and its metabolites are not significantly excreted via the kidney, and no dose adjustment is required on the basis of renal function.

Adverse Effects, Treatment, and Precautions

The adverse effects of gefitinib are similar to those of erlotinib (p. 789.2), although severe hepatic and renal toxicity seems to be rare. Haemorrhage, such as epistaxis or haematuria, is common. There are also reports of tumour haemorrhage, sometimes fatal, after use of gefitinib in patients with head and neck cancer.

Other common adverse effects include nausea, vomiting, stomatitis, dry mouth, alopecia, nail disorders, asthenia, pyrexia, proteinuria, and elevations in blood creatinine.

Effects on survival. In chemotherapy-naive patients with advanced non-small cell lung cancer, gefitinib, given with gemcitabine plus cisplatin,[1] or paclitaxel plus carboplatin,[2] showed no survival advantage over chemotherapy

without gefitinib. In a large study in patients with non-small cell lung cancer given gefitinib or placebo, after failure of one or two previous treatment regimens, no survival benefit was shown with gefitinib;[3] recommendations restricting the use of gefitinib to selected patients have been made in the USA (see Uses and Administration, p. 800.2).[4] However, a subset analysis of study data found an improvement in survival in a subgroup of patients of Asian origin.[5] In reports of the IMEX study in patients with head and neck cancer, no survival advantage for gefitinib was found when compared with methotrexate; an increased incidence of tumour haemorrhage was seen in those treated with gefitinib.[6] Studies have suggested that there are subgroups of patients with non-small cell lung cancer who have specific biomarkers or mutations in the epidermal growth factor receptor (EGFR) gene which correlate with clinical response to gefitinib.[7-10] A subsequent study established EGFR mutation status as the most important independent predictor of survival benefit with gefitinib treatment.[11]

A small retrospective study found that further treatment with gefitinib prolonged survival in patients who were initially responsive, but who had subsequent disease progression upon stopping therapy.[12]

Interactions

Gefitinib is metabolised via the cytochrome P450 isoenzymes CYP3A4 and CYP2D6. Inhibitors of CYP3A4, such as itraconazole, can decrease the clearance of gefitinib and increase exposure. The increase in gefitinib plasma concentration caused by potent CYP3A4 inhibitors may be higher in patients with CYP2D6 poor-metaboliser genotype. In CYP2D6 extensive metabolisers, use of gefitinib with potent CYP2D6 inhibitors may double gefitinib concentrations. Patients taking gefitinib who are also treated with potent CYP3A4 or CYP2D6 inhibitors should be closely monitored for adverse reactions.

Conversely, CYP3A4 inducers, such as rifampicin, can reduce exposure to gefitinib. Use with potent CYP3A4 inhibitors should be avoided, but if not, dose adjustment is recommended (see Uses and Administration, p. 800.2), and the patient's response should be carefully monitored.

Substances that cause a significant and sustained elevation in gastric pH may reduce gefitinib bioavailability; high doses of short-acting antacids may have a similar effect if taken regularly and at the same time as gefitinib, and ranitidine, with or without sodium bicarbonate, decreased exposure to gefitinib by over 40%.

Elevations in INR or bleeding events have been reported in patients taking gefitinib with warfarin.

Gefitinib also has limited potential to inhibit the cytochrome P450 isoenzyme CYP2D6; substrates of CYP2D6 may need dose modification when given with gefitinib (such as metoprolol, see p. 1322.1).

1. Swaisland HC, *et al.* Pharmacokinetic drug interactions of gefitinib with rifampicin, itraconazole and metoprolol. *Clin Pharmacokinet* 2005; **44:** 1067–81.

Pharmacokinetics

Gefitinib is slowly absorbed, and peak plasma concentrations occur 3 to 7 hours after an oral dose. Bioavailability is about 60%, and is not significantly altered by food. Gefitinib is extensively distributed throughout the body. Plasma protein binding is about 90%. Gefitinib is extensively metabolised in the liver, mainly by the cytochrome P450 isoenzymes CYP3A4 and CYP2D6; the major metabolite is *O*-desmethylgefitinib, which is much less potent than gefitinib, and unlikely to contribute to its clinical activity. Gefitinib is excreted mainly as metabolites via the faeces; renal elimination of gefitinib and its metabolites accounts for less than 4% of the dose given. The elimination half-life is reported to be about 41 to 48 hours.

Gemcitabine Hydrochloride

(BANM, USAN, rINNM)

Gemcitabina, hidrocloruro de; Gemcitabine, Chlorhydrate de; Gemcitabinhydrochlorid; Gemcitabini Hydrochloridum; Hidrocloruro de gemcitabina; LY-188011 (gemcitabine); Гемцитабина Гидрохлорид.

4-Amino-1-(2-deoxy-2,2-difluoro-β-D-ribofuranosyl)pyrimidin-2(1*H*)-one hydrochloride; 2′-Deoxy-2′,2′-difluorocytidine hydrochloride.

$C_9H_{11}F_2N_3O_4HCl$=299.7

CAS — 95058-81-4 (gemcitabine); 122111-03-9 (gemcitabine hydrochloride).

ATC — L01BC05.

ATC Vet — QL01BC05.

UNII — U347PV74IL

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Gemcitabine Hydrochloride). A white or almost white powder. Soluble in water; slightly soluble in methyl alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 2.0 to 3.0.

USP 36: (Gemcitabine Hydrochloride). A white to off-white solid. Soluble in water; practically insoluble in alcohol and in polar organic solvents; slightly soluble in methyl alcohol. pH of a 1% solution in water is between 2.0 and 3.0. Store in airtight containers.

Incompatibility. Gemcitabine hydrochloride was reported to be physically incompatible with aciclovir sodium, amphotericin B, cefoperazone sodium, cefotaxime sodium, furosemide, ganciclovir sodium, imipenem with cilastatin sodium, irinotecan, methotrexate sodium, methylprednisolone sodium succinate, mezlocillin sodium, mitomycin, piperacillin sodium, piperacillin sodium with tazobactam, and prochlorperazine edisilate during simulated Y-site administration.[1]

1. Trissel LA, *et al.* Compatibility of gemcitabine hydrochloride with 107 selected drugs during simulated Y-site injection. *J Am Pharm Assoc* 1999; **39:** 514–18.

Uses and Administration

Gemcitabine is an analogue of cytarabine (p. 774.1) that is metabolised intracellularly to active diphosphate and triphosphate nucleosides, which inhibit DNA synthesis and induce apoptosis. It is mainly active against cells in S phase. It is given in the management of solid tumours including those of the bladder, breast, lung, ovary, and pancreas (see p. 700.2, p. 702.1, p. 710.2, p. 711.2, and p. 712.1, respectively).

Gemcitabine is given intravenously as the hydrochloride. Doses are calculated in terms of the base; gemcitabine hydrochloride 1.14 g is equivalent to about 1 g of gemcitabine. Doses are reconstituted in sodium chloride 0.9%. The concentration of the infusion solution should not exceed the equivalent of gemcitabine 40 mg/mL. Gemcitabine is given by infusion over 30 to 60 minutes; doses are subsequently adjusted according to response and toxicity.

In the treatment of **pancreatic cancer**, an initial course of gemcitabine 1 g/m² once weekly for up to 7 weeks may be given, followed after a one-week recovery period by a regimen of infusions once weekly for 3 consecutive weeks out of 4.

In **non-small cell lung cancer**, gemcitabine may be given as a single agent; 1 g/m² once weekly for 3 consecutive weeks out of 4 is recommended. Alternatively, it may be given before cisplatin. Two schedules have been used; gemcitabine 1.25 g/m² is given on days 1 and 8 of a 21-day cycle, or gemcitabine 1 g/m² is given on days 1, 8 and 15 of a 28-day cycle.

In the treatment of **bladder cancer**, gemcitabine is given before cisplatin. The recommended dose of gemcitabine is 1 g/m² on days 1, 8, and 15 of a 28-day cycle.

In **breast cancer**, gemcitabine is usually given after a taxane such as paclitaxel. A dose of gemcitabine 1.25 g/m² is given on days 1 and 8 of a 21-day cycle.

In **ovarian cancer**, gemcitabine is given before carboplatin. The recommended dose of gemcitabine is 1 g/m² on days 1 and 8 of a 21-day cycle.

Administration. Gemcitabine is recommended as the standard of care in patients with advanced pancreatic cancer (p. 712.1). There is some suggestion that its efficacy may be improved if it is given at a fixed dose rate of 10 mg/m² per minute, rather than by conventional infusion.[1] However, while this regimen has been found to be well tolerated,[2] several studies have not shown an improvement in survival compared with the standard gemcitabine infusion[3] and some do not recommend it for routine use.[4]

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The major dose-limiting adverse effect of gemcitabine is bone-marrow depression, although this is reported to be modest and rarely requires stopping therapy. Gastrointestinal disturbances occur, especially nausea and vomiting, but these are usually of mild to moderate severity. Rashes, often associated with pruritus, and flu-like symptoms are relatively common; severe desquamation and bullous skin eruptions, toxic epidermal necrolysis and Stevens-Johnson syndrome have occurred rarely. Oedema, dyspnoea, myalgia, and alopecia are commonly reported. Pulmonary oedema has been reported infrequently; interstitial pneumonitis, pulmonary fibrosis, and acute respiratory distress syndrome have occurred. Therapy should be stopped if pulmonary toxicity occurs. There are rare cases of hypotension and anaphylactoid reactions. Haematuria,

proteinuria, transient liver enzyme elevations, and serious hepatotoxicity, including liver failure and death, have been reported. It should therefore be used with caution in patients with impaired renal or hepatic function. Haemolytic-uraemic syndrome and/or thrombocytopenic purpura have been reported and have led to irreversible renal failure; gemcitabine should be stopped at the first signs of microangiopathic haemolytic anaemia. Congestive heart failure, myocardial infarction, or arrhythmias may occur rarely. Ischaemic colitis with necrosis (including fatalities), peripheral vasculitis and gangrene, and cerebrovascular accident have also been reported.

Gemcitabine may produce somnolence: patients so affected should not drive or operate machinery. Severe toxicity, in the form of potentially life-threatening oesophagitis and pneumonitis has been seen in patients given radical radiotherapy to the thorax concurrently with gemcitabine.

Effects on the nervous system. A report of autonomic neuropathy associated with gemcitabine therapy.[1] Symptoms resolved 4 weeks after stopping therapy.

1. Dormann AJ, *et al.* Gemcitabine-associated autonomic neuropathy. *Lancet* 1998; 351: 644.

Effects on the skin. A patient who received gemcitabine a week after phototherapy developed a severe sunburn reaction in those areas exposed to UVB. The erythema resolved spontaneously, but recurred with each subsequent dose of gemcitabine, and became progressively more intense. A short course of high-dose prednisone was given with topical triamcinolone, and the patient was safely rechallenged with 2 further doses of gemcitabine.[1]

1. Badger J, *et al.* Photo therapy recall with gemcitabine following ultraviolet B treatment. *J Clin Oncol* 2005; 23: 7224–5.

Peripheral ischaemia. Pain, coldness, colour changes, and distal claudication in the feet have been reported in patients treated with gemcitabine and cisplatin.[1] Pain and colour changes in the fingertips have also been reported after gemcitabine monotherapy.[2]

1. Barceló R, *et al.* Distal ischemic changes related to combination chemotherapy with cisplatin and gemcitabine: description of four cases. *Ann Oncol* 2000; 11: 1191–4.
2. Yildiz R, *et al.* Digital ischemic changes after gemcitabine therapy in a patient with metastatic non-small-cell lung cancer. *Ann Pharmacother* 2007; 41: 901–2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies gemcitabine as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

Antineoplastics. In a study[1] of 14 patients with lung cancer, the use of *paclitaxel* before gemcitabine caused a decrease in the systemic clearance, volume of distribution, and interpatient pharmacokinetic variability of gemcitabine. This resulted in plasma concentrations of gemcitabine slightly higher than the desired range. However, there was no apparent relationship between pharmacokinetic changes and toxicity, and the clinical significance of this possible interaction is unclear.

A study investigating a modified chemotherapy regimen in which gemcitabine was substituted for etoposide was stopped because of unexpected pulmonary toxicity. This was considered to be due to the combination of gemcitabine and *bleomycin*, as the adverse effect was apparent in other studies using this combination.[2]

2. Bredenfeld H, *et al.* Severe pulmonary toxicity in patients with advanced-stage Hodgkin's disease treated with a modified bleomycin, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone, and gemcitabine (BEACOPP) regimen is probably related to the combination of gemcitabine and bleomycin: a report of the German Hodgkin's lymphoma study group. *J Clin Oncol* 2004; 22: 2424–9.

Pharmacokinetics

After intravenous doses gemcitabine is rapidly cleared from the blood and metabolised by cytidine deaminase in the liver, kidney, blood, and other tissues. Clearance is about 25% lower in women than in men. Almost all of the dose is excreted in urine as 2'-deoxy-2',2'-difluorouridine (dFdU), only about 1% being found in the faeces. Intracellular metabolism produces mono-, di-, and triphosphate metabolites, the latter two active. The half-life of gemcitabine ranges from 42 to 94 minutes depending on age and gender. The intracellular half-life of the triphosphate is stated to range from 0.7 to 12 hours.

Gemtuzumab Ozogamicin *(USAN, rINNM)*

CDP-771; CMA-676; Gemtuzumab ozogamicina; Gemtuzumab Ozogamicine; Gemtuzumab Zogamicin; Gemtuzumabum Ozogamicinum; WAY-CMA-676; Гемтузумаб Озогамицин.

Immunoglobulin G4 (human-mouse monoclonal hP67.6 κ4-chain anti-human antigen CD 33), disulfide with human-mouse monoclonal hP67.6 κ-chain, dimer conjugate with ozogamicin.

CAS — 220578-59-6.
ATC — L01XC05.
ATC Vet — QL01XC05.
UNII — 8GZG754X6M.

Uses and Administration

Gemtuzumab ozogamicin is a recombinant humanised monoclonal antibody conjugated with calicheamicin, a cytotoxic antibiotic. The antibody binds specifically to the CD33 antigen, which is expressed on leukaemic myeloblasts but not normal haematopoietic stem cells. Gemtuzumab ozogamicin has been used for the second-line treatment of CD33-positive acute myeloid leukaemia (p. 693.1) in elderly patients who are unable to tolerate conventional chemotherapy. It is given in 100 mL of sodium chloride 0.9% via a low protein-binding in-line filter. A usual dose has been 9 mg/m² given by intravenous infusion over 2 hours, repeated once after 14 days. Lower doses have been investigated as part of combined induction or consolidation regimens.

Adverse Effects and Precautions

For general discussions see Antineoplastics, p. 726.1 and p. 732.2.

Myelosuppression is common with gemtuzumab ozogamicin, and thrombocytopenia may be prolonged. Infusion-related reactions characteristic of a cytokine release syndrome (including fever, chills, dyspnoea, and hypotension) and hypersensitivity may occur; prophylactic use of an antihistamine and paracetamol is recommended. Pulmonary sequelae may be fatal. Hepatotoxicity, including severe veno-occlusive disease, has also been reported. Electrolyte imbalances, especially hypokalaemia and hypomagnesaemia, and gastrointestinal disturbances may occur.

Blood and platelet counts, electrolytes, and liver function tests should be regularly monitored.

The drug was withdrawn from the market in the USA after reports of increased mortality in patients with acute myeloid leukaemia who were given gemtuzumab ozogamicin as part of a combination regimen.

Hypersensitivity. A 75-year-old man with acute myeloid leukaemia developed severe respiratory distress and died after being given gemtuzumab ozogamicin and platelets on the same day. He had previously had the drug and platelets on separate occasions with no untoward effects. It was suggested that this combination contributed to a fatal hypersensitivity reaction.[1]

Girentuximab *(USAN, rINN)*

cG-250; Girentuximabum; WX-G250; Гирентуксимаб.

CAS — 916138-87-9.
UNII — 539B57DFJF.

NOTE. The name Rencarex has been used as a trade mark for girentuximab. The name Redectane has been used as a trade mark for girentuximab labelled with iodine-124.

Profile

Girentuximab is a chimeric monoclonal antibody that binds specifically to the protein carbonic anhydrase IX (CA IX, MN, or G250 antigen) expressed on the cell surface in the majority of clear-cell renal cell carcinomas; the antigen is present in various other solid tumours. Girentuximab is under investigation for the treatment of clear-cell renal cell carcinoma.

Girentuximab labelled with iodine-124 (p. 2225.2) is being studied for the imaging of renal tumours.

Givinostat (rINN)

Givinostatum; Гивиностат.
(6-[(Diethylamino)methyl]naphthalen-2-yl)methyl [4-(hydroxycarbamoyl)phenyl]carbamate.
$C_{24}H_{27}N_3O_4$=421.5
CAS — 497833-27-9.
UNII — SP60F84FBH.

Profile

Givinostat is an orally active histone deacetylase inhibitor that is under investigation for the treatment of polycythaemia vera and juvenile idiopathic arthritis.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

CAS — 127-07-1.
ATC — L01XX05.
ATC Vet — QL01XX05.
UNII — X6Q56QN5QC.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Ph. Eur. 8: (Hydroxycarbamide). A white or almost white, hygroscopic, crystalline powder. It exhibits polymorphism. Freely soluble in water; practically insoluble in alcohol. Store in airtight containers. Protect from light.

USP 36: (Hydroxyurea). A white to off-white powder. It is somewhat hygroscopic and decomposes in the presence of moisture. Freely soluble in water and in hot alcohol. Store in airtight containers in a dry atmosphere.

Stability. An oral solution of hydroxycarbamide 100 mg/mL was prepared[1] by first mixing the contents of 500-mg capsules (*Hydrea; BMS, USA*) in sterile water at room temperature to produce a concentration of 200 mg/mL. The mixture was vigorously stirred for several hours and then filtered to remove insoluble excipients. Flavoured syrup (*Syrpalta without color; Humco, USA*) was added to the filtered solution to produce a final concentration of 100 mg/mL.

The resulting solution was found to have lost 5% of its chemical content of hydroxycarbamide during the first 3-months of storage at room temperature in amber plastic bottles but there was no further loss up to 9 months later. The loss of its *in-vitro* inhibitory activity was less than 5% at 3 months, less than 10% at 6 months but activity was about 80% at 9 months. In contrast a solution that had been prepared by dissolving the contents of the capsules in heated water had an immediate loss of 40% of its chemical content and over 60% of its inhibitory activity.

Uses and Administration

Hydroxycarbamide is an antineoplastic that may cause inhibition of DNA synthesis by acting as a ribonucleotide reductase inhibitor. It is S-phase specific. Hydroxycarbamide is used in the treatment of chronic myeloid leukaemia, and may be used in the myeloproliferative disorders polycythaemia vera and primary (essential) thrombocythaemia. It has also been tried, often combined with radiotherapy, in some solid malignancies (see Malignant Neoplasms, p. 804.1). Hydroxycarbamide has also produced benefit in the haemoglobinopathies, particularly in sickle-cell disease (see below).

Hydroxycarbamide is given orally. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

In the treatment of **chronic myeloid leukaemia** and **solid tumours**, hydroxycarbamide is given typically in a single dose of 20 to 30 mg/kg daily or in a single dose of 80 mg/kg every third day. Generally, the continuous regimen is used for chronic myeloid leukaemia, and the intermittent regimen for solid tumours. When used with radiotherapy, hydroxycarbamide is started 7 days before radiotherapy. If a beneficial effect is evident after 6 weeks, therapy may be continued indefinitely.

In **essential thrombocythaemia**, the initial dose of hydroxycarbamide is about 15 mg/kg daily; starting doses of 15 to 20 mg/kg daily are recommended for **polycythaemia vera**. Doses are subsequently adjusted according to platelet counts.

In **sickle-cell disease** initial doses of 15 mg/kg daily are suggested, increased if necessary by 2.5 to 5 mg/kg every 12 weeks according to response and blood counts; usual doses are 15 to 30 mg/kg daily with a maximum of 35 mg/kg daily. For doses in children, see below.

Blood counts and hepatic and renal function should be monitored during therapy; treatment may need to be interrupted if leucopenia or thrombocytopenia occur (see Adverse Effects, Treatment, and Precautions, p. 804.1).

Administration in children. In the UK hydroxycarbamide is licensed for use in children older than 2 years of age for the treatment of sickle-cell disease; doses are the same as for adults, see Uses and Administration, above. The *BNFC* advises that a slightly lower initial oral dose of 10 to 15 mg/kg daily may be used instead. For doses in renal impairment and for more information on hydroxycarbamide use in sickle-cell disease, see below.

For reference to the preparation and stability of an oral solution of hydroxycarbamide 100 mg/mL, see under Stability, above.

Administration in renal impairment. Results from a single-dose study in patients with sickle-cell disease indicated that systemic exposure to hydroxycarbamide correlates to renal function.[1] An initial oral dose of 7.5 mg/kg daily is recommended for adults and children over 2 years of age with sickle-cell disease and a creatinine clearance of less than 60 mL/minute. US product information also recommends this dose adjustment for adults with end-stage renal disease; on dialysis days the dose should be given after haemodialysis.

1. Yan J-H, *et al.* The influence of renal function on hydroxyurea pharmacokinetics in adults with sickle cell disease. *J Clin Pharmacol* 2005; 45: 434–45.

Haemoglobinopathies. Hydroxycarbamide is considered a promising treatment for the haemoglobinopathies. It can stimulate fetal haemoglobin production, which in turn can reduce haemoglobin polymerisation and the numbers of deformed, dense, and damaged erythrocytes.[1] In adult patients with **sickle-cell disease** (p. 1123.2), a randomised controlled study produced evidence that initial oral doses of 15 mg/kg daily, adjusted according to response and tolerance to up to 35 mg/kg daily, reduced the rate of sickle-cell crisis compared with placebo.[2] An observational follow-up study[3] of this group found that patients taking hydroxycarbamide for frequent sickle-cell episodes appeared to have reduced mortality. A report in 2 adults has suggested that it might reverse splenic dysfunction.[4] A systematic review[5] has noted that despite the benefits, the paucity of long-term studies limits conclusions on the toxicity of treatment with hydroxycarbamide.

Despite some concerns about giving a potential carcinogen to children,[6] studies in paediatric populations have also reported evidence of benefit in terms of decreased hospitalisation[7,8] and sickle-cell crisis.[8,9] Although the evidence for the efficacy of hydroxycarbamide in children with sickle-cell disease is not as strong as that for adults[10] and is mostly based on observational studies, a systematic review[11] concluded that there was strong evidence of an increase in haemoglobin and decreased hospitalisations, moderate evidence of decreased painful crises, and weak evidence of decreased neurological events. There was insufficient evidence to draw conclusions on the effect of hydroxycarbamide on the frequency of transfusions or mortality. Hydroxycarbamide may be considered for children with sickle-cell disease and frequent complications such as painful crises, priapism, severe anaemia, or acute chest syndrome.[12] Hydroxycarbamide has also been suggested as an alternative to blood transfusions in children who have had a stroke.[8,13,14] Although a small study[15] has suggested benefit in paediatric patients in terms of splenic preservation, long-term prevention of organ damage remains to be established.[16,17]

It has been suggested that use of the drug with erythropoietin might enhance the production of fetal haemoglobin, but results from studies of the combination have been conflicting.[18,19]

There appear to have been few studies of hydroxycarbamide specifically in **thalassaemia** (p. 1124.1). Initial oral doses of 8.2 to 10.3 mg/kg daily, increased until toxicity occurred, did produce sustained increases in fetal haemoglobin in 3 patients, but did not result in a sustained increase in total haemoglobin.[20] Others have reported[21] that rises in fetal haemoglobin did not necessarily correlate with clinical improvement. Conversely, sustained responses have been seen in other studies.[22–25] Use with sodium phenylbutyrate has produced conflicting results.[26–28]

HIV infection and AIDS. Unlike most drugs used to treat HIV, which target viral enzymes, hydroxycarbamide inhibits ribonucleotide reductase, a host cellular enzyme that is less prone to mutation and subsequent development of resistance.[1] The drug acts synergistically with didanosine (p. 972.3). Of 25 HIV-positive patients given didanosine 200 mg twice daily with hydroxycarbamide 15 mg/kg daily in 2 divided doses, all showed a drop in viral load and an increase in CD4+ lymphocyte count.[2] Viraemia was not detectable in 13 of 24 patients evaluated at 6 months and 10 of 20 patients evaluated at 1 year. In 2 of these patients who subsequently received no antiviral treatments for 1 year there was no viral rebound, although some proviral DNA was detected.[3] In another study in 6 patients, didanosine 200 mg twice daily with hydroxycarbamide 250 mg

four times daily (suggested to be a better regimen because of the short half-life of the antineoplastic) produced a sharp decrease in viraemia, which was maintained for up to 72 weeks.[4] A rebound occurred in 1 patient on interrupting treatment but viral replication was again suppressed when treatment was restarted.

Combinations with didanosine and other HIV drugs have also been tried.[1] A controlled study[5] of hydroxycarbamide, didanosine, and stavudine indicated significantly enhanced activity when the antivirals were used with the antineoplastic rather than placebo. However, in a long-term follow-up[6] there was a high withdrawal rate amongst patients receiving this combination, due to virological failure and adverse effects such as peripheral neuropathy and fatigue. Another study[7] (ACTG 5025) was terminated due to the high risk of toxicity, including fatal pancreatitis, in patients receiving the hydroxycarbamide regimens. The authors noted that the use of a higher daily dosage of 1.2 g of hydroxycarbamide (rather than the usual 1 g daily) and increased exposure to didanosine (itself associated with pancreatitis) may have contributed to toxicity. An analysis of 2613 patients[8] determined that the use of hydroxycarbamide with didanosine, or didanosine and stavudine, resulted in a fourfold increase in the risk for development of pancreatitis, compared with didanosine alone. In a study of patients who had failed protease-inhibitor based regimens,[9] the addition of the antineoplastic to reverse transcriptase inhibitor-based therapy significantly improved virologic response. Despite an increased incidence of adverse events associated with its use, hydroxycarbamide was considered to be a valuable alternative in these patients. A small randomised study[10] of patients with chronic HIV infection given structured treatment interruptions with cycles of HAART, or HAART and hydroxycarbamide, found that use of the latter decreased viral load. There is some suggestion that a lower dose of hydroxycarbamide (300 mg twice daily) may have better antiretroviral activity, and fewer adverse effects, than higher doses.[11] For further discussion of the management of HIV infection and AIDS, see p. 957.2.

Malignant neoplasms. Hydroxycarbamide is used in the treatment of chronic myeloid leukaemia (p. 694.2), and may be used in the myeloproliferative disorders polycythaemia vera (p. 695.2) and primary (essential) thrombocythaemia (p. 695.2). Hydroxycarbamide has been tried, often with radiotherapy, in some solid malignancies such as tumours of the cervix (p. 704.2), head and neck (p. 708.1), and ovary (p. 711.2).

Psoriasis. An immunosuppressant (usually methotrexate or ciclosporin) may be useful in patients with severe refractory psoriasis (p. 1688.1). Hydroxycarbamide has also been tried, although experience is limited.[1,2]

2. Smith CH, *et al.* Use of hydroxyurea in psoriasis. *Clin Exp Dermatol* 1999; **24**: 2–6.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bone-marrow suppression, including megaloblastic changes, is the main adverse effect of hydroxycarbamide. The erythema caused by irradiation may be exacerbated. Other adverse effects reported have included gastrointestinal disturbances, impairment of renal function, pulmonary oedema, dermatological reactions, alopecia, and neurological reactions such as headache, dizziness, drowsiness, disorientation, hallucinations, and convulsions. There are rare reports of acute pulmonary reactions consisting of pulmonary infiltrates or fibrosis, dyspnoea and fever. Symptoms resembling cutaneous vasculitis, including vasculitic ulcerations and gangrene, have occurred in patients with myeloproliferative disorders treated with hydroxycarbamide, especially in those also given interferon. There are reports of hepatotoxicity and pancreatitis, some fatal, in patients with HIV infection, given hydroxycarbamide and antiretrovirals (see also HIV Infection and AIDS, p. 803.3); peripheral neuropathy has also occurred.

Pre-existing anaemia should be corrected before beginning therapy with hydroxycarbamide and the haemoglobin concentration, white cell and platelet counts, and hepatic and renal function should be determined repeatedly during treatment. Treatment should be interrupted if the white cell or platelet count fall below acceptable levels (see also Bone-marrow Depression, p. 730.3). If anaemia occurs when hydroxycarbamide is used as an antineoplastic, it may be corrected by transfusions of whole blood without stopping therapy. If anaemia (haemoglobin less than 4.5 g per 100 mL or reticulocyte count less than 80 000 cells/mm^3 when haemoglobin is less than 9 g per 100 mL) occurs when the drug is used for sickle-cell disease, therapy should be interrupted. Megaloblastic changes are usually self-limiting.

Hydroxycarbamide should be used with caution in patients with impaired renal function. Uric acid concentrations should be monitored, and a high fluid intake maintained during treatment. The elderly may be more sensitive to its adverse effects.

Breast feeding. In breast-milk samples from a woman given hydroxycarbamide 500 mg three times daily, the mean concentration of the drug was found to be about 6 mg/litre. It was estimated that, had the infant been breast-fed, it would have received about 3 to 4 mg daily. Although this amount appears to be low, women are advised not to breast feed while taking hydroxycarbamide.[1]

1. Sylvester RK, *et al.* Excretion of hydroxyurea into milk. *Cancer* 1987; **60**: 2177–8.

Carcinogenicity. Secondary leukaemias have occurred in patients receiving hydroxycarbamide for myeloproliferative disorders, although the extent to which this is due to the treatment or the underlying disorder is unknown.

Skin cancers have also been associated with its use. These are often multiple and include both squamous cell and basal cell carcinomas.

Effects on the skin and nails. Reports of skin reactions with hydroxycarbamide include hyperpigmentation of the skin,[1] and of nails (melanonychia).[2]

Hydroxycarbamide therapy has been associated with scaly erythematous skin lesions often resembling those of dermatomyositis.[1,3,4] Such lesions usually occur after several years of treatment and the course is usually benign. However, withdrawal of the drug is usually necessary for healing or improvement, in which case resolution may take several months.[1,4] Hydroxycarbamide can also cause painful leg ulcers, often on the malleoli, which may require stopping treatment.[1,5,6] Leg ulcers often coexist with dermatomyositis-like eruptions and may be caused by the same mechanism,[7] although mechanical injury may have a role in malleolar ulceration.[5] Licensed product information notes that vasculitic toxicities, including vasculitic ulceration and gangrene, have been associated with hydroxycarbamide use in patients with myeloproliferative disorders (particularly if also given interferon). However, histologically, perivascular lymphocytic infiltration without vasculitis has been reported in both early dermatomyositis-like lesions[1] and in leg ulcers.[5,8]

Skin cancers have also occurred, see Carcinogenicity above.

Interactions

For a general discussion of antineoplastic drug interac tions, see p. 733.3.

Pharmacokinetics

Hydroxycarbamide is readily absorbed from the gastrointestinal tract and distributed throughout the body. Peak plasma concentrations are reached within 2 hours. Up to 50% of a dose is metabolised by the liver; hydroxycarbamide is excreted in urine as metabolites and unchanged drug. Some is excreted as carbon dioxide via the lungs. About 80% of a dose is reported to be excreted in the urine within 12 hours. Hydroxycarbamide crosses the blood-brain barrier and the placenta, and is distributed into breast milk.

Ibritumomab Tiuxetan *(BAN, USAN, rINN)*

Ibritumomab tiuxétan; Ibritumomab Tiuxétan; Ibritumomabum Tiuxetanum; IDEC-129; IDEC-Y2B8; Ибритумомаб Тиуксетан.

Immunoglobulin G1, anti(human CD20 (antigen))(mouse monoclonal IDEC-Y2B8 γ1-chain), disulfide with mouse monoclonal IDEC-Y2B8 κ-chain, dimer tiuxetan conjugate.

CAS — 206181-63-7.
UNII — 4Q52C550XK.

Uses and Administration

Ibritumomab is a murine monoclonal antibody to CD20 antigen, which is conjugated with tiuxetan to provide a chelation site for radioactive isotopes. Radiolabelled ibritumomab tiuxetan is used in the treatment of relapsed or refractory, low-grade or follicular B-cell non-Hodgkin's lymphoma (p. 696.3). Patients are pretreated with a low dose of rituximab (p. 852.1). In the USA this is followed by slow intravenous injection of ibritumomab tiuxetan chelated with indium-111 (p. 2224.3) for imaging to

confirm that biodistribution of tumour cells is acceptable, but in some other countries such imaging is considered to provide relatively little useful information, and is omitted. A second rituximab treatment is given 7 to 9 days after the first, followed by ibritumomab tiuxetan chelated with yttrium-90 (p. 2230.1) for radio-immunotherapy.

Adverse Effects and Precautions

For general discussions, see Antineoplastics, p. 726.1 and p. 732.2.

Myelosuppression is common after doses of ibritumomab tiuxetan, and may be prolonged. Fatal intracranial haemorrhage has occurred. Infections and hypersensitivity reactions may also be severe. As ibritumomab tiuxetan is given with rituximab, severe infusion reactions due to the cytokine release syndrome may occur (see under Rituximab, p. 854.3). Severe cutaneous and mucocutaneous reactions, some fatal, have been reported and therapy should be stopped if they occur. Gastrointestinal disturbances are common. Other adverse effects include anorexia, asthenia, fever, cough, dyspnoea, dizziness, headache, insomnia, anxiety, arthralgia, myalgia, and peripheral oedema. Patients should be monitored for signs of extravasation in order to avoid radiation-associated tissue damage. If extravasation occurs, the infusion should be stopped immediately and restarted in another vein.

Complete blood and platelet counts should be monitored weekly, or more frequently if cytopenia is present, until haematological recovery. Ibritumomab tiuxetan should not be given to patients with extensive marrow involvement, impaired bone marrow reserve, or platelet or neutrophil counts below acceptable levels (see also Bone-marrow Depression, p. 730.3). Care should be taken during and after radiolabelling with indium-111 or yttrium-90 to minimise radiation exposure.

Effects on the skin. Severe cutaneous and mucocutaneous reactions have been reported after use of ibritumomab tiuxetan with rituximab, some of them with a fatal outcome.[1,2] Reactions included erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, bullous dermatitis, and exfoliative dermatitis. Onset was reported to vary from days to months. Treatment should be stopped if any patient has such a reaction.

Ibrutinib *(USAN, pINN)*

CRA-032765; Ibrutinibum; PCI-32765-00; PCI-32765; Ибрутиниб

1-[(3*R*)-3-[4-Amino-3-(4-phenoxyphenyl)-1*H*-pyrazolo[3,4-*d*]pyrimidin-1-yl]piperidin-1-yl]prop-2-en-1-one.

$C_{25}H_{24}N_6O_2$=440.5

CAS — 936563-96-1.

Profile

Ibrutinib is an inhibitor of Bruton's tyrosine kinase that is used in the treatment of relapsed mantle cell lymphoma (p. 698.2). The usual dose is 560 mg orally once daily; capsules should be swallowed whole and not opened. If a daily dose is missed, the next day's dose should not be increased. If severe toxicity occurs, doses should be withheld until recovery to baseline or grade 1. For the first occurrence, treatment is restarted at the usual dose. Subsequently, the dose should be reduced to 420 mg daily after the second occurrence, and to 280 mg daily after the third occurrence. Ibrutinib should be stopped if the patient is unable to tolerate 280 mg daily. Treatment is continued until the patient no longer benefits, or unacceptable toxicity occurs. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Ibrutinib is metabolised in the liver by the cytochrome P450 isoenzyme CYP3A family and use with strong or moderate inhibitors or strong inducers of these enzymes should be avoided. If use together is necessary, ibrutinib treatment may be interrupted for short-term therapy with a strong CYP3A inhibitor; the dose of ibrutinib should be reduced to 140 mg daily when used with a moderate CYP3A inhibitor.

The most commonly reported adverse effects include neutropenia, thrombocytopenia, anaemia, gastrointestinal disturbances, fatigue, musculoskeletal or abdominal pain, peripheral oedema, dyspnoea, rash, and decreased appetite. Haemorrhage, renal failure, and second primary malignancies have occurred.

Ibrutinib is also under investigation for chronic lymphocytic leukaemia.

$C_{26}H_{27}NO_9$,HCl=534.0

CAS — 58957-92-9 (idarubicin); 57852-57-0 (idarubicin hydrochloride).

ATC — L01DB06.

ATC Vet — QL01DB06.

UNII — 5VV3MDU5IE.

Pharmacopoeias. In *Jpn* and *US*.

USP 36: (Idarubicin Hydrochloride). A red-orange to red-brown powder. Slightly soluble in water; insoluble in acetone and in solvent ether; soluble in methyl alcohol. A 0.5% solution in water has a pH between 5.0 and 6.5. Store in airtight containers.

Incompatibility. Licensed product information states that precipitation occurs when idarubicin hydrochloride is mixed with heparin, and that it will degrade in alkaline solution.

Uses and Administration

Idarubicin like daunorubicin (p. 778.3), of which it is an analogue, is an anthracycline antibiotic and has antineoplastic actions similar to those of doxorubicin (p. 783.2). It is used as the hydrochloride, alone or with other drugs, for the induction of remission in patients with acute myeloid leukaemias (p. 693.1). It is also used as a second-line treatment in acute lymphoblastic leukaemia (p. 692.3), and advanced breast cancer (p. 702.1).

Idarubicin hydrochloride is given by *intravenous* injection into a fast-running infusion of sodium chloride 0.9% or glucose 5% over 5 to 15 minutes. The suggested dose in adult acute myeloid leukaemia is 12 mg/m^2 daily for 3 days, with cytarabine. A similar dose, as a single agent, has been given in acute lymphoblastic leukaemia. An alternative dosage schedule in acute myeloid leukaemia is 8 mg/m^2 given daily for 5 days, either alone or in combination therapy. For suggested doses in children with acute lymphoblastic leukaemia see Administration in Children, below.

When the intravenous route cannot be used, idarubicin hydrochloride may be given orally. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* A suggested *oral* dose in adult acute myeloid leukaemia as a single agent is 30 mg/m^2 daily for 3 days; 15 to 30 mg/m^2 may be given daily for 3 days when used with other drugs.

In patients with breast cancer unresponsive to front-line chemotherapy not including anthracyclines, idarubicin hydrochloride has been given orally in doses of 45 mg/m^2, as a single dose or divided over 3 consecutive days; the treatment may be repeated every 3 or 4 weeks depending on the haematological recovery. A total cumulative oral dose of 400 mg/m^2 should not be exceeded.

Blood counts should be performed frequently in patients receiving idarubicin, and monitoring of cardiac, hepatic, and renal function is recommended. Doses should be reduced in patients with hepatic or renal impairment (see also below). In patients who receive a second course of idarubicin, intravenous dosage should be reduced by 25% if severe mucositis developed with the first course; therapy should be delayed until the patient has recovered from this toxicity.

The actions and uses of idarubicin have been reviewed.[1] A study in leukaemia cells *in vitro* suggested that idarubicin was more active than a conventional anthracycline, daunorubicin, against cells with the multidrug resistance (MDR) phenotype.[2] A collaborative overview of randomised studies for acute myeloid leukaemia found that idarubicin-based therapy achieved better remission rates and overall survival than daunorubicin-based regimens.[3] Its oral bioavailability has been suggested to offer an advantage in the management of malignancies in older patients.[4]

2. Berman E, McBride M. Comparative cellular pharmacology of daunorubicin and idarubicin in human multidrug-resistant leukaemia cells. *Blood* 1992; **79:** 3267–73.
3. AML Collaborative Group. A systematic collaborative overview of randomised trials comparing idarubicin with daunorubicin (or other anthracyclines) as induction therapy for acute myeloid leukaemia. *Br J Haematol* 1998; **103:** 100–9.
4. Crivellari D, *et al.* New oral drugs in older patients: a review of idarubicin in elderly patients. *Crit Rev Oncol Hematol* 2004; **49:** 153–63.

Administration in children. Idarubicin hydrochloride may be given as a second-line treatment to children with relapsed acute lymphoblastic leukaemia. The suggested intravenous dose for use as a single agent is 10 mg/m^2 daily for 3 days. Precautions and monitoring are as for adults, see Uses and Administration, above.

Administration in hepatic impairment. UK licensed product information for idarubicin hydrochloride recommends that a dose reduction be considered in patients with hepatic impairment. Although no specific doses are suggested, it is noted that a 50% reduction in dosage has been used with some other anthracyclines in patients whose bilirubin concentrations were between 12 and 20 micrograms/mL. Use of idarubicin is contra-indicated in patients with severe hepatic impairment.

US licensed product information states that in patients with moderate or severe hepatic impairment, the metabolism of idarubicin is expected to be reduced, leading to higher systemic drug concentrations, and that dose reduction should be considered. No specific doses are recommended; idarubicin should be withheld if bilirubin concentrations exceed 50 micrograms/mL.

Administration in renal impairment. Both UK and US licensed product information state renal impairment may affect the disposition of idarubicin and that, in many studies, treatment was contra-indicated if serum creatinine concentrations exceeded 20 micrograms/mL. US licensed product information suggests that dose reduction be considered in renal impairment, but gives no specific doses; UK licensed product information states that idarubicin should not be used in patients with severe renal impairment.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin, p. 784.1. Raised liver enzymes and bilirubin can occur with idarubicin. Severe enterocolitis with perforation has been reported rarely. A cumulative total dose limit has not yet been defined. UK licensed

product information states that total cumulative oral doses up to 400 mg/m² have a low probability of cardiotoxicity. Cardiomyopathy has been reported in some patients with cumulative intravenous doses of 150 to 290 mg/m². It has been suggested that idarubicin may be associated with less cardiotoxicity than doxorubicin. Idarubicin should be given with caution, and in reduced doses, to patients with renal or hepatic impairment.

Effects on the heart. Cardiotoxicity is a major factor in limiting the use of anthracyclines (see under Doxorubicin, p. 784.1). It has been suggested that idarubicin may be associated with less cardiotoxicity than doxorubicin. However, a 34-year-old woman with no risk factors for heart disease developed severe congestive heart failure after her first exposure to idarubicin, which was given as part of an induction regimen for acute myeloid leukaemia. The patient's left ventricular ejection fraction improved after 4 months, supporting the hypothesis that, while chronic anthracycline-induced cardiomyopathy is irreversible, subacute congestive heart failure after short-term anthracycline use may be partially or totally reversible.[1]

1. Yang S-G, *et al.* The development of congestive heart failure and ventricular tachycardia after first exposure to idarubicin in a patient with acute myeloid leukaemia. *Br J Clin Pharmacol* 2010; **69**: 209–11.

Effects on the skin and nails. For a report of transverse hyperpigmented bands of the nails in a patient who received idarubicin, see under Doxorubicin, p. 784.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies idarubicin as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pharmacokinetics

On intravenous dosage idarubicin is rapidly distributed into body tissues and extensively tissue bound, with a volume of distribution which may be in excess of 2000 litres. It is extensively metabolised, both in the liver and extrahepatically; the principal metabolite, idarubicinol (13-dihydroidarubicin) has equal antineoplastic activity. Peak concentrations of idarubicin and idarubicinol in bone marrow and nucleated blood cells are 400 (idarubicin) and 200 (idarubicinol) times greater than those in plasma; cellular concentrations of drug and metabolite decline with apparent terminal half-lives of 15 and 72 hours respectively, whereas plasma half-lives are reported to be 20 to 22 hours and about 45 hours respectively. Idarubicin is excreted in bile, and to a lesser extent in urine, as unchanged drug and metabolites.

Idarubicin is also absorbed orally, reaching peak plasma concentrations within 4 hours. Estimates of its oral bioavailability vary from about 20 to 40%.

$C_7H_{15}Cl_2N_2O_2P$=261.1

CAS — 3778-73-2.

ATC — L01AA06.

ATC Vet — QL01AA06.

UNII — UM20QQM95Y.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Ifosfamide). A white or almost white, hygroscopic, fine crystalline powder. Soluble in water; freely soluble in dichloromethane. Store in airtight containers.

USP 36: (Ifosfamide). A white, crystalline powder. M.p. about 40 degrees. Freely soluble in water; very soluble in alcohol, in methyl alcohol, in isopropyl alcohol, in dichloromethane, and in ethyl acetate; very slightly soluble in hexanes. A 10% solution in water has a pH of between 4.0 and 7.0. Store in airtight containers at a temperature not exceeding 25 degrees.

Incompatibility. Ifosfamide appears to be compatible when mixed in solution with mesna.[1,2] However, ifosfamide appears to be incompatible with benzyl alcohol used as a preservative in Water for Injections: solutions made up with water preserved in this way became turbid, with the formation of aqueous and oily phases, at concentrations of ifosfamide greater than 60 mg/mL.[3]

1. Shaw IC, Rose JWP. Infusion of ifosphamide plus mesna. *Lancet* 1984; **i**: 1353–4.
2. Rowland CG, *et al.* Infusion of ifosfamide plus mesna. *Lancet* 1984; **ii**: 468.
3. Bohme RJ, *et al.* Incompatibility of ifosfamide with benzyl-alcohol-preserved bacteriostatic water for injection. *Am J Hosp Pharm* 1988; **45**: 627–8.

Stability. Ifosfamide undergoes a reversible chemical rearrangement in aqueous solution, which is sensitive to changes in pH.[1] The ratio of these compounds to one another in biological fluids may have a bearing on the toxicity and efficacy of ifosfamide.

1. Küpfer A, *et al.* Intramolecular rearrangement of ifosfamide in aqueous solutions. *Lancet* 1990; **335**: 1461.

Uses and Administration

Ifosfamide is an alkylating agent with properties similar to those of cyclophosphamide (p. 771.1), of which it is a congener. It is used in the treatment of solid tumours including those of the cervix, lung, ovary, testis, and thymus, as well as in sarcoma and in the treatment of lymphomas. For further mention of these uses see the cross-references given below.

Ifosfamide is given intravenously, either by injection as a solution diluted to less than 4%, or by infusion. Licensed dosage regimens include a total dose of 8 to 12 g/m² divided over 3 to 5 days, with the course repeated at 2 to 4 week intervals; a total dose of 6 g/m² divided over 5 days, repeated every 3 weeks; and doses of 5 to 6 g/m², to a maximum of 10 g, given as a single 24-hour infusion, repeated at 3 to 4 week intervals. The interval between courses also depends on the blood count (see also Bone-marrow Depression, p. 730.3). Oral ifosfamide has also been studied but is associated with neurotoxicity (see Effects on the Nervous System, below).

Ifosfamide should be given with mesna (see Administration, below), and adequate hydration should be maintained, to avoid urological toxicity; fluid intake should not be less than 2 litres daily.

Administration. Mesna (p. 1557.2) can combine with urotoxic ifosfamide metabolites in the kidney to form stable and non-toxic compounds. It is therefore given prophylactically with ifosfamide. It has a shorter half-life than ifosfamide so repeated doses are needed to provide adequate protection of the bladder. A common schedule uses intravenous mesna at 60% of the ifosfamide dose, divided into 3 doses given with, or 15 minutes before, ifosfamide, then 4 and 8 hours after ifosfamide.[1] Mesna may also be given orally, but higher doses are required.

1. Siu LL, Moore MJ. Use of mesna to prevent ifosfamide-induced urotoxicity. *Support Care Cancer* 1998; **6**: 144–54.

Malignant neoplasms. Ifosfamide may be used as an alternative to cyclophosphamide in lymphomas such as Burkitt's lymphoma (p. 697.3). It is also used in a variety of solid neoplasms, including in palliative regimens for advanced cervical cancer (p. 704.2); in the treatment of lung cancer (p. 710.2); in ovarian cancer (p. 711.2) and second-line and salvage regimens for testicular cancer (p. 715.1); in thymoma (p. 715.3); in adjuvant therapy for bone sarcomas (p. 717.3) and rhabdomyosarcoma (see Soft-tissue Sarcoma, p. 718.2).

Adverse Effects, Treatment, and Precautions

As for Cyclophosphamide, p. 772.2. Toxic effects on the urinary tract may be more severe with ifosfamide and may involve the kidneys as well as the bladder. CNS adverse effects have been reported, especially confusion, drowsiness, depressive psychosis, hallucinations, and rarely, seizures.

Effects on the heart. Severe myocardial depression, with heart failure and ventricular arrhythmias, has been reported in patients given high-dose ifosfamide.[1] Symptoms were reversible with appropriate treatment in most cases although one patient died of cardiogenic shock.

1. Quezado ZMN, *et al.* High-dose ifosfamide is associated with severe, reversible cardiac dysfunction. *Ann Intern Med* 1993; **118**: 31–6.

Effects on the kidneys. In addition to its effects on the bladder ifosfamide may be associated with serious nephrotoxicity. A prospective study found that moderate and severe nephrotoxicity are common after ifosfamide treatment in children and adolescents, affecting 28% of patients.[1] Both proximal and distal tubular damage,[2,3] and to a lesser extent glomerular effects,[3] are seen, and the Fanconi syndrome (with development of hypophosphataemic rickets in several children),[3-7] and nephrogenic diabetes insipidus[2,7] may result. Progressive chronic renal failure after high-dose ifosfamide has been described.[8] Life-threatening hypokalaemia possibly due to a renal lesion has also occurred.[9] Results in *rats* suggest that generation of toxic metabolites within the kidney itself may be responsible, and that repairable renal damage occurs after the first dose, which is aggravated by repeated toxic insults.[10] This is in agreement with clinical results, since although renal damage has been seen after a single dose, perhaps representing an idiosyncratic reaction,[11,12] most cases have been in children receiving relatively high doses long-term. Renal damage appears to persist after withdrawal of ifosfamide in these patients and may be largely irreversible.[13] Toxicity may also progress over the months or years after treatment,[14] or late renal damage may develop after treatment has stopped.[15] Proximal tubular dysfunction was the most common form of damage in patients who had received ifosfamide at least 5 years previously for childhood malignancies,[14,15] and it has been suggested that reductions in the glomerular filtration rate are secondary to this, rather than a direct result of ifosfamide toxicity.[14] Although the risk of late toxicity was considered low, the damage was moderately severe even when the cumulative dose was small (60 g/m²).[15]

Possible risk factors for nephrotoxicity have included younger age (less than 5 years), high cumulative doses, use with cisplatin, or unilateral nephrectomy.[1,14,16] The cumulative dose appears to be the most important risk factor for the development and severity of toxicity.[1,16] The maximum safe dose of ifosfamide has not been established;[1,14,16] although *significant nephrotoxicity* is relatively infrequent below 84 g/m², doses above 119 g/m² are associated with a high risk of severe damage. Although some found no association between age at treatment and renal damage,[1] others noted that a younger age was associated with more severe nephrotoxicity,[14,16] and suggested that caution is needed when giving cumulative doses of 45 g/m² and above to children aged under 3 years[14] or 60 g/m² and above to those under 5 years.[16] Acetylcysteine has been investigated for its potential protective effect against nephrotoxicity.[17]

Effects on the nervous system. Use of ifosfamide (with or without mesna for urothelial protection) may be associated with the development of severe encephalopathy, which develops in 10 to 40% of patients receiving high doses. Symptoms include confusion, stupor, seizures, hallucinations, blurred vision, and occasionally, coma; fatalities have been reported.[1] The effect has been suggested to be due to a metabolite, chloroacetaldehyde,[1] a hypothesis

supported by the increased incidence of encephalopathy after oral rather than intravenous doses.[2] Others suggest that the dechloroethylated metabolites may contribute, and in particular the *R*-enantiomer of 3-dechloroethyl-ifosfamide, which is a metabolite of *S*-ifosfamide.[3] There is some uncertainty about the contributory role of mesna, if any: encephalopathy has not been seen when mesna is given with cyclophosphamide,[4] and has been seen when ifosfamide is given alone,[2] but an exacerbatory role for mesna cannot be ruled out,[3] perhaps via its chelating properties.[4]

Proposed risk factors include renal and hepatic impairment, pelvic disease, brain metastases, electrolyte imbalances, and drug-drug interactions.[1] A retrospective review of 237 patients given ifosfamide, of whom 38 developed encephalopathy, found no evidence that age or ifosfamide dose influenced the development of the condition, and serum creatinine values were in the normal range in the affected group, although they were slightly higher than in those not affected; however, low serum albumin did seem to be associated with greater risk.[4] It has also been suggested that the drug be given by continuous infusion over several days where possible, since this route has by far the lowest incidence of encephalopathy (7%, versus 26% with intravenous bolus and 43% with oral doses).[7] Care may also be required when giving other antineoplastics to patients who have had encephalopathy after ifosfamide, since a case of encephalopathy with bleomycin (not normally associated with neurotoxicity) has been reported in such a patient.[8] In another case, ifosfamide neurotoxicity developed after the addition of aprepitant to a standard antiemetic regimen that included ondansetron and dexamethasone; induction of ifosfamide metabolism to neurotoxic metabolites may have accounted for the symptoms.[9] Hypoalbuminaemia has been identified as a risk factor in other case reports. A small cohort study identified hypoalbuminaemia, female sex, low total bilirubin, anaemia, and obesity as being associated with the development of ifosfamide-induced encephalopathy.[1]

Methylthioninium chloride has been tried to prevent or reverse signs of encephalopathy (see Glutaric Aciduria under Uses of Methylthioninium Chloride, p. 1559.2).

Handling and disposal. A study[1] found that ifosfamide 8% solution penetrated all of 4 brands of latex glove and one PVC glove, although the diffusion rate was 4 or more times slower than through cadaver skin. Permeation was greater through the PVC glove than the latex gloves, partly due to its lesser thickness, although permeation was not dependent on thickness alone and varied between gloves of the same brand as well as between brands. They recommended that latex gloves of a suitable brand should be worn when handling ifosfamide, and changed at least every 2 hours. For reference to a method for the destruction of ifosfamide waste, see under Cyclophosphamide, p. 773.2.

1. Corlett SA, *et al.* Permeation of ifosfamide through gloves and cadaver skin. *Pharm J* 1991; 247: R39.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies ifosfamide as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

As for Cyclophosphamide, p. 773.2. For a general outline of antineoplastic drug interactions, see p. 733.3. For reference to the effects of ifosfamide on oral anticoagulants, see under Warfarin Sodium, p. 1532.2. For a report of the enhancement of cisplatin-induced ototoxicity and nephrotoxicity, see under Cisplatin, p. 768.3.

Antibacterials. Oral *rifampicin* given twice daily for 6 days, starting 3 days before intravenous ifosfamide (as a 24-hour infusion), increased the clearance of ifosfamide by over 100%; however, exposure to metabolites of ifosfamide was relatively unchanged. The authors considered that rifampicin might decrease the therapeutic efficacy of ifosfamide.[1]

1. Kerbusch T, *et al.* Modulation of the cytochrome P450-mediated metabolism of ifosfamide by ketoconazole and rifampin. *Clin Pharmacol Ther* 2001; 70: 132–41.

Antifungals. *Ketoconazole* given orally for 4 days, starting 1 day before intravenous ifosfamide (given as a 24-hour infusion), decreased ifosfamide clearance. However, ifosfamide metabolism to active metabolites was decreased, and urinary excretion of ifosfamide was increased. Ketoconazole may decrease the therapeutic efficacy of ifosfamide.[1]

1. Kerbusch T, *et al.* Modulation of the cytochrome P450-mediated metabolism of ifosfamide by ketoconazole and rifampin. *Clin Pharmacol Ther* 2001; 70: 132–41.

Pharmacokinetics

Ifosfamide is normally given intravenously, although it is well absorbed from the gastrointestinal tract. The pharmacokinetics of ifosfamide are reported to exhibit considerable interindividual variation. It is a prodrug that is extensively metabolised, chiefly by cytochrome P450 isoenzymes such as CYP3A4 and CYP2B6 in the liver, to both active and inactive metabolites; there is some evidence that metabolism is saturated at very high doses. Although licensed product information states that a mean terminal elimination half-life is about 15 hours after a single high-dose intravenous bolus, most studies at lower doses appear to have recorded elimination half-lives of about 4 to 8 hours. After repeated doses (fractionated therapy) there is a decrease in the elimination half-life, apparently due to autoinduction of metabolism. Ifosfamide is distributed into the CSF. It is excreted largely in urine, as unchanged drug and metabolites.

3. Kerbusch T, *et al.* Clinical pharmacokinetics and pharmacodynamics of ifosfamide and its metabolites. *Clin Pharmacokinet* 2001; 40: 41–62.

In a study[1] in 20 patients receiving intravenous ifosfamide over 3 or 5 days, the median elimination half-life of ifosfamide was 3.85 hours in patients under 60 years of age compared with 6.03 hours in those over age 60; this difference appeared to be due to an increased volume of distribution in the older age group. The autoinduction of metabolism typically seen with multiple doses of ifosfamide was not affected by age. The increased clearance seen over time during a 5-day cycle of ifosfamide treatment[2] was not sustained over the 21 days between cycles, but was reproducible and of similar magnitude in the subsequent cycle.

In another study[3] the half-life of the *S*-enantiomer of ifosfamide was found to be 5.98 hours after an intravenous bolus of the racemate, compared with 7.12 hours for the *R*-enantiomer.

CAS — 152459-95-5 (imatinib); 220127-57-1 (imatinib mesilate).

ATC — L01XE01.

UNII — 8A1O1M485B.

Uses and Administration

Imatinib is a tyrosine kinase inhibitor that inhibits the BCR-ABL tyrosine kinase created by the Philadelphia chromosome abnormality in chronic myeloid leukaemia (p. 694.2) and acute lymphoblastic leukaemia (p. 692.3). It also inhibits the tyrosine kinase for platelet-derived growth factor and stem cell factor, c-kit (CD117), which is overexpressed in gastrointestinal stromal tumours (see Soft-tissue Sarcoma, p. 718.2). Imatinib is also indicated for patients with myelodysplastic syndromes (p. 694.3), hypereosinophilic syndrome, aggressive systemic mastocytosis (p. 1226.3), and dermatofibrosarcoma protuberans. Imatinib is given orally as the mesilate but doses are expressed as the base. Imatinib mesilate 119.5 mg is equivalent to about 100 mg of imatinib. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

In the treatment of **chronic myeloid leukaemia**, patients in chronic phase may be given the equivalent of 400 mg of the base daily, increased to 600 mg daily or 400 mg twice daily if required. Patients in blast crisis or accelerated phase are given 600 mg daily, increased to 400 mg twice daily if necessary.

In the treatment of patients with newly diagnosed **acute lymphoblastic leukaemia**, imatinib 600 mg daily may be given with induction, consolidation, or maintenance chemotherapy. The same dose may be given as monotherapy for patients with relapsed or refractory disease.

In the treatment of **gastrointestinal stromal tumours** (GIST), 400 mg daily is recommended. In patients with unresectable or metastatic disease that progresses at this dose, a dose increase up to 400 mg twice daily may be considered.

For patients with **myelodysplastic disease**, the recommended dose of imatinib is 400 mg daily. For **mastocytosis**, 400 mg daily is given, unless there is associated eosinophilia, in which case a starting dose of 100 mg daily is recommended, increased to 400 mg if response is inadequate. Similarly, the recommended dose for **hypereosinophilic syndrome** is 400 mg daily, although a subset of patients with FIP1L1-platelet-derived growth factor receptor-α fusion kinase should be started on 100 mg daily, increased to 400 mg if response is insufficient. Patients with **dermatofibrosarcoma protuberans** may be given 400 mg twice daily.

Doses should be taken with food, and accompanied by plenty of water, to minimise gastric irritation. Dose adjustments may be necessary if myelosuppression or hepatotoxicity occurs; blood counts and liver function should be regularly monitored (see Administration in Hepatic Impairment, p. 808.1). Doses are also adjusted in renal impairment, see p. 808.1.

Doses of imatinib should be increased by 50%, and clinical response should be carefully monitored, in patients given potent CYP3A4 inducers such as rifampicin or phenytoin. For children's doses, see Administration in Children, below.

Administration in children. In the UK, the licensed oral dose of imatinib for children with chronic myeloid leukaemia (CML) is 340 mg/m² daily, for those in chronic or advanced phase; a total dose of 800 mg should not be exceeded. The dose may be increased to 570 mg/m² daily (maximum total dose 800 mg) in children with disease progression, with unsatisfactory haematological response after at least 3 months of treatment, with no cytogenetic response after 12 months of treatment, or with loss of a previously achieved haematological or cytogenetic response.

In the USA, imatinib is given in a usual dose of 340 mg/m² daily in children with newly diagnosed CML or with chemotherapy in newly diagnosed acute lymphoblastic leukaemia; the dose should not exceed 600 mg.

Treatment can be given as a once-daily dose, or, in CML, split into morning and evening doses. There is no experience with the use of imatinib in children under 1 year of age.

Use in children has been reviewed.[1]

1. Barr RD. Imatinib mesylate in children and adolescents with cancer. *Pediatr Blood Cancer* 2010; 55: 18–25.

Administration in hepatic impairment. Imatinib is metabolised in the liver. Licensed product information in the UK recommends that patients with mild, moderate, or severe liver impairment should be given the minimum recommended oral dose of 400 mg daily. In the USA, patients with mild and moderate impairment should be given the recommended daily dose, but in those with severe hepatic impairment, a 25% decrease in dose is recommended. In both countries, degrees of hepatic impairment are defined as:

- mild: total bilirubin equal to 1.5 times the upper limit of normal (ULN); aspartate aminotransferase (AST/SGOT) greater than ULN. AST/SGOT can be normal or less than ULN if the total bilirubin is greater than ULN
- moderate: total bilirubin > 1.5 and up to 3 times the ULN
- severe: total bilirubin > 3 to 10 times the ULN

US licensed product information also states that if, during treatment, elevations in bilirubin > 3 times the ULN or liver transaminases > 5 times the ULN occur, imatinib should be withheld until bilirubin levels have returned to less than 1.5 times the ULN and transaminase levels to less than 2.5 times the ULN. Treatment may then be continued at a reduced daily dose. In adults the dose is reduced from 800 mg to 600 mg, from 600 mg to 400 mg, and from 400 mg to 300 mg. In children, the dose should be reduced from 340 mg/m^2 daily to 260 mg/m^2 daily, or from 260 mg/m^2 daily to 200 mg/m^2 daily.

Administration in renal impairment. UK licensed product information for imatinib states that patients with mild or moderate renal impairment, defined as creatinine clearance (CC) of 20 to 59 mL/minute, may be given an initial oral dose of 400 mg daily. Patients with severe renal impairment (CC less than 20 mL/minute) or on dialysis can also be started at this dose, although caution is recommended; the dose can be adjusted as needed.

In the USA, patients with mild renal impairment (CC 40 to 59 mL/minute) should not be given a dose greater than 600 mg. Patients with moderate renal impairment (CC 20 to 39 mL/minute) should have their initial dose halved; the dose can then be adjusted as needed, although a maximum dose of 400 mg is recommended. Caution is advised in those with severe impairment; doses of 100 mg daily have been used.

Hypereosinophilic syndrome. Imatinib has been reported to produce clinical responses in patients with the hypereosinophilic syndrome (HES).[1-4] Some reports suggest that imatinib also has activity in mast-cell disease, even in the absence of associated eosinophilia.[5] However, not all patients with HES respond to imatinib.[4] Many patients with the myelodysplastic variant of HES express a novel kinase derived from an abnormal fusion of platelet-derived growth factor receptor-α gene with a neighbouring gene, FIP1L1. Almost all patients with this FIP1L1-platelet-derived growth factor receptor-α fusion kinase will respond to imatinib, but a subset of patients with HES without known imatinib targets have also been reported to respond to the drug.[6,7]

Adverse Effects and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The most common adverse effects of imatinib mesilate include gastrointestinal disturbances, myelosuppression, superficial oedema, myalgia, arthralgia, muscle cramps, rashes, fatigue, and headache. Myelosuppression usually manifests as neutropenia, thrombocytopenia, anaemia, or febrile neutropenia; haemolytic anaemia has occurred rarely. Other common adverse effects include dizziness, taste disturbances, anorexia, paraesthesia, insomnia, eye disorders or visual disturbances, epistaxis, cough, dyspnoea, dry skin, pruritus, alopecia, night sweats, pyrexia, weakness, and rigors. Hepatotoxicity may occur; fatal cases of hepatic necrosis have been reported. Aseptic necrosis of bone, mainly in the femoral head, has been reported rarely. There are reports of serious and severe skin disorders, including erythema multiforme, Stevens-Johnson syndrome, acute generalised exanthematous pustulosis, exfoliative dermatitis, and bullous eruptions. Rhabdomyolysis has also occurred. Haemorrhages are common; gastrointestinal bleeding, however, is more frequent in those patients treated for stromal tumours. Ulceration can occur; gastrointestinal perforation, fatal in some cases, has been reported rarely.

Severe fluid retention commonly occurs, and may result in pleural and pericardial effusion, pulmonary oedema, and ascites. Some fatalities have been reported, and treatment may need to be stopped if there is unexpected, rapid weight gain. Elderly patients and those with a history of cardiac disease may be at increased risk. Isolated cases of left ventricular dysfunction have been reported; patients with cardiac disease or risk factors for cardiac failure should be monitored. Other reported cardiac disorders include congestive heart failure, palpitations, tachycardia, arrhythmias, angina pectoris, and myocardial infarction. There are reports, including fatalities, of cerebral oedema, increased intracranial pressure and papilloedema. Hypothyroidism has been reported in patients on levothyroxine replacement therapy; TSH concentrations should be monitored in these patients.

Imatinib mesilate should be taken with food and a large glass of water to minimise gastrointestinal irritation. Complete blood counts and liver function should be monitored regularly.

Effects on the heart. Ten patients receiving imatinib developed severe congestive heart failure without obvious cause; all patients had normal left ventricular function before imatinib was started. Mitochondrial abnormalities were found after myocardial biopsy on 2 of the patients. These findings were confirmed by studies on *mice* and *in vitro*. The authors suggested that patients be closely followed for clinical manifestations of left ventricular dysfunction.[1]

Subsequent evaluation by the manufacturer (*Novartis*) established that the frequency of reported cardiac events was less than 1%. However, they recommended that patients with known cardiac disease or risk factors for cardiac failure be monitored accordingly, that those developing clinical manifestations suggestive of congestive cardiac failure be thoroughly evaluated and treated, and that elderly patients or those with underlying heart disease be evaluated for baseline left ventricular ejection fraction.[2]

Effects on the kidneys. Imatinib has been associated with the development of acute renal failure, requiring haemodialysis.[1-3]

1. Kitiyakara C, Atichartakarn V. Renal failure associated with a specific inhibitor of BCR-ABL tyrosine kinase, STI 571. *Nephrol Dial Transplan* 2002; 17: 685–7.

Effects on the lungs. Interstitial pneumonitis has been reported with imatinib;[1-8] presenting symptoms include dry cough and dyspnoea. Doses of imatinib ranged from 100 mg to 600 mg daily. In most cases, the pneumonitis resolved after stopping imatinib and starting corticosteroid therapy. The mechanism was unclear, and may involve a hypersensitivity reaction. In an analysis of 27 cases of interstitial lung disease associated with imatinib therapy,[8] 30% of patients showed a hypersensitivity reaction radiological pattern. Pre-existing lung disease may be a risk factor.

Effects on reproductive potential. Oligospermia[1] and ovarian failure[2] have been reported after treatment with imatinib. Patients should be counselled before therapy about the risk of impaired fertility.

1. Seshadri T, *et al.* Oligospermia in a patient receiving imatinib therapy for the hypereosinophilic syndrome. *N Engl J Med* 2004; 351: 2134–5.
2. Christopoulos C, *et al.* Primary ovarian insufficiency associated with imatinib therapy. *N Engl J Med* 2008; 358: 1079–80.

Effects on the skin, hair, and nails. There are reports of acute generalised exanthematous pustulosis in patients given imatinib.[1,2] The authors noted that severe skin reactions had been reported in some other patients given the drug, and speculated that the effect might be dose-dependent and related to its pharmacological action. In subsequent reports[3-5] of cutaneous adverse effects, this dose-dependency has also been seen, with effects especially at doses of 600 mg daily and above. In a report of a livedoid pattern of rash in 3 patients taking imatinib, the authors noted that adverse skin reactions to imatinib tend to be strongly dose-dependent, are self-limiting, and do not usually affect the mucous membranes.[4] Epidermal necrolysis occurred in a patient who underwent stem cell transplantation after treatment with imatinib.[7] The authors suggested that prolonged inhibition of platelet-derived growth factor by imatinib may have impaired the repair of skin damage caused by the conditioning therapy. In a report of 19 patients with skin reactions, the authors suggested that the actions of imatinib on platelet-derived growth factor may have caused an increase in dermal interstitial fluid pressure, capable of inducing oedema and the subsequent erythema and desquamation that was seen. Rare reactions included psoriasis, hyaline cell syringoma, and malpighian epithelioma, all of which occurred after at least 1 year of therapy.[8] Follicular mucinosis[9] and panniculitis[10] have also been reported with use of imatinib, as has Stevens-Johnson syndrome.[11,12] Palmoplantar hyperkeratosis and nail dystrophy can occur,[13,14] as can lichenoid eruptions.[14] Repigmentation of grey hair has also been reported.[15]

Oral corticosteroids have been used to resolve most cases of skin eruptions.[8] In other instances, re-introduction of imatinib at low doses, gradually increased to full dosage, has been successfully tolerated.[8,12,16] In one patient, who developed exfoliative dermatitis with imatinib and had recurrent reactions despite decreased doses, a once-weekly dose of imatinib was associated with a less severe rash that eventually disappeared over a period of 4 months.[17]

Gynaecomastia. Gynaecomastia was noted in 7 of 38 men assessed for hormone concentrations while enrolled in studies of imatinib; the authors attributed the disorder to reductions in testosterone concentrations due to imatinib.[1]

1. Gambacorti-Passerini C, *et al.* Gynaecomastia in men with chronic myeloid leukaemia after imatinib. *Lancet* 2003; 361: 1954–56.

Hypophosphataemia. Hypophosphataemia and associated changes in bone and mineral metabolism were reported in a study of patients receiving imatinib. Patients with normal serum-phosphate concentrations also had similar changes in bone turnover. Hypophosphataemia was apparently related to patient age and imatinib dose; it was also associated with decreased serum concentrations of calcium and vitamin D.[1] In a review of data, the manufacturers (*Novartis*) noted an incidence of 50% of patients in 2 studies; overall 1.5% had grade 4 hypophosphataemia. However, the reported incidence of hypophosphataemia as an adverse effect of imatinib was only 3%. They suggested that phosphate concentrations be monitored in patients taking imatinib until further elucidation of the effect of the drug on bone is available.[2] While some have questioned the association between treatment with imatinib and hypophosphataemia,[3] others have also reported hypophosphataemia during treatment with the drug.[4] The effect, however, appears to be reversible on stopping imatinib.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies imatinib as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/09/11)

Pregnancy. Two of 3 pregnancies in 2 patients taking imatinib were successful; the infants were both small for weight, but healthy and without congenital abnormalities. In the third case, a first trimester miscarriage occurred. Both women continued imatinib throughout their pregnancies.[1]

In another report,[2] 10 women became pregnant while being treated with imatinib for chronic myeloid leukaemia. Imatinib therapy was stopped upon discovery of the pregnancy; exposure to imatinib ranged from 4 to 9 weeks. Two patients had a spontaneous abortion shortly after stopping imatinib, and another patient elected to have a therapeutic abortion. Seven other pregnancies went to term, resulting in 8 babies. One infant had hypospadias which was surgically corrected without complications; all other infants were healthy. The partners of 8 male patients also conceived while the men were receiving imatinib, one of them twice. All male patients continued therapy with imatinib. One spontaneous abortion occurred. Of the 8 babies born, 1 was found to have a mild rotation of the small intestine requiring surgery shortly after birth. The authors considered it possible that the brief exposure to imatinib may have slightly increased the risk of spontaneous abortion. While concluding that normal pregnancies are possible during imatinib therapy, the authors of both reports emphasised that possible teratogenic effects cannot be ruled out, and that patients should still be advised to use appropriate and effective contraception.

A similar warning was issued in a review of outcome data from 125 pregnancies involving exposure to imatinib. The authors noted that 63 pregnancies had resulted in the live birth of normal infants; a further 35 women terminated the pregnancy (in 3 cases because fetal abnormalities were found), and 18 ended in spontaneous abortion.[3] However, there were 9 infants with congenital abnormalities, several of which were strikingly similar, a fact that was considered to be of some concern.

Syndrome of inappropriate ADH secretion. Hyponatraemia, leading to a syndrome of inappropriate ADH secretion (SIADH) has been reported after therapy with imatinib at a dose of 800 mg daily. Fluid restriction and dose reduction to 600 mg daily restored sodium concentrations to normal.[1]

1. Liapis K, *et al.* Syndrome of inappropriate secretion of antidiuretic hormone associated with imatinib. *Ann Pharmacother* 2008; 42: 1882–6.

Tumour lysis syndrome. Tumour lysis syndrome has been reported with imatinib;[1,2] patients should be monitored closely. Allopurinol and adequate hydration have been suggested as prophylaxis in patients with a high tumour burden.[2]

Interactions

Imatinib mesilate is metabolised by the cytochrome P450 isoenzyme CYP3A4, and drugs that inhibit this enzyme, such as azole antifungals and macrolide antibacterials, may increase blood concentrations of imatinib. Equally, inducers of CYP3A4 (such as carbamazepine, dexamethasone, St John's wort, phenobarbital, phenytoin, and rifampicin) may reduce blood concentrations of imatinib; imatinib dosage may need to be increased in these patients (see Uses and Administration, p. 807.3).

In vitro studies have indicated that imatinib itself inhibits the cytochrome P450 isoenzymes CYP3A4, CYP2C9, and CYP2D6, and may increase blood concentrations of drugs that are substrates of these enzymes.

The dose of levothyroxine may need to be increased before imatinib is given to patients with hypothyroidism (see Antineoplastics under Interactions of Levothyroxine, p. 2341.3).

Antifungals. In a small study in healthy subjects, *ketoconazole* significantly increased imatinib exposure; mean maximum plasma concentration and area under the concentration-time curve increased, and clearance of imatinib decreased. The half-life of imatinib appeared relatively unchanged. To avoid overexposure, single subtherapeutic doses of imatinib had been used (200 mg); the authors noted that clinical significance might arise with use of imatinib in daily doses of 800 mg or more.[1]

1. Dutreix C, *et al.* Pharmacokinetic interaction between ketoconazole and imatinib mesylate (Glivec) in healthy subjects. *Cancer Chemother Pharmacol* 2004; 54: 290–4.

Calcium-channel blockers. For a report of a possible interaction between imatinib and *nifedipine*, see Antineoplastics under Interactions of Nifedipine, p. 1453.3.

St John's wort. Exposure to imatinib was significantly reduced when it was given after 2 weeks of treatment with St John's wort; area under the concentration-time curve was decreased, maximum plasma concentration and half-life of imatinib were reduced, and clearance increased.[1,2]

1. Frye RF, *et al.* Effect of St John's wort on imatinib mesylate pharmacokinetics. *Clin Pharmacol Ther* 2004; 76: 323–9.
2. Smith PF, *et al.* The influence of St. John's wort on the pharmacokinetics and protein binding of imatinib mesylate. *Pharmacotherapy* 2004; 24: 1508–14.

Pharmacokinetics

Imatinib mesilate is well absorbed after oral doses and peak blood concentrations occur after 2 to 4 hours. The mean bioavailability is about 98%. Imatinib is reported to be about 95% bound to plasma proteins. Plasma elimination half-lives of imatinib and its major active metabolite, the *N*-demethylated piperazine derivative, are about 18 and 40 hours respectively. The major enzyme responsible for the metabolism of imatinib is cytochrome P450 isoenzyme CYP3A4; isoenzymes CYP1A2, CYP2D6, CYP2C9, and CYP2C19 also play a minor role. About 81% of a dose is eliminated within 7 days in the faeces (68%) and urine (13%). It is excreted mostly as metabolites, with only 25% as unchanged drug.

Imexon *(rINN)*

BM-06002; Imexón; Imexonum; Имексон.
(5*R*,*S*)-4-Amino-1,3-diazabicyclo[3.1.0]hex-3-en-2-one.
$C_4H_5N_3O$=111.1
CAS — 59643-91-3.
UNII — 8F63U28T2V.

NOTE. The name Amplimexon has been used as a trade mark for imexon.

Profile

Imexon is a cyanoaziridine compound that appears to act as an antineoplastic in several ways, one of which is by causing mitochondrial disruption in the cancer cell, thus inducing apoptosis. It is under investigation for the treatment of malignant neoplasms, including ovarian cancer, pancreatic adenocarcinoma, multiple myeloma, and metastatic malignant melanoma.

Ingenol Mebutate *(USAN, rINN)*

Ingenol Mebutato; Ingenoli Mebutas; 3-Ingenyl Angelate; Mébutate d'Ingénol; PEP-005; Ингенол Мебутат.
(1a*R*,2*S*,5*R*,5a*S*,6*S*,8a*S*,9*R*,10a*R*)-5,5a-Dihydroxy-4-(hydroxymethyl)-1,1,7,9-tetramethyl-11-oxo-1a,2,5,5a,6,9,10,10a-octahydro-1*H*-2,8a-methanocyclopenta[*a*]cyclopropa[*e*]cyclodecen-6-yl (2*Z*)-2-methylbut-2-enoate.
$C_{25}H_{34}O_6$=430.5
CAS — 75567-37-2.
ATC — D06BX02.
ATC Vet — QD06BX02.
UNII — 7686550JAH.

Uses and Administration

Ingenol mebutate is a protein kinase C activator isolated from the plant *Euphorbia peplus*. It is used in the topical treatment of actinic keratosis (see Basal Cell and Squamous Cell Carcinoma, p. 714.2). A gel containing 0.015% is applied once daily for 3 consecutive days to affected areas on the face and scalp. For areas on the trunk and extremities, a 0.05% gel is applied once daily for 2 days. Patients should wash their hands immediately after applying the gel, and treated areas should not be touched or washed for 6 hours.

Ingenol mebutate is also under investigation in the treatment of non-melanoma skin cancer.

2. Siller G, *et al.* PEP005 (ingenol mebutate) gel, a novel agent for the treatment of actinic keratosis: results of a randomized, double-blind, vehicle-controlled, multicentre, phase IIa study. *Australas J Dermatol* 2009; 50: 16–22.
3. Siller G, *et al.* PEP005 (ingenol mebutate) gel for the topical treatment of superficial basal cell carcinoma: results of a randomized phase IIa trial. *Australas J Dermatol* 2010; 51: 99–105.

Adverse Effects and Precautions

The topical application of ingenol mebutate typically causes local skin reactions including erythema, flaking, crusting,

swelling, blistering, and ulceration. These effects usually occur within 1 day of starting treatment, peak up to 1 week after finishing treatment, and resolve within 2 weeks for affected areas on the face and scalp and within 4 weeks for areas on the trunk and extremities. Reactions can sometimes be severe. Ingenol mebutate should not be used until the skin is healed from any previous drug or surgical treatment.

Severe eye pain, eyelid oedema, eyelid ptosis, and periorbital oedema have occurred after inadvertent ocular exposure to ingenol mebutate gel. Patients should wash their hands well after handling the gel, and avoid transferring the drug to the eye during and after application.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Neth.*: Picato; *UK*: Picato; *USA*: Picato.

Iniparib *(rINN)*

BSI-201; Iniparibum; Инипариб.

4-Iodo-3-nitrobenzamide.

$C_7H_5IN_2O_3$=292.0

CAS — 160003-66-7.

Profile

Iniparib is a poly (ADP-ribose) polymerase-1 (PARP-1) inhibitor that is under investigation for the treatment of several malignant neoplasms including brain, breast, ovarian, uterine, and non-small cell lung cancer. Initial studies have had mixed results.

References.

Inotuzumab Ozogamicin *(USAN, rINN)*

CMC-544; Inotuzumab ozogamicina; Inotuzumab Ozogamicine; Inotuzumabum Ozogamicinum; WAY-207294; Иноту-зумаб Озогамицин.

Immunoglobulin G4, anti-(human CD22 (antigen)) (human-mouse monoclonal G544 heavy chain), disulfide with human-mouse monoclonal G544 κ-chain, dimer, conjugate with ozogamicin.

CAS — 635715-01-4.

UNII — P93RUU11P7.

Profile

Inotuzumab ozogamicin is a recombinant humanised monoclonal antibody conjugated to calicheamicin, a cytotoxic antibiotic. It is under investigation for the treatment of non-Hodgkin's lymphomas.

Interleukin-2

BG-8301 (teceleukin); Epidermal Thymocyte Activating Factor; ETAF; Factor de crecimiento de células T; IL-2; Interleucina 2; T-cell Growth Factor; TCGF; Интерлейкин-2.

Description. Interleukin-2 is a naturally-occurring 133-amino-acid glycoprotein with a molecular weight of about 15 000. It is available from natural sources or as a product of recombinant DNA technology (rIL-2).

In addition to aldesleukin (below) modified forms of interleukin-2 produced by recombinant DNA technology have included celmoleukin and teceleukin.

Aldesleukin *(BAN, USAN, rINN)*

Aldesleukiini; Aldesleukina; Aldesleukine; Aldesleukinum; Aldeslokin; Des-alanyl-1, Serine-125 Human Interleukin-2; Recombinant Interleukin-2; 125-L-Serine-2–133-interleukin 2 (human reduced); Альдеслейкин.

CAS — 110942-02-4.

ATC — L03AC01.

ATC Vet — QL03AC01.

UNII — M89N0Q7EQR.

Description. Aldesleukin (modified human recombinant interleukin-2) is produced by recombinant DNA technology using an *Escherichia coli* strain containing an analogue of the human interleukin-2 gene. It differs from native interleukin-2 in that it is not glycosylated, it has no N-terminal alanine, and it has serine substituted for cysteine at position 125.

Incompatibility. Aldesleukin 33 800 units/mL in glucose 5% lost significant biological activity when mixed with other drugs including ganciclovir sodium, lorazepam, pentamidine isetionate, prochlorperazine edisilate, and promethazine hydrochloride.[1] However, the incompatibility was not detectable by spectrophotometric methods and only lorazepam was visually incompatible, suggesting that these methods may be invalid for assessing the compatibility of proteins.

1. Alex S, *et al.* Compatibility and activity of aldesleukin (recombinant interleukin-2) in presence of selected drugs during simulated Y-site administration: evaluation of three methods. *Am J Health-Syst Pharm* 1995; 52: 2423–6.

Stability. Aldesleukin lost 75 to 100% of activity when reconstituted with glucose 5% or sodium chloride 0.9% in a plastic syringe and given over 24 hours with a syringe driver.[1,2] Loss of activity was not seen if aldesleukin was reconstituted with water alone[2] or with the addition of albumin.[1,2] It was suggested that loss of activity could be suspected because of lack of toxicity,[1,2] and that the lack of toxicity in some published studies could be due to this.[1,3] However, the authors of these studies indicated that they had reconstituted aldesleukin with albumin.[4,5] Reconstitution with low concentrations of albumin has been advocated to avoid bioavailability problems,[1,4,6] but is not recommended for currently licensed preparations. Vials of aldesleukin are reconstituted with water for injection.

However, UK licensed product information allows for further dilution of reconstituted aldesleukin with up to 500 mL of glucose 5%, containing human albumin 0.1%, when infused over a 24-hour period; the albumin should be added and mixed with the glucose before addition of the reconstituted aldesleukin.

For short intravenous infusion, the US licensed product information indicates that dilution in glucose 5% outside of a specified range (below 30 micrograms/mL and above 70 micrograms/mL) results in increased variability in drug delivery.

Reconstitution or dilution of aldesleukin preparations with sodium chloride 0.9% is not recommended because increased aggregation occurs.

Units

100 units of human interleukin-2 are contained in one ampoule of the first International Standard Preparation (1987). The activity of interleukin-2 has also been expressed in Nutley and Cetus units: 100 international units is reportedly equivalent to about 83.3 Nutley units and to about 16.7 Cetus units. US licensed product information states that 18 million international units of aldesleukin are equivalent to 1.1 mg of protein.

Uses and Administration

Interleukin-2 is a lymphokine which stimulates the proliferation of T-lymphocytes and thus amplifies immune response to an antigen; it also has actions on B-lymphocytes, and induces the production of interferon-γ and the activation of lymphokine-activated killer (LAK) cells and natural killer (NK) cells. Interleukin-2 is used in the immunotherapy of metastatic renal cell carcinoma in selected patients (see p. 708.3). It is also used in metastatic melanoma (p. 714.3), and has been tried in non-Hodgkin's lymphoma and acute myeloid leukaemia (see also below).

Interleukin-2 is usually given by intravenous infusion or subcutaneous injection of one of its recombinant forms, such as aldesleukin.

Many dosage regimens have been tried. In the UK, the recommended dose of aldesleukin for metastatic renal cell carcinoma is 18 million units given subcutaneously once daily for 5 days, followed by 2 days rest for the first week. For the next 3 weeks, 18 million units are then given on days 1 and 2 of each week, and 9 million units on days 3 to 5 of each week, followed by 2 days rest. This 4-week cycle may be repeated after an interval of 1 week. Doses may be delayed or reduced if the regimen is not tolerated.

Intravenous infusion of aldesleukin is now rarely used because of an association with capillary leak syndrome (see Adverse Effects and Treatment, p. 811.2). If it is used, 18 million units/m² per 24 hours is given as a continuous intravenous infusion for 5 days, followed by 2 to 6 days of rest. Then another 5 days of infusion is given, followed by 3 weeks of rest. This constitutes one induction cycle; a second cycle may be given after the 3-week rest period of the first cycle. After either subcutaneous or intravenous use, up to 4 maintenance cycles may be given, at 4-week intervals, to patients who respond or whose disease stabilises. In the USA, aldesleukin is licensed for use by intravenous infusion for metastatic renal cell carcinoma or metastatic melanoma. The recommended dose is an infusion of 600 000 units/kg over 15 minutes, every 8 hours for up to 14 doses. This 5-day cycle is repeated after 9 days. Further courses may be given at intervals of at least 7 weeks in patients who respond. Doses should be withheld for toxicity.

Interleukin-2 given by inhalation is being investigated in the treatment of renal cell carcinoma.

Interleukin-2 has also been studied in adaptive immunotherapy with LAK cells or tumour-infiltrating lymphocytes (TIL), which are harvested from the patient, activated *ex vivo*, and then re-infused.

Interleukin-2 is also being tried in patients with HIV infection and AIDS in an attempt to restore immune response (see below) and has been given in some other infections or immune diseases.

Other interleukins are under investigation (see also Interleukin-1, p. 2533.3). Conjugates of interleukin-2 with macrogol (PEG-IL2; pegaldesleukin) have also been investigated and liposome-encapsulated interleukin-2 has also been investigated for the treatment of renal, brain and CNS tumours.

A mixture of naturally occurring cytokines, including interleukins, interferons, chemokines, and colony-stimulating factors (Multikine) is under investigation for neoadjuvant therapy in patients with squamous cell carcinoma of the head and neck.

Acute myeloid leukaemia. Interleukin-2 is given with histamine hydrochloride (p. 2525.2) to patients with acute myeloid leukaemia in first remission after consolidation therapy.[1,2] The role of histamine hydrochloride is to protect lymphocytes, especially NK and T cells, which are responsible for immune-mediated destruction of residual leukaemic cells.

Interleukin-2 is given by subcutaneous injection in a dose of 16 400 units/kg twice daily with a minimum of 6 hours between each dose. These doses of interleukin-2 are followed after 1 to 3 minutes by histamine hydrochloride in a dose of 500 micrograms by subcutaneous injection over 5 to 15 minutes (injection rate not to exceed 100 micrograms/min). The maximum injection time of 15 minutes for histamine hydrochloride may be necessary to reduce severe histamine-induced adverse effects (see p. 2525.3). Patients should rest for 20 minutes after the histamine dose. Histamine hydrochloride should not be injected at the same time as interleukin-2 nor into the same anatomical region. The regimen is given over a treatment cycle of 3 weeks and repeated for a total of 10 treatment cycles; the first 3 cycles are followed by a treatment-free interval of 3 weeks, increased to 6 weeks after subsequent cycles. Doses of either drug may be modified if adverse effects are severe.

HIV infection and AIDS. The immunodeficiency of HIV infection and AIDS (p. 957.2) has been associated with a defect in interleukin-2 production. Interleukin-2 stimulates the proliferation of lymphocytes and activates natural killer cells and studies have therefore examined the potential benefits of adding interleukin-2 to the treatment of patients with HIV infection.[1,2] After earlier pilot studies,

trials of antiretroviral therapy plus interleukin-2 have shown it to produce a much greater increase in CD4 cell counts than antiretroviral therapy alone,[3-7] even where therapy included HAART. However, it is not clear that this results in any additional clinical benefit. A pooled analysis[8] of earlier results showed a non-significant trend towards improved clinical outcome but the ESPRIT and SILCAAT studies[9] could not show any clinical benefit in terms of survival or risk of opportunistic disease from adding subcutaneous interleukin-2 to antiretroviral regimens, despite sustained increases in CD4 cell counts over a median of 7 years or more.

Although teceleukin has been tried[3] most studies of interleukin-2 therapy in HIV have used aldesleukin. Doses and routes have varied: in general doses seem to have ranged from 6 to 18 million units daily by intravenous infusion, or 3 to 30 million units daily subcutaneously, given in most cases for a 5-day cycle every 8 weeks. Subcutaneous dosage appears to be as effective as intravenous,[4,10] is more convenient,[4] and may be less toxic.[11] There is evidence that 5-day dose cycles of 3, 4.5 or 7.5 million units twice daily by subcutaneous injection are effective,[5,6,10,12-14] whereas cycles with a lower dose of 1.5 million units twice daily are not.[5,12,14] A meta-analysis[15] of 3 studies found that subcutaneous doses of 7.5 million units twice daily for 5 days every 8 weeks resulted in greater increases in CD4 cell counts after 3 cycles of therapy than doses of 4.5 million units or 1.5 million units. However, others have reported benefit from a dose as low as 3 million units daily when used with HAART in patients with advanced disease.[16] Continuous low-dose daily therapy appears to accelerate the normalisation of T-cell and natural killer cell concentrations over the course of several months.[11]

Adverse effects are common, particularly at higher doses and with intravenous infusion rather than subcutaneous use.[7,11] However, concerns about a potential stimulant effect on viral replication with a consequent increase in viral load do not seem to have been borne out.[4-7,10] Some studies have reported reduced viral loads in interleukin-treated patients,[4,17] including decreases in hepatitis C viral load in those HIV patients co-infected with hepatitis C.[10,18]

The macrogol conjugate of interleukin-2, PEG-IL2, has also been investigated in this context, but results have been disappointing, since it appears markedly less effective than aldesleukin in stimulating CD4 counts.[4,19]

Postherpetic neuralgia. A 46-year-old HIV patient with chronic, treatment-resistant postherpetic neuralgia (p. 10.3) received 1 cycle of subcutaneous interleukin-2 (7.5 million units twice daily for 5 consecutive days) within the context of a clinical HIV study. He reported immediate resolution of his postherpetic neuralgia, and no recurrence of pain occurred during 3 years of follow-up.[1]

Adverse Effects and Treatment

Toxicity is related to dose and route and is often severe; fatalities have been recorded. Decreased vascular resistance and increased capillary permeability (the 'capillary leak syndrome') is common in patients given aldesleukin, and results in hypotension, reduced organ perfusion, and oedema. The incidence and severity of this syndrome is lower after subcutaneous than intravenous dosage. Fluid replacement may be necessary to treat the resultant hypovolaemia and dopamine or other pressor agents may be needed to help maintain organ perfusion. Capillary leak syndrome may also be associated with cardiac effects including tachycardia, angina, myocardial infarction; respiratory effects such as dyspnoea, pulmonary oedema, and respiratory failure; renal abnormalities including uraemia and oliguria or anuria; mental status changes including irritability, depression, confusion, and drowsiness. Therapy should be stopped if patients develop severe lethargy or somnolence, as continuing may result in coma. Raised liver enzymes, gastrointestinal disturbances, fever and flu-like symptoms (malaise, rigors, chills, arthralgia, and myalgia), rashes, pruritus, anaemia, leucopenia, and thrombocytopenia, are also relatively common. Paracetamol (but not NSAIDs, see Effects on the Kidneys, below) may be used prophylactically for fever. Pethidine may be used to control rigors. Antiemetics and antidiarrhoeals may also be required. Antihistamines may benefit some patients with pruritic rash. Injection site reactions are common after subcutaneous doses; necrosis has occurred. Aldesleukin therapy is associated with impaired neutrophil function, and an increased risk of bacterial infections (see below), including sepsis and bacterial endocarditis; this has been reported mainly after intravenous use, and antibacterial prophylaxis may be necessary.

4. Schwartz RN, *et al.* Managing toxicities of high-dose interleukin-2. *Oncology (Huntingt)* 2002; **16** (suppl 13): 11–20.

Bacterial infections. The incidence of sepsis and bacteraemia is increased in patients receiving interleukin-2 via intravenous catheters,[1,2] and possibly subcutaneously,[3] although others have not found this to be the case.[4,5] The increased incidence of nonopportunistic bacterial infection may be a particular problem in patients with AIDS who are treated with interleukin-2.[6] The mechanism is uncertain, but may be related to impairment of neutrophil function by the cytokine.[7]

Effects on the cardiovascular system. Interleukin-2 treatment can cause cardiotoxicity such as arrhythmias and acute myocardial infarction. High-dose therapy (600 000 units/kg intravenously every 8 hours) has been associated with myocarditis, which appears to be reversible; haemodynamic instability that can lead to an acute coronary syndrome has also been described. Careful screening of patients for cardiopulmonary disease is recommended.[1]

1. Elsner RM, *et al.* Case report and brief review: IL-2-induced myocarditis. *Cancer Invest* 2004; **22**: 401–4.

Effects on endocrine function. It has been suggested that patients with adrenal metastases may be particularly susceptible to adrenal haemorrhage and consequent failure during interleukin therapy.[1] Results also suggested that lack of endogenous steroid production may increase the risk of early severe interleukin-2 toxicity.[1]

Effects on thyroid function have also been reported, with the development of hypothyroidism[2-4] and goitre.[3]

Effects on the kidneys. Intravenous aldesleukin therapy was associated with varying degrees of acute renal dysfunction in almost all of 99 adult patients.[1] The clinical syndrome of hypotension, oliguria, fluid retention, and associated azotaemia with intense tubular avidity for filtered sodium all support prerenal acute renal failure as the cause of renal dysfunction. However, renal function values returned to baseline levels within 7 days in 62% of patients and in 95% by 30 days. Patients with elevated pretreatment serum-creatinine values, particularly those aged over 60 years, and those who had previously undergone a nephrectomy, were at risk of more severe and prolonged changes in renal function, and might be particularly vulnerable to the use of indometacin for associated fever and chills, which could potentiate renal impairment through its effects on intrarenal prostaglandin production. Similar effects were noted in a study[2] of 15 children given continuous infusion of aldesleukin. A further study[3] of the renal haemodynamic effects of aldesleukin infusion found it to have a specific renal vasoconstrictor effect; changes in renal prostaglandin synthesis contributed to the decreased renal blood flow.

1. Belldegrun A, *et al.* Effects of interleukin-2 on renal function in patients receiving immunotherapy for advanced cancer. *Ann Intern Med* 1987; **106**: 817–22.
2. Cochat P, *et al.* Renal effects of continuous infusion of recombinant interleukin-2 in children. *Pediatr Nephrol* 1991; **5**: 33–7.
3. Geertsen PF, *et al.* Renal haemodynamics, sodium and water reabsorption during continuous intravenous infusion of recombinant interleukin-2. *Clin Sci* 1998; **95**: 73–81.

Effects on the skin. Pseudosystemic sclerosis has been reported after use of aldesleukin; a reduction in skin thickening was seen after aldesleukin therapy was stopped and corticosteroids started.[1]

1. Marie I, *et al.* Pseudosystemic sclerosis as a complication of recombinant human interleukin 2 (aldesleukin) therapy. *Br J Dermatol* 2007; **156**: 182–3.

Precautions

Aldesleukin should be given with great care, if at all, to patients with pre-existing cardiac or pulmonary disease, and those with severe renal or hepatic impairment. It should be avoided in patients with CNS metastases or seizure disorders.

Risk factors for toxicity and poor response include restricted physical activity (Eastern Cooperative Oncology Group performance status of 1 or greater), 2 or more metastatic sites, and a period of less than 24 months between diagnosis of primary tumour and consideration for aldesleukin therapy. UK licensed product information states that aldesleukin should not be used to treat metastatic renal cell carcinoma in patients with all three of these risk factors.

Aldesleukin may worsen auto-immune diseases, and should be used with caution in patients with these conditions. Bacterial infections should be adequately treated before beginning therapy. Aldesleukin may increase effusions from serosal surfaces, and these should generally be treated before starting aldesleukin therapy.

Vital signs, blood counts, renal and hepatic function, serum electrolytes, and pulmonary and cardiac function should be monitored before starting treatment and then regularly during therapy.

Activity. For mention of the loss of activity when aldesleukin was given by continuous infusion without albumin, see Stability p. 810.2.

Inflammatory bowel disease. Two patients with a history of Crohn's disease had a recurrence of the condition when given aldesleukin. It was suggested that interleukin-2 should be contra-indicated in such patients.[1]

1. Sparano JA, *et al.* Symptomatic exacerbation of Crohn disease after treatment with high-dose interleukin-2. *Ann Intern Med* 1993; **118**: 617–18.

Psoriasis. Exacerbations of psoriasis developed in 3 patients during therapy with aldesleukin alone or with lymphokine-activated killer cells. The psoriatic symptoms remitted with topical therapy.[1]

1. Lee RE, *et al.* Interleukin 2 and psoriasis. *Arch Dermatol* 1988; **124**: 1811–15.

Interactions

Corticosteroids (which reduce some of the adverse effects of interleukin-2) may also reduce its antineoplastic properties: use together should generally be avoided. The use of iodinated contrast media after aldesleukin therapy may result in symptoms resembling the immediate adverse effects of aldesleukin. Although most events were reported to occur within 2 to 4 weeks of the last dose of aldesleukin, some occurred several months afterward.

Antivirals. For the effect of interleukin-2 on plasma concentrations of *indinavir*, see p. 987.3.

NSAIDs. NSAIDs are effective in preventing or reducing fever and myalgia caused by interleukin-2. However, there is concern that they could exacerbate renal toxicity (see also Effects on the Kidneys, p. 811.3). Use of *indometacin* in patients receiving interleukin-2 led to more severe weight gain, oliguria, and azotaemia in 1 study.[1] However, *ibuprofen* was used successfully to reduce interleukin-2 toxicity in another study.[2]

1. Sosman JA, *et al.* Repetitive weekly cycles of interleukin-2 II: clinical and immunologic effects of dose, schedule, and addition of indomethacin. *J Natl Cancer Inst* 1988; **80**: 1451–61.
2. Eberlein TJ, *et al.* Ibuprofen causes reduced toxic effects of interleukin 2 administration in patients with metastatic cancer. *Arch Surg* 1989; **124**: 542–7.

Pharmacokinetics

After intravenous bolus, the serum distribution and elimination half-lives of aldesleukin are 13 and 85 minutes, respectively. After subcutaneous doses, the absorption half-life is 45 minutes and the elimination half-life is 5.3 hours, while bioavailability ranges between 35 and 47%.

Aldesleukin is metabolised to amino acids by the kidneys.

Ipilimumab *(USAN, rINN)*

BMS-734016; Ipilimumabum; MDX-010; MDX-CTLA-4; Ипилимумаб.

Immunoglobulin G1, anti-(human CTLA-4 (antigen)) (human γ1-chain), disulfide with human κ-chain, dimer.

CAS — 477202-00-9.

UNII — 6T8C155666.

Uses and Administration

Ipilimumab is a recombinant, human monoclonal antibody to the cytotoxic-T-lymphocyte-associated antigen 4 (CTLA-4), which is a cell surface receptor involved in the downregulation of T-cell activation. Ipilimumab is used for the treatment of unresectable or metastatic melanoma (p. 714.3). The recommended intravenous dose is 3 mg/kg every 3 weeks, to a total of 4 doses; the dose is diluted in sodium chloride 0.9% or glucose 5% to a final concentration ranging from 1 to 2 mg/mL, and the infusion given over 90 minutes, via a low-protein-binding in-line filter.

Ipilimumab may be withheld or permanently stopped if immune-mediated reactions occur, see Adverse Effects, Treatment, and Precautions, below.

Ipilimumab is also under investigation for the treatment of prostate cancer and various other solid tumours.

Adverse Effects, Treatment, and Precautions

The most common adverse effects of ipilimumab are fatigue, diarrhoea, pruritus, rash, and colitis. Severe, life-threatening, or fatal immune-mediated reactions, involving any organ, can occur. Enterocolitis (including intestinal perforation), hepatitis, dermatitis (including toxic epidermal necrolysis), neuropathy, and endocrinopathy (including hypopituitarism and adrenal insufficiency) have been reported most commonly. Rare effects considered to be immune-mediated include pneumonitis, meningitis, nephritis, eosinophilia, and pericarditis. Myocarditis, angiopathy, temporal arteritis, vasculitis, polymyalgia rheumatica, conjunctivitis, blepharitis, episcleritis, scleritis, erythema multiforme, psoriasis, pancreatitis, arthritis, and auto-immune thyroiditis have also been reported.

Ipilimumab should be stopped permanently if any severe immune-mediated reactions occur, and the patient treated with high-dose systemic corticosteroids. Ipilimumab therapy should be withheld in those with moderate reactions; the patient may require corticosteroids and symptomatic treatment. Therapy may be resumed after complete or partial resolution of the reaction in patients who are taking prednisone at less than 7.5 mg daily (or equivalent); ipilimumab is restarted at the recommended dose, until all 4 doses are given, or until 16 weeks have elapsed from the first dose, whichever occurs earlier. If moderate disease persists, or the corticosteroid dose cannot be reduced to prednisone 7.5 mg daily (or equivalent), ipilimumab should be stopped permanently. Corticosteroid eye drops can be used to treat patients who develop uveitis, iritis, or episcleritis; ipilimumab should be stopped permanently if immune-mediated ocular disease occurs that is unresponsive to local immunosuppressive therapy. Patients should be monitored for any signs and symptoms of immune-mediated reactions. Liver function tests and thyroid function tests should be assessed at baseline and before each dose.

Pharmacokinetics

Ipilimumab steady-state concentrations occur by the third dose. Clearance was found to increase with increasing bodyweight. The mean terminal half-life is 14.7 days.

Irinotecan Hydrochloride

(BANM, USAN, rINNM)

Camptothecin 11 (irinotecan); CPT-11 (irinotecan); DQ-2805; Hidrocloruro de irinotecán; Irinotécan, Chlorhydrate d'; Irinotecán, hidrocloruro de; Irinotecani Hydrochloridum; Irinotekaanihydrokloridi; Irinotekan Hidroklorür; Irinotekan-hydroklorid; U-101440E; Иринотекана Гидрохлорид.

(+)-7-Ethyl-10-hydroxycamptothecine 10-[1,4′-bipiperidine]-1′-carboxylate hydrochloride trihydrate; (*S*)-4,11-Diethyl-3,4,12,14-tetrahydro-4-hydroxy-3,14-dioxo-1*H*-pyrano[3′,4′:6′,7′]indolizino[1,2-*b*]quinolin-9-yl [1,4′-dipiperidine]-1′-carboxylate hydrochloride trihydrate.

$C_{33}H_{38}N_4O_6HCl,3H_2O$=677.2

CAS — 97682-44-5 (irinotecan); 136572-09-3 (irinotecan hydrochloride trihydrate).

ATC — L01XX19.

ATC Vet — QL01XX19.

UNII — 042LAQ1IIS.

Pharmacopoeias. In *US.*

USP 36: (Irinotecan Hydrochloride). Pale yellow to yellow, crystalline powder. Sparingly soluble in water and in organic solvents. Store in airtight containers at a temperature of 20 degrees to 25 degrees, excursions permitted between 15 degrees and 30 degrees. Protect from light.

Uses and Administration

Irinotecan is a semisynthetic derivative of the alkaloid camptothecin, obtained from the shrub *Camptotheca acuminata*. The camptothecin derivatives are inhibitors of the enzyme topoisomerase I and thus interfere with the coiling and uncoiling of DNA during replication and prevent nucleic acid synthesis. This action is specific for S phase.

Irinotecan is used in the treatment of advanced colorectal cancer (p. 706.3). It may be used with fluorouracil and folinic acid (with or without bevacizumab), or with capecitabine (with or without bevacizumab), as first-line therapy, and is also given as monotherapy in patients whose disease has recurred or progressed after initial fluorouracil-based therapy. It is further indicated for use with cetuximab (p. 762.3) in the treatment of EGFR-expressing, *KRAS* wild-type, metastatic colorectal cancer, either first-line or after the failure of other regimens containing irinotecan. It has been tried in the management of other solid tumours including those of the lung (p. 710.2).

It is given as the hydrochloride, by intravenous infusion in at least 250 mL of glucose 5%, or sodium chloride 0.9%. In the treatment of refractory colorectal malignancies one suggested single-agent dose regimen is irinotecan hydrochloride 125 mg/m² infused over 90 minutes once a week for 4 weeks, followed by a 2-week rest period. Additional courses may be given if required, with doses modified according to toxicity. Another regimen requires an initial dose of 350 mg/m² over 30 to 90 minutes repeated every 3 weeks and adjusted according to toxicity (for dosage in hepatic impairment, see p. 813.1).

For the suggestion that initial doses should be modified to reduce toxicity in those with certain genotypes, see Genetic Factors, p. 813.3.

Irinotecan may also be given as part of a regimen with fluorouracil and folinic acid in the first-line treatment of metastatic colorectal cancer. Many regimens exist. The irinotecan hydrochloride component of the course may be given at a dose of 180 mg/m² over 30 to 90 minutes every 2 weeks. Alternatively, 125 mg/m² may be given weekly usually on days 1, 8, 15, and 22 of a 42-day cycle. (For reference to toxicity from such regimens see under Interactions, p. 814.1.)

Treatment cycles may be continued indefinitely as long as patients continue to benefit.

In the treatment of EGFR-expressing metastatic colorectal cancer, in patients who have failed previous treatment, irinotecan is given usually at the same dose as was used in the last cycles of the previous irinotecan-containing regimen; irinotecan should not be given for at least 1 hour after the end of the cetuximab infusion. When used first-line with cetuximab, the dose of irinotecan will depend on the specific regimen used.

A formulation of irinotecan with hyaluronic acid is being developed for colorectal cancer. A stable nanoliposomal formulation, MM-398, is under investigation for the treatment of pancreatic cancer. Also under investigation is a pegylated formulation of irinotecan (NKTR-102) for various malignancies including ovarian cancer, and irinotecan-eluting beads, for injection directly into the brain in the treatment of glioma, or for chemoembolisation in colorectal cancer.

Administration. The intravenous formulation of irinotecan (*Camptosar, Pfizer, USA*) has been given orally to children with refractory solid tumours.[1] The dose (typically 15 mg/m²) was drawn up in a plastic oral syringe on the day of dosing, although the reconstituted solution has been reported to be stable for 21 days at 4 degrees in these syringes. The dose was mixed with cranberry-grape juice immediately before use.

When this single oral dose of irinotecan was given with oral *gefitinib*, median irinotecan bioavailability was significantly higher, and systemic exposure to irinotecan and its metabolite SN-38 was greater, than that seen in patients not given gefitinib.[1]

1. Furman WL, *et al.* Tyrosine kinase inhibitor enhances the bioavailability of oral irinotecan in pediatric patients with refractory solid tumors. *J Clin Oncol* 2009; 27: 4599–4604.

Administration in the elderly. UK licensed product information states that elderly patients treated with irinotecan require more intensive monitoring, and that the dose should be chosen with care. US licensed product information reports that exposure to the active metabolite SN-38 is increased by about 11% in patients aged 65 years and older compared with younger patients. No change in the initial dose is recommended for elderly patients given weekly irinotecan, but in those given the 3-weekly schedule, a lower initial dose is recommended in patients 70 years and older based on clinical toxicity with this schedule (although the pharmacokinetics of this schedule have not been studied in a geriatric population). A review[1] found that delayed diarrhoea was increased in elderly patients, although response rates appear unaffected by age. While there were no data to support a specific dose modification, it was recommended that those older than 70 years, those with previous pelvic irradiation, or those with poor performance status, be treated with reduced initial doses.

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; 25: 1832–43.

Administration in hepatic impairment. In patients with hyperbilirubinaemia, the clearance of irinotecan is decreased, exposure to the active metabolite SN-38 is increased, and the risk of haematological toxicity is increased. US licensed product information recommends a reduction in the initial dose of irinotecan for those patients with increased bilirubin concentrations. However, doses in patients with bilirubin greater than 2 mg per 100 mL cannot be determined due to insufficient data.

In the UK, licensed product information recommends the following dosage reduction for monotherapy regimens in which irinotecan hydrochloride is normally given at 350 mg/m² every 3 weeks (see Uses and Administration, p. 812.3):

- in patients with bilirubin up to 1.5 times the upper limit of normal range (ULN): no dosage reduction is considered necessary and irinotecan hydrochloride 350 mg/m² is recommended;
- in patients with bilirubin ranging from 1.5 to 3 times the ULN: irinotecan hydrochloride 200 mg/m² may be given;
- in patients with bilirubin over 3 times the ULN: the use of irinotecan is not recommended.

Administration in renal impairment. UK and US licensed product information state that irinotecan is not recommended or should be used with caution in patients with renal impairment due to a lack of data; creatinine clearance was reported[1] to be inversely related to the risk of severe neutropenia in one study. US licensed product information states that irinotecan is not recommended for use in dialysis. However, there is a report of its use in a colorectal cancer patient on long-term haemodialysis;[2] the initial intravenous dose used was irinotecan 50 mg/m² weekly for 3 weeks, repeated after a rest period of 1 week. This dose was well tolerated, and irinotecan was increased to 80 mg/m² after 2 cycles. Pharmacokinetic study showed a lower apparent clearance and a higher maximum concentration of the active metabolite SN-38, compared with patients with normal renal function. The authors concluded that an initial dose of 80 mg/m² (about ⅔ of the standard dose) given weekly for 3 weeks followed by a rest period of 1 week might be feasible in patients with end-stage renal failure.

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2. Neutropenia and diarrhoea may be dose-limiting in patients given irinotecan. The nadir of the white cell count usually occurs about 8 days after a dose, with recovery by about day 22. Leucopenia and anaemia also occur and, less commonly, thrombocytopenia. Complete blood counts should be monitored weekly during treatment. Those who are homozygous for the uridine diphosphate glucuronosyltransferase allele UGT1A1*28 are at increased risk of neutropenia (see Genetic Factors, below). Radiotherapy also increases the risk of myelosuppression. Treatment should be withheld until neutropenia recovers to at least grade 1, and further doses reduced for severe haematological toxicity.

Nausea, vomiting, and diarrhoea are common with irinotecan, and can be severe. Acute diarrhoea, occurring within 24 hours of a dose, may be part of a transient cholinergic syndrome which can also include sweating, hypersalivation, abdominal cramps, lachrymation, miosis, conjunctivitis, vasodilatation, hypotension, chills, and dizziness. These symptoms can be controlled with atropine. However, a more severe, prolonged diarrhoea may occur, beginning more than 24 hours after a dose, and can be life-threatening; prompt management with high-dose loperamide and fluid replacement is required (see Effects on the Gastrointestinal Tract, below), and irinotecan treatment should be interrupted and any further doses reduced. Elderly patients, women, those who have had abdominal or pelvic radiotherapy, those with pre-existing hyperleucocytosis, and those with poor performance status are at increased risk of diarrhoea. There is also an increased risk of infection and haematological toxicity in patients with severe diarrhoea. A prophylactic antibacterial should be given if there is diarrhoea and severe neutropenia (neutrophil count < 500 cells/mm³) or fever. Dehydration can occur and in severe cases has led to acute renal failure, hypotension, and cardio-circulatory failure. Other gastrointestinal disturbances include toxic megacolon, colitis including typhlitis, ischaemia, and ulceration, leading to haemorrhage, obstruction, and perforation. Pseudomembraneous colitis has also been reported. Irinotecan should not be given to patients with inflammatory bowel disease or bowel obstruction.

Other adverse effects include hiccups, weakness, reversible alopecia, skin reactions, pancreatitis, and increases in liver enzymes, bilirubin, creatinine, amylase, and lipase. Liver function tests should be carried out at baseline and before each cycle. Hypertension has occurred rarely during or after infusion. There are rare reports of hypersensitivity reactions including anaphylaxis, mild injection site reactions, transient speech disorders (dysarthria), muscular contraction or cramps, and paraesthesia. Interstitial lung disease with pulmonary infiltrates is uncommon during irinotecan treatment, but can be fatal; patients with risk factors should be closely monitored. If symptoms such as dyspnoea, cough, and fever occur, irinotecan and any other chemotherapy should be withheld, and stopped permanently if interstitial lung disease is diagnosed.

Thromboembolic events have occurred, including myocardial ischaemia and infarction, cerebral infarction, pulmonary embolism, arterial thrombosis, angina, and vascular disorders.

Severe toxicity resulting in an increased number of deaths has been reported when irinotecan was given with fluorouracil and folinic acid (see under Interactions, p. 814.1).

Effects on the gastrointestinal tract. *Acute* diarrhoea occurring as part of a cholinergic syndrome with irinotecan is rarely severe. The syndrome is usually treated or prevented with atropine, but pretreatment with hyoscine butylbromide has also been tried.[1,2] In contrast, *delayed* diarrhoea can be dose-limiting or even fatal in some patients. Standard treatment involves fluid and electrolyte replacement and a high-dose loperamide regimen consisting of 4 mg loperamide immediately after the first loose stool, then 2 mg every 2 hours until 12 hours after the last liquid stool. During the night, the patient may take 4 mg every 4 hours. The high-dose therapy should not be given for more than 48 hours and should never be given prophylactically. Specific recommendations[3] state that if the diarrhoea persists for more than 24 hours despite loperamide therapy, patients should also take an oral fluoroquinolone for 7 days. If the diarrhoea persists for more than 48 hours, patients should be hospitalised for parenteral hydration. Other treatments have been tried, including acetorphan, activated charcoal, budesonide, glutamine, and octreotide.[2,4-9] A regimen of thalidomide with irinotecan has been reported to have a striking lack of gastrointestinal adverse effects such as diarrhoea and nausea.[2,10] However, a pharmacokinetic study found no decrease in gastrointestinal toxicity when these 2 drugs were given together, see Thalidomide, under Interactions, p. 814.2.

Diarrhoea may be caused by direct intestinal damage due to SN-38, the active metabolite of irinotecan; reduction of intestinal SN-38 concentrations using the poorly absorbed aminoglycoside neomycin as prophylaxis was reported to ameliorate diarrhoea in 6 of 7 patients who had this adverse effect.[11]

Genetic factors. Irinotecan is hydrolysed to SN-38, an active metabolite, which is inactivated by glucuronidation by uridine diphosphate glucuronosyltransferase (UGT) enzymes.[1] Genetic variation in the UGT family may affect irinotecan pharmacodynamics. Although UGT1A1*28 polymorphism appears to be only one of several identified causes of altered SN-38 pharmacokinetics,[1,2] it has been strongly associated with the development of severe neutropenia, and genotyping has been proposed as a method of identifying patients at risk of severe toxicity from irinotecan.[3,4] However, genotyping does not predict for all toxicities, and a significant association between the UGT1A1*28 homozygous genotype and diarrhoea has not been proven. Furthermore, a normal UGT1A1 genotype does not ensure lack of toxicity, although the risk is less; the possibility of underdosing in those with the normal genotype may need to be considered.[5] Despite these limitations, it has been suggested that every patient receiving irinotecan for the first time be tested for UGT1A1 genotype.[5]

Licensed product information in the USA states that reduced initial doses should be considered for patients known to be homozygous for the UGT1A1*28 allele; however, the most appropriate dose reduction in the homozygous population is unknown. Some have suggested an initial 20% dose reduction, with escalation to full dosage in subsequent courses in the event of little or no toxicity.[5] A prospective study[6] found that the UGT1A1*28 genotype (homozygous or heterozygous) was significantly associated with haematological toxicity, but only during the first cycle of irinotecan-containing chemotherapy. This called into question the need for a dose reduction in irinotecan for patients with this genotype, particularly since homozygous patients showed a trend to improve clinical response. A study in paediatric patients[7] found that, for low-dose, protracted schedules of irinotecan (doses ranged from 15 to 75 mg/m² daily, given either intravenously or orally, for 5 days, for 2 consecutive weeks), UGT1A1 genotyping was not a useful prognostic indicator of severe toxicity. A similar lack of influence of UGT1A1 genotype was seen in adults given a low-dose regimen for metastatic colon cancer.[8] A meta-analysis[9] found that the risk of haematological toxicity was similar for all genotypes at lower doses of irinotecan. The authors suggested that at low doses of irinotecan, decisions about treating individual patients could be made according to standard clinical practice, whereas genotype-based decisions were advisable at higher doses. Many studies on so-called 'irinogenetics' have been conducted.[10,11] One such study[11] examined 42 common genetic variants, as well as some non-genetic variables. UGT1A1*93 was found to be a strong predictor for neutropenia, and drug

transporter polymorphisms may also have a significant impact on irinotecan pharmacokinetics and pharmacodynamics. Non-genetic factors were also found to be significant; females were more prone to neutropenia, for example, and total bilirubin may also be a factor.[11] Since smoking and other medications can also influence irinotecan disposition, it has been asked whether the drug-elimination phenotype needs to be ascertained, rather than genotype alone, and whether too many genes are involved in drug elimination for genotyping to be of practical clinical use. However, further studies might elucidate a drug elimination genotype with relevance for other drugs, not only irinotecan.[12]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies irinotecan as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/08/11)

Interactions

Irinotecan is partly metabolised by cytochrome P450 CYP3A isoenzymes. Inducers of this system such as carbamazepine, phenobarbital, or phenytoin reduce exposure to irinotecan and its active metabolite SN-38; use with St John's Wort is contra-indicated. Conversely, inhibitors of this system such as ketoconazole increase exposure to irinotecan and SN-38; use with ketoconazole is contra-indicated.

Antidepressants. In a small, crossover study[1] of cancer patients, use of *St John's wort* during irinotecan therapy was found to decrease plasma concentrations of SN-38, the active metabolite of irinotecan. Myelosuppression was also reduced with this combination. The interaction is thought to be due to the induction of the cytochrome P450 isoenzyme CYP3A4 by St John's wort.

1. Mathijssen RHJ, *et al.* Effects of St. John's wort on irinotecan metabolism. *J Natl Cancer Inst* 2002; **94**: 1247–9.

Antineoplastics. Although previously reported to be effective, and not associated with excessive toxicity,[1] a regimen of irinotecan with bolus *fluorouracil* and folinic acid was found to be associated with an excess of early deaths in 2 further studies, which were consequently terminated.[2] Deaths were associated with a variety of events including dehydration (due to diarrhoea, nausea, and vomiting), neutropenia, and sepsis. It has been suggested that use of irinotecan with fluorouracil by continuous infusion might be better tolerated,[3,4] and a small study[5] found that the sequence may be important. Irinotecan followed by an infusion of fluorouracil over 48 hours, was associated with less dose-limiting toxicity, and higher maximum tolerated doses, than fluorouracil infusion followed by irinotecan.

Sorafenib may increase systemic exposure to irinotecan.

Gefitinib has been used to increase the bioavailability of *oral* irinotecan, see under Administration, p. 813.1.

5. Falcone A, *et al.* Sequence effect of irinotecan and fluorouracil treatment on pharmacokinetics and toxicity in chemotherapy-naive metastatic colorectal cancer patients. *J Clin Oncol* 2001; **19**: 3456–62.

Smoking. A study found that tobacco smoking significantly affected the pharmacokinetics and toxicity of irinotecan.[1] Clearance of irinotecan was faster in smokers, and systemic exposure to the active metabolite SN-38 (see Pharmacokinetics, below) was almost 40% lower in smokers. This effect probably contributed to the significantly lower haematological toxicity seen in smokers; no significant difference in diarrhoea was seen between smokers and non-smokers. Smoking may induce cytochrome P450 isoenzymes, or possibly affect carboxylesterase activity. The study did not determine an effect of smoking on the outcome of treatment with irinotecan. However, smokers may need a higher dose of irinotecan relative to non-smokers, since the lower exposure to irinotecan and SN-38 may indicate a potential risk of treatment failure.

1. van der Bol JM, *et al.* Cigarette smoking and irinotecan treatment: pharmacokinetic interaction and effects on neutropenia. *J Clin Oncol* 2007; **25**: 2719–26.

Thalidomide. A pharmacokinetic study found that the metabolism of irinotecan to SN-38 was significantly decreased by thalidomide. Despite reports of reduced gastrointestinal toxicity when these 2 drugs were given together (see Effects on the Gastrointestinal System, p. 813.2), 3 out of 19 patients enrolled in the study had severe delayed diarrhoea after being given irinotecan with thalidomide.[1]

1. Allegrini G, *et al.* Irinotecan in combination with thalidomide in patients with advanced solid tumors: a clinical study with pharmacodynamic and pharmacokinetic evaluation. *Cancer Chemother Pharmacol* 2006; **58**: 585–93.

Pharmacokinetics

Irinotecan exhibits biphasic or triphasic pharmacokinetics, with a terminal half-life of about 14 hours. After intravenous doses it is hydrolysed by carboxylesterase in body tissues to active SN-38 (7-ethyl-10-hydroxycamptothecin), which has a biphasic elimination profile with a terminal half-life of about 14 hours. Plasma protein binding for irinotecan and SN-38 is about 65% and 95%, respectively. SN-38 is mainly eliminated by glucuronidation, predominantly by the enzyme uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1). Irinotecan is also partly metabolised by cytochrome P450 isoenzymes CYP3A4 and perhaps CYP3A5. More than 50% of an intravenous dose of irinotecan is excreted as unchanged drug, with about 30% in the faeces via the bile and about 20% in the urine.

Pharmacopoeial Preparations

USP 36: Irinotecan Hydrochloride Injection.

Ixabepilone *(USAN, rINN)*

Azaepothilone B; BMS-247550-01; Ixabepilona; Ixabépilone; Ixabepilonum; Иксабепильон.

(1*S*,3*S*,7*S*,10*R*,11*S*,12*S*,16*R*)-7,11-Dihydroxy-8,8,10,12,16-pentamethyl-3-[(1*E*)-1-methyl-2-(2-methylthiazol-4-yl)ethenyl]-17-oxa-4-azabicyclo[14.1.0]heptadecane-5,9-dione.

$C_{27}H_{42}N_2O_5S$=506.7

CAS — 219989-84-1.

ATC — L01DC04.

ATC Vet — QL01DC04.

UNII — K27005NP0A.

Uses and Administration

Ixabepilone is an analogue of the epothilone compound patupilone (p. 843.3) that is used for the treatment of patients with metastatic or locally advanced breast cancer. It is given as monotherapy in those whose tumours are resistant or refractory to anthracyclines, taxanes, and capecitabine. Ixabepilone is also used with capecitabine in those whose tumours are resistant to anthracycline and taxanes, or in those with cancer resistant to taxanes, and for whom further anthracycline therapy is contra-indicated.

The recommended dose of ixabepilone is 40 mg/m² (to a maximum of 88 mg) given by intravenous infusion over 3 hours every 3 weeks. Ixabepilone is diluted with a suitable infusion fluid (pH 6 to 9), such as lactated Ringer's solution, to a final concentration of 200 to 600 micrograms/mL before infusion.

Doses are adjusted for toxicity. If moderate or severe neuropathy, or any severe toxicity (other than neuropathy) occurs, the dose should be decreased by 20%. If severe neuropathy lasts 7 days or more, or any disabling toxicity occurs, therapy should be stopped. If the neutrophil count falls below 500 cells/mm³ for 7 days or more, if platelets fall below 25 000 cells/mm³ (or below 50 000 cells/mm³ with bleeding), or if febrile neutropenia occurs, the dose should be decreased by 20%. If toxicities recur, an additional 20% dose reduction should be made. Patients should not begin a new cycle of treatment unless the neutrophil count is at least 1500 cells/mm³, the platelet count is at least 100 000 cells/mm³, and non-haematological toxicities have improved to grade 1 (mild) or resolved.

Doses are also adjusted in hepatic impairment (see Administration in Hepatic Impairment, below).

Use of strong inhibitors of CYP3A4 should be avoided with ixabepilone. If no alternative is available, a dose reduction of ixabepilone to 20 mg/m² should be considered. Once the inhibitor is stopped, a washout period of about 1 week should be allowed before the dose of ixabepilone is increased back to the original dose.

Use of strong CYP3A4 inducers should also be avoided with ixabepilone, but if they must be used, the dose of ixabepilone may be gradually increased up to 60 mg/m² if increased doses should be given as an intravenous infusion over 4 hours. Once the inducer is stopped, ixabepilone should be reduced to the original dose.

3. Thomas ES, *et al.* Ixabepilone plus capecitabine for metastatic breast cancer progressing after anthracycline and taxane treatment. *J Clin Oncol* 2007; **25**: 5210–17.
4. Moen MD. Ixabepilone: in locally advanced or metastatic breast cancer. *Drugs* 2009; **69**: 1471–81.

Administration in hepatic impairment. Ixabepilone and capecitabine *combination therapy* is contra-indicated in patients with aspartate aminotransferase (AST) or alanine aminotransferase (ALT) greater than 2.5 times the upper limit of normal (ULN), or in those with bilirubin greater than the ULN. Patients with values equal to or below these figures may be given the standard dose of ixabepilone.

In *monotherapy*, the following doses of ixabepilone may be given:

- mild; AST and ALT up to 2.5 times the ULN, and normal bilirubin: 40 mg/m² *or* AST or ALT equal to or less than 10 times the ULN and bilirubin equal to or less than 1.5 times the ULN: 32 mg/m²
- moderate; AST and ALT equal to or less than 10 times the ULN and bilirubin greater than 1.5 times the ULN, but equal to or less than 3 times the ULN: patients should be started at 20 mg/m², and the dosage in subsequent cycles escalated up to, but not exceeding, 30 mg/m² if tolerated
- severe; AST or ALT greater than 10 times the ULN or bilirubin greater than 3 times the ULN: not recommended

Data are limited for patients with a baseline AST or ALT greater than 5 times the ULN.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Peripheral neuropathy is common with ixabepilone, but is generally reversible. Dose reduction, or delaying or stopping treatment may be necessary (see Uses and Administration, p. 814.3). Dose-dependent myelosuppression can occur, manifested mainly as neutropenia; febrile neutropenia and fatalities have been reported. Frequent blood counts are recommended. Ixabepilone is formulated in polyoxyl castor oil and should be avoided in patients hypersensitive to this substance; patients should be premedicated with a histamine H_1-and histamine H_2-antagonist about 1 hour before infusion. Therapy should be stopped if a hypersensitivity reaction occurs, and symptomatic treatment given. Subsequent cycles may be given with additional corticosteroid therapy, and extension of the infusion time should be considered.

Cardiac adverse effects such as hypotension, myocardial ischaemia, myocardial infarction, arrhythmias, ventricular dysfunction, and cardiomyopathy have been reported. Caution is advised in patients with a history of cardiac disease and therapy may need to be stopped if cardiac effects occur. Effects on the respiratory system include dyspnoea, cough, pneumonitis, pulmonary oedema, and respiratory failure. Increases in hepatic enzymes, jaundice, and acute hepatic failure have occurred, as has renal failure.

Other adverse effects include gastrointestinal disturbances, anorexia, myalgia, arthralgia, fatigue, alopecia, insomnia, headache, taste disorders, dizziness, increased lachrymation, hot flushes, nail disorders, skin disorders including rashes, erythema multiforme, palmar-plantar erythrodysesthesia syndrome, pruritus, and skin exfoliation or hyperpigmentation, renal calculi, electrolyte disturbances, coagulopathy, cognitive disorders, syncope, thrombotic or haemorrhagic events, and vasculitis.

Interactions

Ixabepilone undergoes extensive metabolism by cytochrome P450 isoenzyme CYP3A4. Inhibitors of CYP3A4, such as ketoconazole, can increase exposure to ixabepilone. Conversely, CYP3A4 inducers can reduce exposure to ixabepilone. Use of ixabepilone with strong inhibitors or inducers of CYP3A4 should be avoided. If strong inhibitors are used, dose adjustments may be required (see Uses and Administration, p. 814.3). Grapefruit juice may also increase plasma concentrations of ixabepilone and should be avoided. St John's wort may decrease plasma concentrations of ixabepilone unpredictably and should also be avoided.

Pharmacokinetics

Ixabepilone is extensively distributed. Plasma protein binding is about 67 to 77%. It is extensively metabolised in the liver, mainly by oxidation via cytochrome P450 isoenzyme CYP3A4. It is eliminated mainly as metabolites; about 86% of a dose is eliminated within 7 days, 65% in faeces, and 21% in the urine. The terminal elimination half-life is reported to be about 52 hours.

Lapatinib Tosilate *(rINNM)*

GW-572016F; Lapatinib Ditosylate (USAN); Lapatinib, Tosilate de; Lapatinibi Tosilas; Tosilato de lapatinib; Лапатиниба Тозилат.

N-[3-Chloro-4-[(3-fluorobenzyl)oxy]phenyl]-6-[5-([[2-(methylsulfonyl)ethyl]amino}methyl)furan-2-yl]quinazolin-4-amine bis(4-methylbenzenesulfonate) monohydrate.

$C_{29}H_{26}ClFN_4O_4S.2C_7H_8O_3S.H_2O$=943.5

CAS — 231277-92-2 (lapatinib); 388082-78-8 (lapatinib tosilate).

UNII — G873GX646R.

Uses and Administration

Lapatinib tosilate is a dual tyrosine kinase inhibitor directed against two members of the human epidermal growth factor receptor family, namely epidermal growth factor receptor (EGFR; ErbB1) and human epidermal receptor type 2 (HER2; ErbB2). Lapatinib is used in the treatment of breast cancer (p. 702.1) that overexpresses HER2, either with capecitabine (p. 757.3) in patients with advanced or metastatic disease who have had previous therapy including an anthracycline, a taxane, and trastuzumab, or, in some countries, with an aromatase inhibitor in postmenopausal women with hormone-receptor positive metastatic disease.

Doses of lapatinib tosilate are expressed in terms of the base; lapatinib tosilate 405 mg is equivalent to about 250 mg of lapatinib. It is given orally, at least one hour before or one hour after food. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

When given with capecitabine, the recommended dose of lapatinib is 1.25 g once daily on days 1 to 21 of a 21-day cycle. Capecitabine is given at a dose of 2 g/m² daily (given orally in 2 doses about 12 hours apart, with food or within 30 minutes after food) on days 1 to 14 of the cycle. Treatment may be continued until disease progression or unacceptable toxicity occurs. If a daily dose is missed, the next day's dose should not be doubled.

When given with an aromatase inhibitor, the recommended dose of lapatinib is 1.5 g given orally once daily.

Dosage should be reduced in patients with severe hepatic impairment (see Administration in Hepatic Impairment, below). Treatment with lapatinib should be stopped in patients who develop a decreased left ventricular ejection fraction (LVEF); however, patients may be restarted at a reduced dose of lapatinib after a minimum of 2 weeks if the LVEF recovers to normal and if the patient is asymptomatic. When given with capecitabine, lapatinib is restarted at 1 g daily, or when given with an aromatase inhibitor, lapatinib 1.25 g daily is used. Lapatinib may need to be stopped or treatment interrupted if other severe toxicities develop. Patients can be restarted at the recommended dose when the toxicity improves. However, if toxicity recurs, lapatinib should be restarted at a lower dose; when given with capecitabine, lapatinib is restarted at 1 g daily, or when given with an aromatase inhibitor, lapatinib 1.25 g daily is used.

If use with potent inhibitors or inducers of cytochrome P450 isoenzyme CYP3A4 cannot be avoided, US licensed product information recommends dose adjustments of lapatinib based on pharmacokinetic studies. Lapatinib should be given at a dose of 500 mg daily when given with a potent CYP3A4 inhibitor; if the inhibitor is stopped, a washout period of about 1 week should be allowed before the lapatinib dose is increased to the usual recommended dose. When given with a potent inducer of this isoenzyme, the dose of lapatinib should be increased gradually, based on tolerability. When given with capecitabine, lapatinib is titrated from 1.25 g daily up to 4.5 g daily; when given with the aromatase inhibitor letrozole, lapatinib is titrated from 1.5 g daily up to 5.5 g daily. If the inducer is stopped, the dose of lapatinib should be reduced to the usual recommended dose.

Lapatinib is also under investigation for the treatment of gastric cancer and head and neck squamous cell carcinoma.

Administration in hepatic impairment. US licensed product information states that systemic exposure to lapatinib after a single 100-mg oral dose increased by about 14% and 63% in subjects with moderate (Child-Pugh Class B) and severe (Child-Pugh Class C) hepatic impairment, respectively, when compared with healthy control subjects. Caution is advised when lapatinib is given to patients with severe hepatic impairment. Oral doses should be reduced; when given with capecitabine, lapatinib is reduced to 750 mg daily, or when given with letrozole, a dose of lapatinib 1 g daily is used. However, licensed product information warns that there are no clinical data with this dose adjustment in patients with severe hepatic impairment.

Adverse Effects, Treatment, and Precautions

The most common adverse effects of lapatinib tosilate are gastrointestinal disturbances, dermatological reactions such as palmar-plantar erythrodysesthesia and rash, and fatigue. Diarrhoea may be severe and dose-limiting. Decreases in left ventricular ejection fraction (LVEF) have been reported with lapatinib, usually within the first 12 weeks of treatment. LVEF should be evaluated in all patients before therapy is started, and periodically evaluated during treatment. Prolongation of the QT interval has also been reported, and lapatinib should be given with caution to those patients with relevant risk factors such as hypokalaemia or hypomagnesaemia, congenital QT prolongation, use of antiarrhythmics, or cumulative high-dose anthracycline therapy. Other reported adverse effects include stomatitis, mucosal inflammation, pain in extremities, back pain, dyspnoea, insomnia, epistaxis, alopecia, nail disorders such as paronychia, and hypersensitivity reactions including anaphylaxis. Lapatinib has been associated with interstitial lung disease and pneumonitis, and treatment should be stopped if severe pulmonary symptoms develop. Hepatotoxicity has occurred and may be severe; deaths have been reported. Liver function should be monitored before, and every 4 to 6 weeks during, treatment. If severe hepatotoxicity develops during treatment, lapatinib should be permanently stopped. Lapatinib should be given with caution to those with pre-existing severe hepatic impairment; doses may need to be reduced.

Effects on the heart. A pooled analysis[1] of data from 44 studies, involving 3689 subjects given lapatinib, found that asymptomatic changes in ventricular ejection fraction occurred in 53 cases and symptomatic events in 7 cases; there were no cardiac deaths attributed to the drug. Of the symptomatic cases 5 were receiving monotherapy and 2 were also taking letrozole or paclitaxel. Symptoms, which included dyspnoea, heart failure, or palpitations, lasted for 2 and 6 weeks respectively in 2 patients who recovered fully, and one of these patients subsequently restarted lapatinib treatment. Of the remaining 5, 2 died due to disease progression (including one in whom lapatinib was not withdrawn as in the other cases), 2 had partial recovery (one of whom later restarted lapatinib), and one remained symptomatic. The frequency of cardiac events was similar in control patients who did not take lapatinib, and there was no evidence of cumulative cardiotoxicity with the drug, nor did previous anthracycline or trastuzumab treatment seem to increase the risk of a reaction in this relatively small group of patients. Despite these results, which suggested a reassuringly low level of cardiotoxicity, the authors considered that cardiac monitoring every 3 months during lapatinib treatment should still be recommended until more data were available.

1. Perez EA, *et al.* Cardiac safety of lapatinib: pooled analysis of 3689 patients enrolled in clinical trials. *Mayo Clin Proc* 2008; **83**: 679–86.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies lapatinib as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/09/11)

Interactions

Lapatinib tosilate undergoes extensive metabolism by cytochrome P450 isoenzyme CYP3A4. Inhibitors of CYP3A4, such as ketoconazole, can increase exposure to lapatinib. Conversely, CYP3A4 inducers, such as carbamazepine, can reduce exposure to lapatinib. Use of lapatinib with strong inhibitors or inducers of CYP3A4 should be avoided; if they are to be given together, dose adjustments may be required (see Uses and Administration, above). Grapefruit juice may also increase plasma concentrations of lapatinib and should be avoided. *In vitro* studies indicate that lapatinib itself inhibits CYP3A4 and CYP2C8; it should be used cautiously with substrates of these isoenzymes that have a narrow therapeutic index.

Lapatinib is a substrate of P-glycoprotein and P-glycoprotein inhibitors can increase plasma concentrations of lapatinib. Lapatinib itself also inhibits human P-glycoprotein and may in turn increase plasma concentrations of drugs that are substrates of P-glycoprotein.

Pharmacokinetics

Absorption after an oral dose of lapatinib tosilate is variable and incomplete. Peak plasma concentrations occur after about 4 hours. Systemic exposure to lapatinib is increased when it is given with food. It is highly protein bound. Lapatinib undergoes extensive metabolism, mainly by cytochrome P450 isoenzymes CYP3A4 and CYP3A5; CYP2C19 and CYP2C8 account for some minor metabolism. The terminal half-life after a single dose has been reported to be about 14 hours; accumulation with repeated dosing indicates an effective half-life of 24 hours. About 27% and 14% of an oral dose is recovered in the faeces, as parent

lapatinib and metabolites, respectively; renal excretion is negligible.

Lenalidomide *(BAN, USAN, rINN)*

CC-5013; CDC-501; CDC-5013; ENMD-0997; IMiD-3; Lenalidomid; Lenalidomida; Lénalidomide; Lenalidomidum; Леналидомид.

3-(4-Amino-1-oxo-1,3-dihydro-2*H*-isoindol-2-yl)piperidine-2,6-dione.

$C_{13}H_{13}N_3O_3$=259.3

CAS — 191732-72-6.

ATC — L04AX04.

ATC Vet — QL04AX04.

UNII — F0P408N6V4.

NOTE. IMiD-3 has also been used as a synonym for pomalidomide (p. 847.3).

Uses and Administration

Lenalidomide is an analogue of thalidomide (p. 867.3) that has immunomodulatory and antiangiogenic properties. It is used for the treatment of transfusion-dependent anaemia due to myelodysplastic syndromes (p. 694.3) associated with certain abnormalities of chromosome 5 (deletion 5q abnormalities), and is given with dexamethasone for multiple myeloma (p. 699.2) in patients who have received at least one prior therapy. Lenalidomide is also used for relapsed or refractory mantle cell lymphoma (p. 698.2).

Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

For transfusion-dependent anaemia due to myelodysplastic syndromes the recommended initial oral dose is 10 mg daily; UK licensed product information recommends that this is given for 21 days of a 28-day cycle, whereas in the USA it is given continuously.

For multiple myeloma or mantle cell lymphoma the recommended initial oral dose of lenalidomide is 25 mg daily, given for 21 days of a 28-day cycle. In multiple myeloma it is given with oral dexamethasone at a dose of 40 mg daily on days 1 to 4, days 9 to 12, and days 17 to 20 of each 28-day cycle, for the first 4 cycles, and then 40 mg daily on days 1 to 4 of each 28-day cycle thereafter.

Lenalidomide is associated with significant neutropenia and thrombocytopenia, and dosage is adjusted according to haematological toxicity. Doses are also adjusted for some other severe toxicities and for renal impairment (see Administration in Renal Impairment, below).

Administration in renal impairment. Lenalidomide is eliminated mainly via the kidneys as unchanged drug. Clearance decreases as renal function decreases, prolonging the half-life and increasing exposure to the drug. A study recommended that dose adjustments be made for patients with creatinine clearance (CC) less than 50 mL/minute; a 40% reduction to 60% of the starting dose was recommended for these patients. For those with CC less than 30 mL/minute, the reduced dose should be given at extended dosing intervals. About 30% of circulating lenalidomide was removed by a 4-hour session of haemodialysis.[1]

Licensed product information also recommends that doses are adjusted according to the degree of renal impairment; moderate impairment is defined as CC from 30 to less than 50 mL/minute in UK product information or from 30 to less than 60 mL/minute in US literature, severe as CC less than 30 mL/minute, and end-stage renal disease as CC less than 30 mL/minute and requiring dialysis. In patients with **multiple myeloma** or **mantle cell lymphoma**, initial oral doses are adjusted as follows:

- moderate renal impairment: 10 mg once daily. In multiple myeloma this dose may be increased to 15 mg once daily after 2 cycles if the patient is not responding to treatment, but is tolerating lenalidomide
- severe renal impairment: 7.5 mg once daily or 15 mg every other day. In multiple myeloma this dose may be increased to 10 mg daily if tolerated
- end-stage renal disease: 5 mg once daily; on dialysis days the dose should be given after haemodialysis

In **myelodysplastic syndromes**, initial oral doses are adjusted as follows:

- moderate impairment: 5 mg once daily
- severe impairment and end-stage renal disease: 2.5 mg once daily; on dialysis days the dose should be given after haemodialysis

1. Chen N, *et al.* Pharmacokinetics of lenalidomide in subjects with various degrees of renal impairment and in subjects on hemodialysis. *J Clin Pharmacol* 2007; 47: 1466–75.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Because of potential teratogenicity lenalidomide use is restricted in women of child-bearing potential and similar precautions to thalidomide are required, see p. 869.2.

Lenalidomide is associated with significant neutropenia and thrombocytopenia. Anaemia is also common and other haematological toxicities can occur. Dose reduction or delaying or stopping therapy may be needed; supportive therapy such as growth factors may be necessary. Full blood counts should be monitored at baseline, weekly for the first 8 weeks of therapy, and monthly thereafter. In multiple myeloma patients given lenalidomide with dexamethasone, US product information recommends monitoring full blood counts every 2 weeks for the first 12 weeks, and then monthly thereafter. There is also an increased risk of thrombotic events with lenalidomide, particularly deep-vein thrombosis and pulmonary embolism in multiple myeloma patients; prophylactic therapy may be considered. Haemorrhagic disorders have also occurred. Cardiac disorders including hypotension or hypertension, arrhythmias, myocardial infarction, and heart failure have also been reported.

Renal failure has been reported during lenalidomide treatment. Caution is advised in patients with renal impairment as lenalidomide is excreted via the kidneys; dose adjustments may be required, see above. Hepatotoxicity has also been reported; liver function should be monitored.

Peripheral neuropathy, insomnia, headache, hypoaesthesia, dizziness, and changes to mental status such as depression, hallucinations, mood swings, dysgeusia, and tremor have occurred.

Endocrine disorders that may occur include hirsutism and hypothyroidism; thyroid function should be monitored. Erectile dysfunction has occurred.

Tumour flare reactions and tumour lysis syndrome (p. 730.2) may be seen, and those with a high tumour burden should be monitored closely and appropriate precautions taken, see p. 732.2. An increased rate of second primary malignancies has been noted in some multiple myeloma patients including those taking lenalidomide plus dexamethasone (mainly skin cancers and solid tumours, those taking lenalidomide plus melphalan (acute myeloid leukaemia, myelodysplastic syndromes, and solid tumours, or those taking lenalidomide after high-dose melphalan and stem cell transplantation (B-cell malignancies including Hodgkin's disease).

Lenalidomide has been associated with hypersensitivity reactions including angioedema and severe skin reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. If these are suspected, or if a severe, exfoliative, or bullous rash develops, lenalidomide treatment should be permanently stopped. For other forms of skin reaction, lenalidomide should be withheld or stopped depending on the severity. Cross sensitivity may occur in patients with previous hypersensitivity to thalidomide, and such patients should be monitored closely; patients who have previously had a severe skin reaction with thalidomide should not be treated with lenalidomide.

Other adverse effects include gastrointestinal disturbances, pruritus, fatigue, dyspnoea, respiratory distress cough, interstitial pneumonitis, skin hyperpigmentation dry skin, hyperhidrosis, cerebrovascular accident, pancreatitis, infections such as pneumonia and herpes, alopecia peripheral oedema, pyrexia, electrolyte disturbances, and vertigo. Eye disorders include blurred vision, irritation cataracts, and loss of vision. Musculoskeletal effects include muscle cramps, myopathy, myalgia, arthralgia, and musculoskeletal pain.

Elderly patients may be more susceptible to adverse effects.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies lenalidomide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Tumour flare. Tumour flare characterised by painful lymphadenopathy, and sometimes accompanied by musculoskeletal pain and fever, has been reported in patients receiving lenalidomide for relapsed or refractory chronic lymphocytic leukaemia (CLL)[1-3] or for refractory Hodgkin's disease.[4] A lower incidence was noted in CLL patients given a low-dose continuous oral regimen (10 mg once daily for 28 days, increased as tolerated by 5 mg every 28 days to a maximum of 25 mg daily) compared with those given 25 mg once daily orally for 21 days of a 28-day cycle.[1,2] Although serious consequences have been reported in some cases, including one fatality,[3] most cases were not severe and responded to treatment with corticosteroids or NSAIDs;[1,2,4] a reduction in lenalidomide dose has also allowed continued treatment.[4] Lenalidomide-induced B-cell activation has been suggested as contributing to the reaction.[3]

Interactions

Lenalidomide may increase peak plasma concentrations of digoxin. Epoetins or other drugs that increase the risk of thrombosis should be used with caution in patients taking lenalidomide.

Pharmacokinetics

Lenalidomide is rapidly absorbed with peak plasma concentrations occurring between about 0.6 and 1.5 hours after an oral dose. Giving lenalidomide with food does not alter the extent of absorption. Binding to plasma proteins is about 30%. About 80% of a dose is eliminated unchanged through the kidneys. The mean half-life is 3 hours in healthy subjects and 3 to 5 hours in patients with multiple myeloma, myelodysplastic syndromes, or mantle cell lymphoma. Clearance decreases proportionally with renal function. Lenalidomide is distributed into the semen in

small amounts, less than 0.01% of the dose, and semen concentrations are undetectable 3 days after stopping treatment (male patients should use barrier methods of contraception, see Adverse Effects and Precautions, under Thalidomide, p. 869.2).

CAS — 857890-39-2.
UNII — 3J78384F61.

Profile

Lenvatinib is an oral tyrosine kinase inhibitor that targets the vascular endothelial growth receptor VEGFR2, and several other kinases involved in angiogenesis and tumour proliferation. Lenvatinib is under investigation for the treatment of various solid tumours, including thyroid cancer, melanoma, glioma, and endometrial cancer.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

Lestaurtinib *(USAN, rINN)*

A-154475.0; CEP-701; KT-5555; Lestaurtinibum; SP-924; Лестауртиниб.
(9*S*,10*S*,12*R*)-10-Hydroxy-10-(hydroxymethyl)-9-methyl-2,3,9,10,11,12-hexahydro-1*H*-9,12-epoxydiindolo[1,2,3-*fg*:3',2',1'-*kl*]pyrrolo[3,4-*i*][1,6]benzodiazocin-1-one.
$C_{26}H_{21}N_3O_4$=439.5
CAS — 111358-88-4.
UNII — DO989GC5D1.

Profile

Lestaurtinib is a tyrosine kinase inhibitor directed against the FLT3 receptor, that is under investigation for the treatment of acute myeloid leukaemia.

Letrozole *(BAN, USAN, rINN)* ⊗

CGS-20267; Letrotsoli; Letrozol; Létrozole; Letrozolum; Летрозол.
4,4'-(1*H*-1,2,4-Triazol-1-ylmethylene)dibenzonitrile.
$C_{17}H_{11}N_5$=285.3
CAS — 112809-51-5.
ATC — L02BG04.
ATC Vet — QL02BG04.
UNII — 7LKK855W8I.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Letrozole). A white or yellowish, crystalline powder. Practically insoluble in water; sparingly soluble in methyl alcohol; freely soluble in dichloromethane.

USP 36: (Letrozole). A white to yellowish, crystalline powder. Practically insoluble in water; slightly soluble in alcohol; freely soluble in dichloromethane. Store in airtight containers.

Uses and Administration

Letrozole is a selective nonsteroidal inhibitor of the aromatase (oestrogen synthetase) system, similar to anastrozole (p. 742.2). It is used in the treatment of advanced or locally advanced breast cancer (p. 702.1) in postmenopausal women. It may be given as neoadjuvant (pre-operative) therapy to those with localised hormone-receptor positive disease, to allow subsequent breast-conserving surgery. Letrozole is also used for the adjuvant treatment of postmenopausal women with hormone receptor-positive early breast cancer; treatment is generally given for 5 years or until tumour relapse occurs, although optimal duration of therapy is unknown. In postmenopausal women given 5 years of adjuvant tamoxifen for early breast cancer, letrozole may be used as extended adjuvant therapy; treatment should continue for 5 years or until tumour relapse occurs, although optimal duration of therapy is unknown. The usual oral dose is 2.5 mg daily.

References.

4. Geisler J. Differences between the non-steroidal aromatase inhibitors anastrozole and letrozole—of clinical importance? *Br J Cancer* 2011; **104**: 1059–66.

Administration in hepatic impairment. Licensed product information in the UK and USA states that no dosage adjustment of letrozole is required for patients with mild to moderate hepatic impairment (Child-Pugh category A and B). While letrozole is contra-indicated in the UK in severe hepatic impairment (Child-Pugh category C), in the USA, it is recommended that the dose of letrozole be reduced by 50% in those patients with cirrhosis and severe hepatic impairment; the recommended oral dose for these patients is 2.5 mg given every other day.

Endometriosis. Aromatase inhibitors have been investigated for the treatment of endometriosis, see under Uses of Anastrozole, p. 742.2.

Infertility. Letrozole has been investigated[1-5] as an adjunct to assisted reproduction technologies in the management of infertility (p. 2253.1). A systematic review and meta-analysis[6] concluded that there was insufficient evidence to judge the benefits of letrozole and other aromatase inhibitors in ovulation induction, although use appeared to be associated with a higher number of mono-ovulatory cycles. A recommended regimen for intra-uterine insemination was letrozole 2.5 mg daily from day 3 to day 7 of the cycle, followed by follicle-stimulating hormone from day 8; this might be an attractive alternative to the use of gonadotrophins because of the reduced risk of ovarian hyperstimulation syndrome and multiple gestation.

Aromatase inhibitors such as anastrozole and letrozole have been used for infertility associated with polycystic ovary syndrome;[7] although there is not enough evidence to recommend them routinely for ovulation induction, they may be considered in women who have not responded to clomifene, or where other treatments are not suitable. Letrozole has also been tried successfully[8] in a male patient with azoospermia.

However, concerns about unlicensed use have been raised by the Canadian manufacturer (*Novartis, Canad.*) because of the potential for maternal and fetal toxicity, and fetal malformations:[9] licensed product information contra-indicates the use of letrozole in premenopausal women, and there have been reports of congenital anomalies in the infants of women treated with letrozole for infertility.

Precocious puberty. A pilot study assessing the use of letrozole in the treatment of 9 girls with precocious puberty (p. 2254.1) due to the McCune-Albright syndrome concluded that it could be an effective initial therapy and might offer an alternative for those who fail to respond to tamoxifen. Possible adverse effects included ovarian enlargement and cyst formation, and further studies were considered necessary.[1]

For a report of the effective use of letrozole with bicalutamide in the treatment of familial male precocious puberty (testotoxicosis), see Precocious Puberty, under Bicalutamide, p. 749.2.

1. Feuillan P, *et al.* Letrozole treatment of precocious puberty in girls with the McCune-Albright syndrome: a pilot study. *J Clin Endocrinol Metab* 2007; **92**: 2100–6.

Adverse Effects, Treatment, and Precautions

As for Anastrozole, p. 742.3.

Breast feeding. Licensed product information states that it is unknown whether letrozole is distributed into human milk; in the UK its use during breast feeding is contra-indicated while in the USA a decision to use may be made based on clinical judgement.

Effects on blood lipids. For a comparison of the effects of anastrozole, letrozole, and exemestane on blood lipids see under Exemestane, p. 792.3.

Effects on the musculoskeletal system. Postmenopausal women with primary breast cancer were reported to have significant decreases in bone mineral density at the hip and lumbar spine after 24 months of letrozole therapy.[1]

See also Effects on the Musculoskeletal System, under Anastrozole, p. 743.1.

1. Perez EA, *et al.* Effect of letrozole versus placebo on bone mineral density in women with primary breast cancer completing 5 or more years of adjuvant tamoxifen: a companion study to NCIC CTG MA.17. *J Clin Oncol* 2006; **24**: 3629–35.

Effects on the skin. Toxic epidermal necrolysis, attributed to letrozole, has been reported in a patient with breast cancer who was also receiving dexamethasone and omeprazole.[1] She had been switched from tamoxifen to letrozole a few weeks before the reaction occurred.

1. Chia WK, *et al.* Toxic epidermal necrolysis in patient with breast cancer receiving letrozole. *Lancet Oncol* 2006; **7**: 184–5.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies letrozole as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Interactions

Tamoxifen. In a study[1] of postmenopausal women with breast cancer, the addition of tamoxifen reduced letrozole plasma concentrations by a mean of about 38%, but the effect of letrozole on hormone concentrations was unchanged. The mechanism and possible clinical effect of this interaction are unknown.

1. Dowsett M, *et al.* Impact of tamoxifen on the pharmacokinetics and endocrine effects of the aromatase inhibitor letrozole in postmenopausal women with breast cancer. *Clin Cancer Res* 1999; **5**: 2338–43.

Pharmacokinetics

Letrozole is rapidly and completely absorbed from the gastrointestinal tract. Food decreases the rate but not the extent of absorption. About 60% of letrozole in the circulation is bound to plasma protein, mainly albumin. Letrozole is rapidly and extensively distributed to tissues. *In vitro* data suggest that it is metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2A6. Most of an oral dose is slowly metabolised to an inactive carbinol metabolite, which is then excreted as the glucuronide in the urine. Letrozole has a terminal elimination half-life of about 2 days, and steady-state concentrations occur within 2 to 6 weeks.

Preparations

Proprietary Preparations (details are given in Volume B)

Pharmacopoeial Preparations
USP 36: Letrozole Tablets.

Lintuzumab *(rINN)*

HuM-195; Lintuzumabum; SGN-33; Линтузумаб.
Immunoglobulin G1, anti-(human CD33 (antigen)) (human-mouse monoclonal HuM195γ1-chain), disulfide with human-mouse monoclonal HuM195κ-chain, dimer.
CAS — 166089-32-3.

Profile

Lintuzumab is a humanised anti-CD33 monoclonal antibody that is under investigation for the treatment of myelodysplastic syndromes and acute myeloid leukaemia.

Lobaplatin *(rINN)*

D-19466; Lobaplatine; Lobaplatino; Lobaplatinum; Лобаплатин.
cis-[*trans*-1,2-Cyclobutanebis(methylamine)][(*S*)-lactato-O^1,O^2]platinum.
$C_9H_{18}N_2O_3Pt$=397.3
CAS — 135558-11-1.
UNII — OX5XK1JD8C.

Profile

Lobaplatin is a platinum derivative that is used as an antineoplastic in the treatment of breast cancer, small cell lung cancer, and chronic myelogenous leukaemia. The main adverse effect is thrombocytopenia. Lobaplatin is reported to show some cytotoxic effect upon cisplatin-resistant cells.

Lomustine *(BAN, USAN, rINN)*

CCNU; Lomustiini; Lomustin; Lomustina; Lomustinas; Lomustinum; Lomustyna; Lomusztin; NSC-79037; RB-1509; WR-139017; Ломустин.
1-(2-Chloroethyl)-3-cyclohexyl-1-nitrosourea.
$C_9H_{16}ClN_3O_2$=233.7
CAS — 13010-47-4.
ATC — L01AD02.
ATC Vet — QL01AD02.
UNII — 7BRF0Z81KG.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Ph. Eur. 8: (Lomustine). A yellow, crystalline powder. Practically insoluble in water; soluble in alcohol; freely soluble in acetone and in dichloromethane. Protect from light.

USP 36: (Lomustine). A yellow crystalline powder. Practically insoluble in water; soluble in alcohol; freely soluble in acetone, and in dichloromethane. Store at a temperature of 2 degrees to 8 degrees.

Uses and Administration

Lomustine is a nitrosourea with actions and uses similar to those of carmustine (p. 761.2). It has been used in the treatment of brain tumours (p. 701.2) and resistant or relapsed Hodgkin's disease and other lymphomas (p. 696.1), and also lung cancer (p. 710.2), malignant melanoma (p. 714.3), and various solid tumours.

When given as a single agent, lomustine is licensed for oral use in adults and children as a single dose of 120 to 130 mg/m^2; division of the dose over 3 consecutive days may reduce gastrointestinal effects. A dose of 100 mg/m^2 should be given to patients with compromised bone-marrow function. Doses are also generally reduced when lomustine is given as part of a combination regimen. Providing blood counts have returned to acceptable levels, doses may be repeated every 6 to 8 weeks, and should be adjusted according to the haematological response (see also Bone-marrow Depression, p. 730.3).

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

Adverse Effects, Treatment, and Precautions

As for Carmustine, p. 761.3. Neurological reactions such as confusion and lethargy have been reported.

Handling and disposal. A method for the destruction of lomustine *waste* by reaction with hydrobromic acid in glacial acetic acid has been described.[1] The residue produced by the degradation of lomustine by this method showed no mutagenicity. This method is not suitable for the degradation of carmustine.

1. **Castegnaro M, *et al.*, eds.** Laboratory decontamination and destruction of carcinogens in laboratory wastes: some antineoplastic agents. *IARC Scientific Publications 73*. Lyon: WHO/International Agency for Research on Cancer, 1985.

Overdosage. A patient who inadvertently received 200 mg of lomustine for 7 days instead of a single 200-mg dose developed pancytopenia and subsequent multiorgan dysfunction including liver dysfunction, abdominal pain, pulmonary toxicity with tachypnoea and hypoxaemia, and CNS toxicity leading to confusion and disorientation.[1] Although the white cell count recovered other signs of toxicity did not and the patient developed fever and hypotension and died 59 days after the initial dose of lomustine. In another case of accidental overdose, a 30-year old female received a cumulative dose of 28 mg/kg over 7 days.[2] Severe myelosuppression developed soon after the overdose and lasted for 50 days. The patient was treated with granulocyte colony-stimulating factor and antibacterial cover, norethisterone (to prevent menstruation), and acetylcysteine (to protect against organ toxicity). Gastrointestinal necrosis occurred, and liver enzymes remained elevated even after recovery from the overdose, but the patient survived and her tumour regressed without further chemotherapy.

2. **Abele M, *et al.*** CCNU overdose during PCV chemotherapy for anaplastic astrocytoma. *J Neurol* 1998; 245: 236–8.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies lomustine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. **The Drug Database for Acute Porphyria.** Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Cimetidine. For a report of a possible interaction between lomustine and cimetidine, see under Carmustine, p. 762.1.

Theophylline. Leucopenia and thrombocytopenia in a 45-year-old woman were believed to have been secondary to an interaction between theophylline and lomustine.[1]

1. **Zeltzer PM, Feig SA.** Theophylline-induced lomustine toxicity. *Lancet* 1979; ii: 960–1.

Pharmacokinetics

Lomustine is absorbed from the gastrointestinal tract and is rapidly metabolised, with peak plasma concentrations of metabolites occurring within 4 hours of an oral dose. Metabolites have a prolonged plasma half-life reported to range from 16 to 48 hours. Active metabolites readily cross the blood-brain barrier and appear in the CSF in concentrations higher than those in plasma. About half a dose is excreted as metabolites in the urine within 24 hours and about 75% is excreted within 4 days.

Lonidamine *(BAN, rINN)*

AF-1890; Diclondazolic Acid; Lonidamina; Lonidaminum; T-H-070; Лонидамин.
1-(2,4-Dichlorobenzyl)indazole-3-carboxylic acid.
$C_{15}H_{10}Cl_2N_2O_2$=321.2
CAS — 50264-69-2.
ATC — L01XX07.
ATC Vet — QL01XX07.
UNII — U78804BIDR.

Profile

Lonidamine is an antineoplastic that is thought to act by inhibiting mitochondrial function in tumour cells. It has been given orally in the treatment of various solid neoplasms, including those of the lung, breast, prostate, and brain. It has also been used as a radiosensitiser.

Lumiliximab *(USAN, rINN)*

Gomiliximab; IDEC-152; Lumiliximabum; Лумиликсимаб.
Immunoglobulin G1, anti-(human immunoglobulin E receptor type II) (human-*Macaca irus* monoclonal IDEC-152 γ1-chain), disulfide with human-*Macaca irus* monoclonal IDEC-152 κ-chain, dimer.
CAS — 357613-86-6.
UNII — 8Z13529R5A.

Profile

Lumiliximab is a chimeric anti-CD23 monoclonal antibody that is under investigation for the treatment of chronic lymphocytic leukaemia.

References.

Mafosfamide *(rINN)*

Mafosfamid; Mafosfamida; Mafosfamidi; Mafosfamidum; Мафосфамид.
(±)-2-([2-[Bis(2-chloroethyl)amino]tetrahydro-2*H*-1,3,2-oxazaphosphorin-4-yl]thio)ethanesulphonic acid *P*-*cis* oxide.
$C_9H_{19}Cl_2N_2O_5PS_2$=401.3
CAS — 88859-04-5.
UNII — 5970HH9923.

Profile

Mafosfamide is a derivative of cyclophosphamide (p. 771.1) that has been used to treat bone marrow for transplantation. Intrathecal mafosfamide has been investigated for the treatment of meningeal tumours.

Marimastat *(BAN, USAN, rINN)*

BB-2516; Marimastatum; TA-2516; Маримастат.
(2*S*,3*R*)-3-[(*S*)-[2,2-Dimethyl-1-(methylcarbamoyl)propyl]carbamoyl]-2-hydroxy-5-methylhexanohydroxamic acid.
$C_{15}H_{29}N_3O_5$=331.4
CAS — 154039-60-8.
UNII — D5EQV23TDS.

Profile

Marimastat is an oral inhibitor of matrix metalloproteinases, enzymes which are thought to play a role in the metastasis of cancer cells. It has been investigated in various malignant disorders.

Masitinib *(rINN)*

AB-1010; Masitinibum; Маситиниб.
4-[(4-Methylpiperazin-1-yl)methyl]-*N*-(4-methyl-3-([4-(pyridin-3-yl)-1,3-thiazol-2-yl]amino)phenyl)benzamide.
$C_{28}H_{30}N_6OS$=498.6
CAS — 790299-79-5.
ATC — L01XE22.
ATC Vet — QL01XE22.
UNII — M59NC4E26P.

Profile

Masitinib is a tyrosine kinase inhibitor active against c-kit and platelet-derived growth factor tyrosine kinases, that is under investigation for the treatment of malignancies such as gastrointestinal stromal tumours, pancreatic cancer, and multiple myeloma. It is also being investigated in inflammatory conditions such as asthma, mastocytosis, and rheumatoid arthritis.

Melphalan *(BAN, USAN, rINN)*

CB-3025; Melfalaani; Melfalan; Melfalán; Melphalanum; NSC-8806 (melphalan hydrochloride); PAM; Phenylalanine Mustard; Phenylalanine Nitrogen Mustard; L-Sarcolysine; WR-19813; Мелфалан.
4-Bis(2-chloroethyl)amino-L-phenylalanine.
$C_{13}H_{18}Cl_2N_2O_2$=305.2
CAS — 148-82-3 (melphalan); 3223-07-2 (melphalan hydrochloride).
ATC — L01AA03.
ATC Vet — QL01AA03.
UNII — Q41OR9510P.

NOTE. Merphalan (CB-3007; NSC-14210; sarcolysine) is the racemic form of melphalan; Medphalan (CB-3026; NSC-35051) is the D-isomer of melphalan.

Pharmacopoeias. In *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Melphalan). A white or almost white, hygroscopic powder. Practically insoluble in water; slightly soluble in methyl alcohol; dissolves in dilute mineral acids. Store in airtight containers. Protect from light.

USP 36: (Melphalan). An off-white to buff powder with a faint odour. Practically insoluble in water, in chloroform, and in ether; slightly soluble in alcohol and in methyl alcohol; soluble in dilute mineral acids. Store in airtight, glass containers. Protect from light.

Stability. A study of the stability of melphalan 40 and 400 micrograms/mL in infusion fluids reported that the time for a 10% loss of drug at 20 degrees in sodium chloride 0.9% injection was 4.5 hours, compared with 2.9 hours in lactated Ringer's injection, which has a considerably lower chloride ion content, and only 1.5 hours in glucose 5% injection.[1] At 25 degrees the corresponding figures were 2.4, 1.5, and 0.6 hours, and at 37 degrees they were 0.6, 0.4, and 0.3 hours. It was concluded that melphalan is sufficiently stable at 20 degrees in sodium chloride injection to permit infusion, but that increased temperature and decreased chloride ion concentration were associated with faster degradation rates.[1] Another study recommended that solutions of melphalan be handled at temperatures above 5 degrees for the minimum time but found that a solution containing 20 micrograms/mL in sodium chloride 0.9% could be stored for at least 6 months at -20 degrees without significant deterioration.[2] A more recent study, while recommending storage at 4 degrees between preparation and use of the infusion, considered that giving it at a room temperature of 20 degrees or below, and use of hypertonic (3%) saline as a diluent, would be sufficient to allow prolonged infusion.[3] The practicalities of such a procedure were not addressed.

Uses and Administration

Melphalan is an antineoplastic that acts as a bifunctional alkylating agent. It is used mainly in the treatment of multiple myeloma. Melphalan has also been given to patients with carcinoma of the breast and ovary, neuroblastoma, Hodgkin's disease, and in polycythaemia vera, and has been given by intra-arterial regional perfusion for malignant melanoma and soft-tissue sarcomas. See also the cross-references given below. Melphalan is also used in the treatment of amyloidosis, see below.

Melphalan is usually given orally as a single daily dose or in divided doses; it is also given intravenously as the hydrochloride. Doses are calculated in terms of the base; 1.12 mg of melphalan hydrochloride is equivalent to about 1 mg of melphalan. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration; p. 732.3.* Frequent blood counts are essential and dosage should be adjusted according to haematological response. Therapy should be interrupted if the platelet or white cell count fall below acceptable levels (see also Bone-marrow Depression, p. 730.3). It should be given with great caution if the neutrophil count has recently been depressed by chemotherapy or radiotherapy.

Many conventional-dose regimens have been tried for the treatment of multiple myeloma and there is still uncertainty as to the best schedule. Melphalan is usually combined with corticosteroids. Licensed **oral** dosage regimens that have been used include:

- 150 micrograms/kg daily in divided doses for 4 days, repeated at 6-week intervals
- 150 micrograms/kg daily for 7 days followed by a rest period of at least 14 days, or as long as 5 to 6 weeks; a maintenance dose of 50 micrograms/kg daily or less is given when the white blood cells and platelet counts increase with further adjustments according to the blood count
- 250 micrograms/kg daily for 4 days *or* 200 micrograms/kg daily for 5 days, for a total dose per course of 1 mg/kg; the course is repeated at intervals of 4 to 6 weeks according to the blood count
- 6 mg daily for 2 to 3 weeks adjusted according to the blood count; treatment is then stopped for up to 4 weeks until the white blood cells and platelet counts increase, after which a maintenance dose of 2 mg daily may be started
- 10 mg daily for 7 to 10 days followed by a maintenance dose of 2 mg daily when the white blood cells and platelet counts exceed 4000 cells/mm^3 and 100 000 cells/mm^3, respectively; the dose should then be further adjusted to 1 to 3 mg daily, according to blood counts

For optimum effect, therapy is usually adjusted to produce a moderate leucopenia, with white cell counts in the range 3000 to 3500 cells/mm^3.

In the treatment of breast cancer, licensed doses of 150 micrograms/kg daily or 6 mg/m^2 daily for 5 days, repeated every 6 weeks have been used. Doses of 200 micrograms/kg daily for 5 days every 4 to 8 weeks may be given to patients with ovarian carcinoma.

In patients with polycythaemia vera, doses of 6 to 10 mg daily for 5 to 7 days, and then 2 to 4 mg daily, have been used for remission induction; a dose of 2 to 6 mg weekly has been used for maintenance.

Melphalan is also given **intravenously**; for ovarian adenocarcinoma a single dose of 1 mg/kg, repeated at 4-week intervals if the platelet and neutrophil counts permit, may be given as monotherapy. It can be infused in sodium chloride 0.9% or injected slowly into the tubing of a fast-running drip; when given by infusion the time from reconstitution of the solution to completion of infusion should not exceed 1.5 hours and prolonged infusions should be carried out with several batches of solution, each freshly prepared. In multiple myeloma, the licensed dose for use as a single agent is an intravenous dose of 400 micrograms/kg or 16 mg/m^2, infused over 15 to 20 minutes; the first 4 doses may be given at 2-week intervals, but further doses should be given at 4-week intervals depending on toxicity.

High-dose melphalan has been given intravenously in some malignancies: doses of 100 to 240 mg/m^2 have been licensed in neuroblastoma, and 100 to 200 mg/m^2 in multiple myeloma, generally followed by autologous stem cell rescue, which becomes essential where doses exceed 140 mg/m^2. High doses should be given through a central venous catheter.

Melphalan may be given by **regional arterial perfusion** in the management of melanoma and soft-tissue sarcomas. A typical dosage range for hyperthermic regional perfusion for upper extremity perfusions is 0.6 to 1 mg/kg, whereas for lower extremity perfusions doses of 0.8 to 1.5 mg/kg (in melanoma) or 1 to 1.4 mg/kg (in sarcoma) are typically used.

The dose of melphalan should be reduced in patients with **renal impairment** (see below).

Administration in the elderly. Higher toxicity, mainly myelosuppression, has been reported when melphalan is used in patients older than 70 years, but a review concluded that dose modification is not recommended on the basis of age alone.[1] Dose reduction of melphalan is recommended for declining renal function (see Administration in Renal Impairment, below).

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; **25**: 1832–43.

Administration in renal impairment. The initial dose of intravenous melphalan should be reduced by about 50% in patients with renal impairment and dosage reduction should be considered when giving it orally. For high-dose intravenous melphalan regimens (melphalan 100 to 140 mg/m^2) given **without** stem cell rescue to patients with moderate renal impairment (creatinine clearance 30 to 50 mL/min), UK licensed product information advises that the dose is also usually reduced by 50%.

High-dose intravenous melphalan (up to 200 mg/m^2) **with** stem cell rescue has been used successfully without dose reductions in patients with severe renal impairment (creatinine clearance less than 20 mL/min), including those on dialysis.[1]

1. Bird JM, *et al.* The clinical outcome and toxicity of high-dose chemotherapy and autologous stem cell transplantation in patients with myeloma or amyloid and severe renal impairment: a British Society of Blood and Marrow Transplantation study. *Br J Haematol* 2006; **134**: 385–90.

Amyloidosis. Amyloidosis refers to a group of conditions characterised by accumulation of a waxy proteinaceous infiltrate within body tissues.[1-3] They include:

- primary or AL amyloidosis, in which the amyloid is derived from immunoglobulin light chains
- ATTR amyloidosis (a familial form), in which amyloid is derived from transthyretin
- AA amyloidosis, which is most often secondary to chronic inflammation, such as that associated with rheumatoid arthritis, tuberculosis, or familial Mediterranean fever (p. 605.1)

Symptoms vary, depending on where the amyloid is deposited. The organs most commonly affected are the heart and kidneys. Renal amyloidosis can present as proteinuria, leading to nephrotic syndrome and renal failure. While renal disease is common in the AA and AL forms, it is less prevalent in ATTR amyloidosis, which commonly presents with neuropathy. Cardiac involvement, rare in AA amyloidosis, is variable in the ATTR form, and common in the AL form; it manifests as restrictive cardiomyopathy, leading to congestive heart failure. Painful peripheral sensory neuropathy and carpal tunnel syndrome also occur frequently. Amyloid deposition in the gastrointestinal tract can lead to malabsorption. Hepatomegaly is common. Macroglossia, due to deposition of amyloid in the tongue, occurs only in the AL form.[1,2]

Management depends to some extent upon the type of amyloidosis involved, and the site, but no drug or combination of drugs is unequivocally effective.

Liver transplantation is the definitive therapy for patients with ATTR amyloidosis.[1,4] Tafamidis meglumine is used for the treatment of ATTR amyloidosis in adult patients with symptomatic polyneuropathy to delay peripheral neurological impairment; it is used before liver transplantation.

Treatment for AA amyloidosis secondary to chronic inflammation is aimed at the underlying disease; immunosuppressants such as chlorambucil, cyclophosphamide, and methotrexate have been used, as well as inhibitors of tumour necrosis factor and interleukin-1 receptor antagonists.[5] Colchicine is effective in the treatment of AA amyloidosis complicating familial Mediterranean fever, but is not considered to be of benefit in other forms of amyloidosis.[1,6]

Melphalan plus prednisone or prednisolone has been shown to increase median survival in primary amyloidosis patients.[7] It is considered the treatment of choice in AL amyloidosis for patients in whom more intensive chemotherapy is not appropriate; evidence of benefit from the addition of a corticosteroid has not been evaluated and in some patients, it may be reasonable not to include a corticosteroid.[6] Melphalan, prednisone, and colchicine was found to be more effective than colchicine alone in the treatment of AL amyloidosis,[8] but a later study[9] found no benefit in adding colchicine to the standard therapy.

Addition of multiple alkylating agents such as vincristine, carmustine, and cyclophosphamide to the standard therapy[10] did not improve survival or response. Evidence to support the use of alkylating-based combination chemotherapy for primary amyloidosis is lacking.[6] Alternatively, cycles of vincristine, doxorubicin, and dexamethasone (VAD) may be effective, but patients with cardiac amyloidosis may be at increased risk of anthracycline toxicity.[11] In the UK, VAD is considered as first-line therapy in patients under the age of 70 years who do not have cardiac failure, autonomic neuropathy, or peripheral neuropathy.[6]

High-dose intravenous melphalan with autologous haematopoietic stem cell transplantation (HSCT) has been used;[12] it may result in complete remission of primary amyloidosis.[13-15] Some[1] consider it the treatment of choice, but while it may improve renal disease,[13] the therapy remains very toxic; patient selection on the basis of limited organ disease and no significant cardiac involvement may reduce morbidity and mortality.[6,14] The outcome of treatment with high-dose intravenous melphalan with

autologous HSCT was not superior to standard-dose oral melphalan plus oral dexamethasone in patients with newly diagnosed AL amyloidosis.[16]

High-dose dexamethasone or thalidomide may be considered in patients in whom other regimens may not be feasible due to expected toxicity or in those refractory to chemotherapy;[6] good results have been reported in patients with AL amyloidosis given a regimen combining cyclophosphamide with dexamethasone and thalidomide.[17] Local application or oral dosage of dimethyl sulfoxide, and 4'-iodo-4'-deoxydoxorubicin has been investigated.[1,11]

Symptomatic management is also important. Care must be taken to avoid digitalis toxicity when cardiac amyloid is present, as well as to avoid salt and water depletion through injudicious use of diuretics. Calcium-channel blockers and beta blockers should be avoided.[1] Renal transplantation may be considered in end-stage renal failure due to amyloidosis, but unless amyloid production has been stopped disease is likely to recur in the new kidney. Cardiac transplantation, and subsequent chemotherapy with epirubicin, carmustine, and cyclophosphamide to suppress the underlying disease and control amyloid deposition in the graft has also been described.[18]

Because amyloid deposits contain a plasma glycoprotein serum amyloid P component (SAP) that contributes to the stability of the deposits, and thus contributes to the pathogenesis of amyloidosis, future therapeutic approaches include the targeting of SAP to deplete it from the tissues and clear it from the plasma. Ro-63-8695 (CPHPC) is being investigated.[3,19] Eprodisate disodium is under investigation for AA amyloidosis.[20]

Bone disorders, non-malignant. Fibrogenesis imperfecta ossium is a rare progressive bone disease in which disorders of bone collagen and mineralisation, and subsequent abnormal bone structure, result in bone pain and fractures. A patient responded to melphalan 10 mg and prednisolone 20 or 30 mg given daily, in 7-day courses every 2 months.[1,2] Another showed some improvement with intermittent 5-day courses of melphalan 10 mg daily and prednisolone 40 mg daily.[3] However, melphalan alone was reported to be ineffective in 2 other patients; both had bone-marrow depression.[3,4]

4. Lafage-Proust M-H, *et al.* Fibrogenesis imperfecta ossium: ineffectiveness of melphalan. *Calcif Tissue Int* 1996; 59: 240–4.

Malignant neoplasms. The important role played by melphalan in the management of multiple myeloma is discussed on p. 699.2. Melphalan is also used as part of salvage regimens for relapsed Hodgkin's disease (see p. 696.1), in ovarian cancer (p. 711.2), and for local perfusion of melanoma (p. 714.3).

Organ and tissue transplantation. Melphalan is used as part of non-myeloablative or reduced intensity conditioning regimens before haematopoietic stem cell transplantation, see p. 1937.1.

Adverse Effects and Treatment

For general discussions see Antineoplastics, p. 726.1 and p. 730.2.

The onset of neutropenia and thrombocytopenia is variable; the nadir of bone-marrow depression usually occurs at 2 to 3 weeks after starting treatment with melphalan, with recovery after 4 to 5 weeks.

Skin rashes and hypersensitivity reactions, including anaphylaxis, may occur. Cardiac arrest has been reported in association with such effects. Gastrointestinal disturbances may sometimes occur, particularly at high doses where diarrhoea, vomiting, and stomatitis may become dose-limiting. Haemolytic anaemia, vasculitis, pulmonary fibrosis, and hepatic disorders including hepatitis and jaundice have been reported. Suppression of ovarian function is common in premenopausal women; temporary or permanent sterility may occur in male patients. Extravasation of melphalan injection can cause skin ulceration and necrosis. As with other alkylating agents, melphalan also has carcinogenic, mutagenic, and teratogenic potential.

Mucositis. Amifostine has been shown to reduce the frequency and severity of melphalan-induced oral mucositis.[1]

1. Spencer A, *et al.* Prospective randomised trial of amifostine cytoprotection in myeloma patients undergoing high-dose melphalan conditioned autologous stem cell transplantation. *Bone Marrow Transplant* 2005; 35: 971–7.

Overdosage. A 12-month old child given melphalan 140 mg intravenously (a tenfold overdose) developed pronounced lymphopenia within 24 hours but had no other significant adverse effects until the seventh day, when neutropenia, thrombocytopenia, oral ulceration, and diarrhoea developed.[1] Bone marrow recovered within 40 days. Treatment was by vigorous hyperalimentation and close surveillance during this period and the patient subsequently remained well 9 months afterwards, without complications. Cases of intravenous melphalan overdose have also been reported in adults,[2] resulting in bone-marrow depression, haemorrhagic diarrhoea, and electrolyte disturbances. Bone-marrow depression has also been reported after cumulative oral doses of 360 mg over 3 weeks,[3] and 560 mg over 2 weeks.[4] Filgrastim was used in one of these cases to stimulate bone-marrow recovery.[4]

4. Jirillo A, *et al.* Accidental overdose of melphalan per os in a 69-year-old woman treated for advanced endometrial carcinoma. *Tumori* 1998; 84: 611.

Precautions

For general discussions see Antineoplastics, p. 732.2.

Care is required in patients with impaired renal function.

Handling and disposal. *Urine and faeces* produced for up to 48 hours and 7 days respectively after an oral dose of melphalan should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies melphalan as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

Use of nalidixic acid with high-dose intravenous melphalan in children has resulted in fatal haemorrhagic enterocolitis.

Ciclosporin. For reference to enhanced toxicity when melphalan was given with ciclosporin, see under Ciclosporin, p. 1957.2.

Food. The bioavailability of oral melphalan is significantly reduced, by up to 45%, by food. Some recommend that melphalan should not be taken with food, and that if dosage is switched from after to before food patients should be monitored for increased toxicity.[1]

1. Nathan C, Betmouni R. Melphalan: avoid with food. *Pharm J* 1996; 257: 264.

Interferons. The fever induced by interferon alfa resulted in a reduction in the area under the plasma concentration-time curve for melphalan in a study of 10 patients, although the peak plasma concentration and time to peak concentration were not affected.[1] The effect was thought to represent increased chemical reactivity of melphalan at the elevated temperature.

1. Ehrsson H, *et al.* Oral melphalan pharmacokinetics: influence of interferon-induced fever. *Clin Pharmacol Ther* 1990; 47: 86–90.

Pharmacokinetics

Absorption of melphalan from the gastrointestinal tract is variable; the mean bioavailability is reported to be 56% but it may range from 25 to 89%. Absorption is reduced by the presence of food (see above). On absorption it is rapidly distributed throughout body water with a volume of distribution of about 0.5 litres/kg, and has been reported to be inactivated mainly by spontaneous hydrolysis. About 60 to 90% is bound to plasma proteins, mainly albumin. The terminal plasma half-life of melphalan has been reported to be about 30 to 150 minutes. Melphalan is excreted in the urine, about 10% as unchanged drug.

Pharmacopoeial Preparations

BP 2014: Melphalan Injection; Melphalan Tablets;
USP 36: Melphalan Tablets.

Mercaptopurine *(BAN, rINN)*

6MP; Mercaptopurin; Mercaptopurina; Mercaptopurinum; Mercaptopurinum Monohydricum; Merkaptopurilni; Merkaptopürin; Merkaptopurin; Merkaptopurin monohydrát; Merkaptopurinas; Merkaptopuryna; NSC-755; Purinethiol; WR-2785; Меркаптопурин.

6-Mercaptopurine monohydrate; Purine-6-thiol monohydrate; 1,7-Dihydro-6*H*-purine-6-thione monohydrate.

$C_5H_4N_4S,H_2O$=170.2

CAS — 50-44-2 (anhydrous mercaptopurine); 6112-76-1 (mercaptopurine monohydrate).

ATC — L01BB02.

ATC Vet — QL01BB02.

UNII — E7WED276I5 (mercaptopurine); PKK6MUZ20G (anhydrous mercaptopurine).

NOTE. In the UK, the CSM noted in October 2004 that confusion had arisen between mercaptopurine and mercaptamine (formerly cysteamine, p. 2554.3) after the switch from prescribing by British Approved Name to prescribing by International Nonproprietary Name. Particular care should be taken to distinguish the two, since they are available in oral dosage forms of similar strength.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Mercaptopurine). A yellow, crystalline powder. Practically insoluble in water; slightly soluble in alcohol; dissolves in solutions of alkali hydroxides. Protect from light.

USP 36: (Mercaptopurine). A yellow, odourless or practically odourless, crystalline powder. Insoluble in water, in acetone, and in ether; soluble in hot alcohol and in dilute alkali solutions; slightly soluble in 2*N* sulfuric acid. Store in airtight containers. Protect from light.

Uses and Administration

Mercaptopurine is an antineoplastic that acts as an antimetabolite. It is an analogue of the natural purines hypoxanthine and adenine. After the intracellular conversion of mercaptopurine to active tioguanine nucleotides, including thioinosinic acid, it appears to have a variety of actions including interfering with nucleic acid synthesis. It also has immunosuppressant properties. Its actions are specific for cells in S phase.

Mercaptopurine is used, usually with other agents, in the treatment of leukaemia. It can be used for remission induction in acute lymphoblastic and myeloid leukaemias (p. 692.3 and p. 693.1, respectively) but other agents are generally preferred and its main use is in maintenance programmes, commonly with methotrexate. It may also be effective in chronic myeloid leukaemia (p. 694.2). There is cross-resistance between mercaptopurine and tioguanine (p. 872.1).

Mercaptopurine has been used for its immunosuppressant properties in the treatment of auto-immune disorders such as inflammatory bowel disease (see below for doses) but has been largely replaced by azathioprine.

Mercaptopurine is given orally usually as tablets; although oral suspensions are available, they are not bioequivalent to tablets and close haematological monitoring is advised when changing between formulations. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* The usual initial antineoplastic dose of mercaptopurine is 2.5 mg/kg or 50 to 75 mg/m^2 daily but dose and duration depend on the combination regimen used; dosage is adjusted according to individual response and tolerance. In maintenance schedules the dose may vary from 1.5 to 2.5 mg/kg daily. Blood counts should be taken daily during remission induction and weekly during maintenance; if there is a steep fall in the white cell count or severe bone-marrow depression mercaptopurine should be stopped immediately.

For dose reductions when mercaptopurine is used with allopurinol, see Interactions, below.

It has been used intravenously as mercaptopurine sodium. Thioinosine (mercaptopurine riboside) has also been used.

Administration in children. Mercaptopurine is given to children for the treatment of leukaemias in the same dose by weight or surface area as that used for adults (see Uses and Administration, above).

There is evidence[1] that the maintenance dosage of mercaptopurine should be tailored individually to achieve an appropriate systemic exposure in children with acute lymphoblastic leukaemia (although this would involve determining mercaptopurine pharmacokinetics in each child). Improvements in survival since 1980 may be associated with changes in the prescribing of mercaptopurine which have resulted in greater cumulative doses being given;[2] some children may have been undertreated in the past because of variations in the pharmacokinetics of mercaptopurine (particularly boys, who tolerate mercaptopurine better than girls,[3] but who have a poorer prognosis).[2] The concentration of tioguanine nucleotide metabolites in the erythrocytes has been shown to be directly related to the risk of relapse in children with acute lymphoblastic leukaemia.[4] Thiopurine methyltransferase (TPMT) activity (which results in methylation and inactivation of mercaptopurine rather than the formation of active nucleotides) may play a substantial role in this variation,[5] but titration of the dose of mercaptopurine until myelotoxicity occurs may prevent the problem;[2] despite gaps in therapy caused by more frequent drug withdrawal, it appears to result in greater accumulation of tioguanine nucleotides in the cells.[6] A pharmacokinetic model has been proposed as offering a more rational approach for mercaptopurine dosing in children, by taking into account body-surface as well as TPMT genotype.[7]

Mercaptopurine is also used for inflammatory bowel disease in children, see below.

Administration in hepatic or renal impairment. Both UK and US licensed product information suggest that consideration be given to reducing the dosage of mercaptopurine in patients with hepatic or renal impairment, but no specific dose recommendations are given.

Inflammatory bowel disease. Mercaptopurine has been reported to be of benefit in ulcerative colitis[1,2] (although the quality of the evidence was considered low by a systematic review[3]) and Crohn's disease,[4–6] although azathioprine has generally been preferred (see p. 1945.1). Although unlicensed in the UK, the *BNF* and the *BNFC* state that mercaptopurine may be given to adults and children from 2 years of age for severe Crohn's disease or ulcerative colitis in an oral dose of 1 to 1.5 mg/kg once daily; in children up to 18 years of age an initial maximum of 50 mg daily is advised, increasing only up to 75 mg daily if necessary.

Polymyositis. Mercaptopurine has been tried in a few patients with polymyositis but has not been formally assessed.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bone-marrow depression with mercaptopurine, manifesting as leucopenia, thrombocytopenia, and anaemia, may be delayed; hypoplasia may occur. Mercaptopurine is less toxic to the gastrointestinal tract than the folic acid antagonists or fluorouracil but gastrointestinal disturbances may occur. Hepatotoxicity has been reported, with cholestatic jaundice and necrosis, sometimes fatal. Gastrointestinal and hepatic toxicity are reported to be more frequent in adults than in children, and are more likely at higher doses. Crystalluria with haematuria has been seen rarely as have skin disorders including hyperpigmentation. Fever may occur.

Mercaptopurine should be used with care in patients with impaired hepatic or renal function. Hepatic function should be monitored periodically.

Breast feeding. For information about the use of mercaptopurine during breast-feeding, see Azathioprine, p. 1946.3.

Effects on the blood. Measurement of the activity of thiopurine methyltransferase (TPMT) or the concentration of its substrate, tioguanine nucleotide, has been suggested as a way of predicting those individuals likely to have severe myelotoxicity with mercaptopurine and related drugs (see Azathioprine, p. 1946.2). Patients with an inherited deficiency of the TPMT enzyme may be at increased risk of myelosuppression from mercaptopurine. TPMT testing may be carried out in patients with evidence of toxicity; dose reductions should be considered in those with TPMT deficiency, although optimal initial doses have not been established for these patients. Tests for TPMT deficiency have not been shown to identify all patients at risk of severe toxicity; close monitoring of blood counts should still be performed.

Effects on the pancreas. Pancreatitis occurred in 13 of 396 patients given mercaptopurine for inflammatory bowel disease.[1] Symptoms resolved on withdrawal but recurred in 7 who were re-challenged with mercaptopurine or azathioprine. Acute pancreatitis has also been reported in 2 children given mercaptopurine during maintenance chemotherapy for acute lymphoblastic leukaemia.[2] They had also suffered pancreatitis from asparaginase during earlier therapy, and the authors suggested that subclinical damage to the pancreas by asparaginase may have been exacerbated by mercaptopurine, but also noted that most patients who develop asparaginase-induced pancreatitis receive mercaptopurine without developing this complication.

1. Present DH, *et al.* 6-Mercaptopurine in the management of inflammatory bowel disease: short- and long-term toxicity. *Ann Intern Med* 1989; 111: 641–9.
2. Willert JR, *et al.* Recurrent mercaptopurine-induced acute pancreatitis: a rare complication of chemotherapy for acute lymphoblastic leukemia in children. *Med Pediatr Oncol* 2002; 38: 73–4.

Handling and disposal. A method for the destruction of mercaptopurine or tioguanine in *wastes* by oxidation with potassium permanganate in sulfuric acid.[1] Residues produced by this method had no mutagenic activity. *Urine and faeces* produced for up to 48 hours and 5 days, respectively after a dose of mercaptopurine should be handled wearing protective clothing.[2]

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Overdosage. Despite substantial overdose, no acute renal or hepatic toxicity occurred in 2 children. In one case, in which no specific detoxification measures were implemented, neutrophils reached a nadir on day 11 followed by a gradual recovery to normal by day 46. In the other case, gastric lavage was performed and activated charcoal was given; no evidence of neutropenia was seen. The authors recommended that management of acute accidental ingestion should include gastric lavage if the patient presents within 1 hour or if the amount ingested is large. Haemodialysis may be considered if the patient presents within 3 hours of ingestion. Liver function should be monitored. Severe myelosuppression may be managed with granulocyte colony-stimulating factor and a bone-marrow harvest may be of benefit if performed within several hours of the overdose.[1]

1. Chow LML, *et al.* Toxic ingestion of 6-mercaptopurine by young siblings of pediatric oncology patients. *J Pediatr* 2004; 144: 669–71.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies mercaptopurine as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pregnancy. For discussion of the safety of mercaptopurine in pregnancy, see Azathioprine, p. 1947.1.

Interactions

Mercaptopurine should be given with particular caution with other hepatotoxic drugs. Its effects are enhanced by allopurinol and the dose of mercaptopurine should be reduced to one-third to one-quarter of the usual dose when allopurinol is also given.

Allopurinol. Mercaptopurine plasma concentrations were markedly increased by allopurinol when mercaptopurine was given orally but not when it was given intravenously.[1] The results appear to indicate that allopurinol inhibits the first-pass metabolism of mercaptopurine.

The use of allopurinol to promote formation of 6-thioguanine nucleotides rather than 6-methylmercaptopurine nucleotides in patients with preferential metabolism via the latter has been investigated.[2,3]

1. Zimm S, *et al.* Inhibition of first-pass metabolism in cancer chemotherapy: interaction of 6-mercaptopurine and allopurinol. *Clin Pharmacol Ther* 1983; 34: 810–17.
2. Gerich ME, *et al.* A prospective evaluation of the impact of allopurinol in pediatric and adult IBD patients with preferential metabolism of 6-mercaptopurine to 6-methylmercaptopurine. *J Crohns Colitis* 2010; 4: 546–52.
3. Gardiner SJ, *et al.* Allopurinol might improve response to azathioprine and 6-mercaptopurine by correcting an unfavorable metabolite ratio. *J Gastroenterol Hepatol* 2011; 26: 49–54.

Anticoagulants. For reference to mercaptopurine diminishing the activity of *warfarin*, see p. 1532.2.

Antineoplastics. For a suggestion that *doxorubicin* might enhance the hepatotoxicity of mercaptopurine, see under Daunorubicin Hydrochloride, p. 779.3.

Giving mercaptopurine with low-dose oral *methotrexate* increased mean peak plasma concentrations of mercaptopurine by 26% compared with the same dose of mercaptopurine alone in a study in 14 patients with acute lymphoblastic leukaemia.[1] The effect was probably due to inhibition of the first-pass metabolism of mercaptopurine by methotrexate, which is a potent inhibitor of xanthine oxidase. In another study[2] of 10 children with acute lymphoblastic leukaemia, high-dose intravenous methotrexate (2 or 5 g/m^2) increased the peak plasma concentrations of mercaptopurine by 108 and 121% respectively. However, the clinical effect of this pharmacokinetic interaction is probably only minor because of the low, and highly variable, mercaptopurine bioavailability and the lack of correlation between mercaptopurine plasma concentrations and effect.[3] Mercaptopurine and methotrexate have been widely used in combination chemother-

apy regimens for acute lymphoblastic leukaemia for their synergistic pharmacodynamic interaction.

Azathioprine. For a report of a fatality when a patient was prescribed mercaptopurine and azathioprine by separate practitioners, see Interactions, under Azathioprine, p. 1947.2.

Gastrointestinal drugs. The enzyme thiopurine methyltransferase is inhibited *in vitro* by *sulfasalazine* and *mesalazine*, raising the possibility of an interaction in patients treated simultaneously with an aminosalicylate and a thiopurine such as mercaptopurine or azathioprine.[1] Myelotoxicity has been reported in a patient receiving mercaptopurine and *olsalazine*.[2] Similarly, severe pancytopenia has occurred in a 13-year-old boy when azathioprine was added to mesalazine therapy.[3] In a study[4] of 34 patients with Crohn's disease in which *balsalazide*, mesalazine, or sulfasalazine was added to established azathioprine or mercaptopurine therapy, mild leucopenia was common in patients given mesalazine or sulfasalazine, and whole blood concentrations of tioguanine nucleotide were found to be increased, probably due to thiopurine methyltransferase inhibition. These effects were not statistically significant in patients given balsalazide.

Pharmacokinetics

Mercaptopurine is variably and incompletely absorbed from the gastrointestinal tract; about 50% of an oral dose has been reported to be absorbed, but the absolute bioavailability is somewhat lower, probably due to gastrointestinal or first-pass metabolism, and is also subject to wide interindividual variation. Once absorbed it is widely distributed throughout body water and tissues. Plasma half-lives ranging from about 20 to 90 minutes have been reported after intravenous injection and the drug is not found in plasma after about 8 hours but this is of limited significance since mercaptopurine is activated intracellularly by conversion to nucleotide derivatives which persist for much longer. It is rapidly and extensively metabolised in the liver, by methylation and oxidation as well as by the formation of inorganic sulfates. Thiol methylation is catalysed by the enzyme thiopurine methyltransferase (TPMT). TPMT activity is highly variable in patients because of a genetic polymorphism in the TPMT gene. Patients with little or no detectable enzyme activity may accumulate excessive cellular concentrations of active tioguanine nucleotides, predisposing them to mercaptopurine toxicity. Considerable amounts of mercaptopurine are also oxidised to thiouric acid by the enzyme xanthine oxidase. Mercaptopurine is excreted in urine as metabolites and some unchanged drug; about half an oral dose has been recovered in 24 hours. A small proportion is excreted over several weeks.

Mercaptopurine crosses the blood-brain barrier to some extent and is found in the CSF, but only in subtherapeutic concentrations.

Therapeutic drug monitoring. For a discussion of therapeutic drug monitoring for mercaptopurine, see under Azathioprine, p. 1947.2.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Puri-Nethol; Varimer; *Austral.*: Puri-Nethol; *Austria*: Puri-Nethol; *Belg.*: Puri-Nethol; *Braz.*: Puri-Nethol; *Canad.*: Purinethol; *Chile*: Puri-Nethol; *Cz.*: Puri-Nethol; *Denm.*: Xaluprine; *Fr.*: Puri-Nethol; *Ger.*: Puri-Nethol; *Gr.*: Puri-Nethol; *Hong Kong*: Puri-Nethol; *India*: Empurine; Mercapto; Puri-Nethol; *Irl.*: Puri-Nethol; *Israel*: Puri-Nethol; *Ital.*: Puri-Nethol; *Mex.*: Puri-Nethol; *Neth.*: Puri-Nethol; Xaluprine; *Norw.*: Puri-Nethol; Xaluprine; *NZ*: Puri-Nethol; *Philipp.*: Capmerin; Empurine; Merpurin; Puri-Nethol; *Rus.*: Puri-Nethol (Пури-нетол); *S.Afr.*: Puri-Nethol; *Singapore*: Puri-Nethol; Purinetone; *Swed.*: Puri-Nethol; *Switz.*: Puri-Nethol; *Thai.*: Empurine†; Puri-Nethol; *Turk.*: Puri-Nethol; *UK*: Puri-Nethol†; Xaluprine; *USA*: Purinethol.

Pharmacopoeial Preparations

BP 2014: Mercaptopurine Oral Suspension; Mercaptopurine Tablets;

USP 36: Mercaptopurine Tablets.

Methotrexate *(BAN, USAN, rINN)*

Amethopterin; Ametopterina; 4-Amino-4-deoxy-10-methylpteroyl-L-glutamic Acid; 4-Amino-10-methylfolic Acid; CL-14377; α-Methopterin; Methotrexat; Methotrexát; Méthotrexate; Methotrexatum; Metotreksaatti; Metotreksatas; Metotrexat; Metotrexát; Metotrexato; MTX; NSC-740; WR-19039; Метотрексат.

N-[4-[(2,4-Diamino-6-pteridinylmethyl)methylamino]benzoyl]-L-glutamic acid.

$C_{20}H_{22}N_8O_5$=454.4

CAS — 59-05-2.

ATC — L01BA01; L04AX03.

ATC Vet — QL01BA01; QL04AX03.

UNII — YL5FZ2Y5U1.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Methotrexate). A yellow or orange, hygroscopic, crystalline powder. It contains not more than 13% of water. Practically insoluble in water, in alcohol, and in dichloromethane; dissolves in dilute solutions of mineral acids and of alkali hydroxides and carbonates. Store in airtight containers. Protect from light.

USP 36: (Methotrexate). It is a mixture of 4-amino-10-methylfolic acid and closely related substances; it contains not less than 98% and not more than 102% of $C_{20}H_{22}N_8O_5$, calculated on the anhydrous basis. A yellow or orange-brown crystalline powder. It contains not more than 12% of water. Practically insoluble in water, in alcohol, in chloroform, and in ether; freely soluble in dilute solutions of alkali hydroxides and carbonates; slightly soluble in 6N hydrochloric acid. Store in airtight containers. Protect from light.

Methotrexate Sodium *(BANM, rINNM)*

Méthotrexate de Sodium; Methotrexate Disodium; Metotreksat Sodyum; Metotrexate sodium; Metotrexato disódico; Metotrexato sódico; Natrii Methotrexatum; Натрий Метотрексат.

$C_{20}H_{20}N_8Na_2O_5$=498.4

CAS — 7413-34-5 (methotrexate disodium); 15475-56-6 (methotrexate sodium, xNa).

ATC — L01BA01; L04AX03.

ATC Vet — QL01BA01; QL04AX03.

UNII — 3KG1E710ZN.

Incompatibility. Methotrexate sodium has been reported to be incompatible with cytarabine, fluorouracil, and prednisolone sodium phosphate;[1] however, another study suggests it is compatible with fluorouracil.[2] Furthermore a mixture of methotrexate sodium with cytarabine and hydrocortisone sodium succinate in various infusion fluids has been reported to be visually compatible for at least 8 hours at 25 degrees, although precipitation did occur on storage for several days.[3]

3. Cheung Y-W, *et al.* Stability of cytarabine, methotrexate sodium, and hydrocortisone sodium succinate admixtures. *Am J Hosp Pharm* 1984; 41: 1802–6.

Stability to light. Methotrexate undergoes photodegradation when stored in the light in diluted solutions, although undiluted commercial preparations are reported to show negligible photodegradation.[1] The bicarbonate ion catalyses this reaction and such admixtures should be avoided if possible, although they may be stable in light for 12 hours. Storage of solutions diluted in sodium chloride 0.9% injection in PVC bags was reported to protect against photodegradation although the length of the study was only 4 hours.[2] Photodegradation can take place under normal lighting, but is more rapid in direct sunlight, with about 11% drug loss from a 1 mg/mL solution after 7 hours; storage under normal lighting resulted in little change in drug concentration over 24 hours with a decrease of up to 12% by 48 hours.[3] Loss was greatest from unprotected polybutadiene tubing, with almost 80% drug loss in 48 hours.

Uses and Administration

Methotrexate is an antimetabolite antineoplastic that acts as an antagonist of folic acid. It also has immunosuppressant properties. Within the cell, folic acid is reduced to dihydrofolic and then tetrahydrofolic acid. Methotrexate competitively inhibits the enzyme dihydrofolate reductase and prevents the formation of tetrahydrofolate which is necessary for purine and pyrimidine synthesis and consequently the formation of DNA and RNA. It is most active against cells in the S phase of the cell cycle. Folinic acid (the 5-formyl derivative of tetrahydrofolic acid) has been given after high doses to bypass the block in tetrahydrofolate production in normal cells and prevent the adverse effects of methotrexate. A suggested schedule for *folinic acid rescue* is described under Folinic Acid, p. 2067.1 (See also Treatment of Adverse Effects, p. 826.3). Methotrexate, in very high doses, followed by folinic acid rescue, is used in treating some malignant diseases.

Methotrexate is used in the management of acute lymphoblastic leukaemia. It is seldom used for the induction of remission but is employed in maintenance programmes and in the prophylaxis and treatment of meningeal leukaemia. It may be used for Burkitt's and other non-Hodgkin's lymphomas. In the solid neoplasms it is an important part of curative regimens for choriocarcinoma and other gestational trophoblastic tumours, and for the adjuvant therapy of osteosarcoma and breast cancer. It may also be used in other malignant neoplasms, see Malignant Neoplasms, p. 824.1.

Methotrexate is of value in the treatment of psoriasis but because of the risks associated with this use, it should only be given when the disease is severe and has not responded to other forms of treatment. It is widely used as a disease-modifying antirheumatic drug in rheumatoid arthritis. Methotrexate may be used to prevent graft-versus-host disease after bone marrow transplantation and may be used as a cytotoxic immunosuppressant and corticosteroid-sparing agent in non-malignant diseases.

Methotrexate has a role in the management of ectopic pregnancy (see p. 823.3) and in the termination of early pregnancy (see p. 824.3).

Methotrexate may be given *orally* as the base or the sodium salt, or by *injection* as the sodium salt. Doses are calculated in terms of methotrexate. Methotrexate sodium 16.5 mg is equivalent to about 15 mg of methotrexate. The doses and regimens used vary enormously, and may need to be adjusted according to bone marrow or other toxicity (see also under Bone-marrow Depression, p. 730.3). *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* Methotrexate regimens are often described as low-, moderate-, and high-dose, although what is meant by these terms may vary slightly. Some UK licensed product information has defined them as follows:

- low-dose: individual doses under 100 mg/m²
- moderate-dose: individual doses between 100 mg/m² and 1 g/m²
- high-dose: individual doses above 1 g/m²

Doses larger than 100 mg are usually given partly or wholly by intravenous infusion over not more than 24 hours.

Some common methotrexate doses are as follows:

For maintenance therapy in **acute lymphoblastic leukaemia**:

- 15 mg/m² orally or intramuscularly twice weekly
- 20 to 30 mg/m² orally or intramuscularly twice weekly
- 2.5 mg/kg intravenously every 14 days

For **meningeal leukaemia**:

- 12 mg/m² intrathecally once weekly for 2 weeks, then once monthly
- 200 to 500 micrograms/kg intrathecally at intervals of 2 to 5 days until the cell count of the CSF returns to normal; one additional dose is advised thereafter
- 12 mg intrathecally once weekly until the cell count of the CSF returns to normal; one additional dose is advised thereafter

For **Burkitt's lymphoma**:

- stages I to II: 10 to 25 mg orally daily for 4 to 8 days
- stage III (with other drugs): 0.625 to 2.5 mg/kg orally daily

In all stages, courses are usually repeated several times at intervals of 7 to 10 days.

For **lymphosarcoma**:

- (with other drugs): 0.625 to 2.5 mg/kg intravenously or intramuscularly daily

For **choriocarcinoma** and similar trophoblastic diseases:

- 15 to 30 mg orally or intramuscularly daily for 5 days, repeated after an interval of 1 week or longer, for 3 to 5 courses

For **osteosarcoma**:

- 8 to 12 g/m² intravenously once weekly, with folinic acid rescue

For **breast cancer**:
- (with *cyclophosphamide* and *fluorouracil* in the CMF regimen, see Table 1, p. 719) 40 mg/m² intravenously on days 1 and 8
- (with other drugs in cyclical regimens) 10 to 60 mg/m² intravenously

For **mycosis fungoides**:
- 2.5 to 10 mg orally daily for weeks or months, adjusted according to response and toxicity
- 50 mg intramuscularly weekly, as a single dose, or in two divided doses

For **psoriasis**:
- 10 to 25 mg orally, intramuscularly, or intravenously once weekly, adjusted according to response and toxicity; a suggested test dose in the range of 5 to 10 mg is recommended one week before the start of therapy
- 7.5 to 20 mg (increased as needed to a maximum of 25 to 30 mg) orally weekly, given as 3 divided doses over 24 hours, or as 3 divided doses at 12-hour intervals, or as 4 divided doses at 8-hour intervals; some suggest a test dose of 2.5 to 5 mg
- 2 to 5 mg (maximum 6.25 mg) orally daily for 5 days, followed by an interval of at least 2 days

For **rheumatoid arthritis**:
- 7.5 mg once weekly, given as a single oral, subcutaneous, intramuscular, or intravenous dose, or as 2.5 mg orally every 12 hours for 3 doses, adjusted according to response to a usual maximum of 20 mg weekly

In psoriasis and rheumatoid arthritis, once an adequate response is seen, the dose should be reduced to the lowest possible effective dose.

For doses in children, see below.

It is essential that blood counts and tests of renal and liver function should be made before, during, and after each course of treatment with methotrexate (see Precautions, p. 827.1). For further information on dosing in hepatic and renal impairment, see below.

Administration in children. Methotrexate is used in some countries for cancer chemotherapy in children, either alone or in combination regimens, and in juvenile idiopathic arthritis, for patients with active polyarticular rheumatoid disease.

For use in cancer chemotherapy such as for **acute lymphoblastic leukaemia** dosage is usually based on body-weight or body-surface in similar doses to those used in adults (see Uses and Administration, p. 822.3); alternatively, an oral or parenteral dose of methotrexate 15 mg/m² once weekly (with other drugs) has been suggested. For **meningeal leukaemia**, some UK licensed product information states that the dose of intrathecal methotrexate is constant regardless of age or body-surface in patients over the age of 3 years, and that those under 3 years be treated in accordance with combination chemotherapy protocols. For **non-Hodgkin's lymphoma** in children, methotrexate is given according to the disease phase and histological type; single intravenous doses range from 300 mg/m² to 5 g/m².

For juvenile **rheumatoid arthritis** the recommended starting oral or parenteral dose in the USA is 10 mg/m² once weekly. Dosage is adjusted gradually to achieve an optimal response. Children have been given doses up to 30 mg/m² weekly, but data are too limited to assess how doses over 20 mg/m² weekly might affect the risk of serious toxicity, although there is some suggestion that children given 20 to 30 mg/m² weekly (0.65 to 1 mg/kg weekly) may have better absorption and fewer gastrointestinal adverse effects if methotrexate is given either intramuscularly or subcutaneously. In the UK, methotrexate is licensed for children aged 3 to 16 years in the treatment of polyarticular juvenile idiopathic arthritis; a usual dose of 10 to 15 mg/m² once weekly by subcutaneous or intramuscular injection can be increased up to a maximum of 20 mg/m² once weekly. While stating that methotrexate is not licensed for use in children with other non-malignant conditions, the *BNFC* recommends a dose for juvenile idiopathic arthritis, juvenile dermatomyositis, vasculitis, uveitis, SLE, localised scleroderma, and sarcoidosis; children aged 1 month to 18 years may be given 10 to 15 mg/m² once weekly initially, increased if needed to a maximum of 25 mg/m² once weekly. Doses may be given orally, subcutaneously, or intramuscularly.

Methotrexate injectable formulations containing the preservative benzyl alcohol are not recommended for use in neonates. See also Neonates, under Benzyl Alcohol, p. 1741.1.

For **psoriasis**, although methotrexate is unlicensed in the UK for this use in children, the *BNFC* allows for specialist use in severe uncontrolled refractory disease. Children aged 2 to 18 years may be given an initial oral dose of 200 micrograms/kg (maximum 10 mg) once weekly, increased according to response to 400 micrograms/kg (maximum 25 mg) once weekly.

For suggested doses in the treatment of **Crohn's disease** in children, see Inflammatory Bowel Disease, p. 824.1.

Administration in the elderly. Licensed product information states that methotrexate should be used with extreme caution in the elderly, and that dosage reduction should be considered. Folate reserves are lower in older people and dosage reduction may be needed based on reduced liver and kidney function. Concomitant disease or drug therapy may contribute to these factors. There is some suggestion that adverse effects such as bone marrow suppression, thrombocytopenia, and pneumonitis may be increased in elderly patients.

A review[1] also states that increased toxicity has been seen in elderly patients given long-term low-dose methotrexate, and that half-life and clearance are significantly prolonged in older patients. A dose reduction based on renal function is recommended, and an alternative dosing formula using creatinine clearance (CC) has been proposed, namely:

$$\text{adjusted dose} = \text{normal dose} \times CC / 70$$

See also Administration in Renal Impairment, below.

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; **25**: 1832–43.

Administration in hepatic impairment. Methotrexate is hepatotoxic, and liver function should be monitored during therapy (see Precautions, p. 827.1). Methotrexate should not be given to patients with severe or significant hepatic impairment, or to those with liver disease, including fibrosis, cirrhosis, or hepatitis. UK licensed product information for one injectable formulation (*Metoject; Medac, UK*) specifies that methotrexate should not be used if the bilirubin concentration is greater than 5 mg per 100 mL (85.5 micromoles/litre). Most UK licensed product information advises that methotrexate therapy be suspended for at least 2 weeks if substantial hepatic function abnormalities develop.

Administration in renal impairment. Methotrexate is renally excreted, and renal function should be monitored before, during, and after treatment. High-dose methotrexate therapy can affect the kidneys, and measures to prevent this may be required, see Effects on the Kidneys, p. 825.2.

Most UK licensed product information contra-indicates use in severe or significant renal impairment and states that doses of methotrexate should be reduced in patients with renal impairment, but gives no specific dose recommendations. However, licensed product information for one injectable formulation (*Metoject; Medac, UK*) gives the following recommendations based on creatinine clearance (CC):
- CC > 50 mL/min: 100% of the usual dose
- CC between 20 and 50 mL/min: 50% of the usual dose
- CC < 20 mL/min: use contra-indicated

Some advise adjustment of dose according to the CC and serum methotrexate concentrations. For a suggested dose in elderly patients based on CC, see Administration in the Elderly, above.

Asthma. Various immunosuppressants, including methotrexate, have been tried for their anti-inflammatory and corticosteroid-sparing properties in chronic asthma (p. 1195.2), but because of fears about toxicity are largely reserved for certain patients dependent upon systemic corticosteroids. Results of individual studies with methotrexate have been conflicting, but it appears that some patients may benefit from the corticosteroid-sparing effects of methotrexate.[1-5] However, some reviewers considered that the reduction in corticosteroid dose was insufficient to offset the adverse effects of methotrexate.[6] Methotrexate therapy must be given for at least 3 months for an adequate assessment of efficacy.

Connective tissue and muscular disorders. Reports in a limited number of patients indicate that methotrexate given once weekly in low to moderate doses may be of benefit in patients with SLE (p. 1613.3), with benefit reported particularly for joint and mucocutaneous symptoms.[1,2] In a retrospective analysis of patients with cutaneous lupus erythematosus, low doses of methotrexate significantly decreased disease activity.[3]

Methotrexate therapy has been investigated for its potential corticosteroid-sparing properties in polymyalgia rheumatica (p. 1610.3). Different regimens have been tried and although one study[4] reported benefit, others[5,6] found no evidence of clinical efficacy or a corticosteroid-sparing effect. *Guidelines from the 3E Initiative*[2] considered it effective and recommended its use as a corticosteroid-sparing agent in polymyalgia rheumatica and giant-cell arteritis.

Methotrexate is widely used in rheumatoid arthritis (see p. 824.2) and in polymyositis (p. 1611.1), and has been tried in Cogan's syndrome (p. 1603.2).

Ectopic pregnancy. Ectopic pregnancy occurs when the fertilised ovum implants outside the uterus, usually in the fallopian tube itself (tubal pregnancy). Earlier detection has become possible due to improved diagnostic techniques. In many countries, there has been a rise in the rate of ectopic pregnancies followed by a decline; this may be partly due to increasing rates of infection with *Chlamydia*, followed by the effect of prevention, and changes in the popularity of intra-uterine devices.[1] Although ectopic pregnancies may spontaneously abort early, without clinical sequelae, the potential adverse effects are serious, ranging from pelvic pain and bleeding at 5 to 6 weeks of gestation (indistinguishable from spontaneous abortion), to potentially fatal intra-abdominal haemorrhage later in the course of an otherwise asymptomatic pregnancy.

Laparoscopic surgery remains the standard treatment.[1-4] In some countries non-surgical methods are increasing in popularity because of earlier diagnosis.[1,5] Perhaps the most experience of the latter has been with methotrexate. Management with intramuscular methotrexate may be appropriate for selected women with small unruptured tubal pregnancies who are haemodynamically stable, have low serum-chorionic gonadotrophin concentrations, and lack contra-indications to methotrexate use.[2-7] Surgery is preferred where there is cardiac activity in the conceptus, since a living embryo increases resistance to methotrexate.[6,7] Two regimens of intramuscular methotrexate have been described. A multiple-dose regimen of 1 mg/kg on 4 alternate days, with folinic acid rescue,[1] has similar efficacy to surgery.[3] A single dose of 50 mg/m² can be used instead[1,3] but systematic reviews have indicated that it has a higher failure rate than surgery[3,8] and about 20% of patients will require more than one cycle of treatment.[3] Some suggest that it is best reserved for women with serum-chorionic gonadotrophin concentrations below 1.5 units/mL.[4] The addition of an oral dose of mifepristone to single-dose methotrexate has been investigated[1,9,10] and may reduce treatment failure rates.

Methotrexate has been given by local injection directly into the ectopic (salpingocentesis). Doses of 1 mg/kg or 50 mg have been used[11] but this technique is significantly less successful than surgery.[3] Systemic methotrexate (with folinic acid rescue) has also been reported to be effective in resolving persistent ectopic pregnancy unsuccessfully treated with surgery.

The role of other agents in the management of ectopic pregnancy is less well established. Local instillation of glucose 50% by salpingocentesis has also been used in the treatment of ectopic pregnancy,[11,12] but one study was stopped because of a higher failure rate with glucose treatment compared with local methotrexate.[13]

Methotrexate may also be used in the termination of early uterine pregnancy (see p. 824.3).

Inflammatory bowel disease. Methotrexate (given intramuscularly once weekly in a dose of 25 mg) was reported to improve symptoms and reduce corticosteroid requirements in a large controlled study in patients with chronic active *Crohn's disease*.[1] Those patients who were in remission after 16 weeks of methotrexate treatment were entered into a further placebo-controlled study[2] of methotrexate 15 mg weekly by intramuscular injection. During 40 weeks of follow-up, a higher proportion of patients receiving methotrexate remained in remission, and had fewer relapses. Smaller studies have also reported modest benefit for oral methotrexate 12.5 to 22.5 mg/week in chronic active disease.[3,4] Subcutaneous methotrexate has also been used.[5] A review[6] concluded that low-dose methotrexate could be recommended for induction of remission and for its corticosteroid-sparing effect in refractory and corticosteroid-dependent Crohn's disease, although the precise indications, dose, and route for its use were still unclear.

Although methotrexate is unlicensed in the UK for Crohn's disease, the *BNF* suggests the following doses in adults over 18 years of age with severe disease:

- induction of remission: 25 mg intramuscularly once weekly
- maintenance of remission: 10 to 25 mg orally once weekly, or 15 mg intramuscularly once weekly

The *BNFC* suggests the following doses for children aged 7 to 18 years:

- induction of remission: 15 mg/m^2 (maximum 25 mg) once weekly, by subcutaneous or intramuscular injection
- maintenance of remission: 15 mg/m^2(maximum 25 mg) once weekly, either orally or by subcutaneous or intramuscular injection; the dose is reduced according to response to the lowest effective dose

The value of methotrexate in *ulcerative colitis* is doubtful: although benefits have been seen in some patients,[5,7] a study in active ulcerative colitis found no significant differences between oral methotrexate 12.5 mg/week and placebo.[8] For a discussion of inflammatory bowel disease, see p. 1811.3.

Malignant neoplasms. Methotrexate is extensively used in the management of malignant disease. In acute lymphoblastic leukaemia it is used for maintenance therapy, and intrathecally for prophylaxis of CNS relapse, as discussed on p. 692.3, while it also forms part of several regimens used for non-Hodgkin's lymphomas such as Burkitt's lymphoma (p. 697.3), mycosis fungoides (p. 698.3) and those associated with AIDS (p. 697.2). In the solid neoplasms it is an important part of curative regimens for gestational trophoblastic tumours (p. 691.2), the adjuvant therapy of osteosarcoma (p. 717.3) and is used in regimens for tumours of the bladder (p. 700.2), brain (p. 701.2), breast (p. 702.1), stomach (p. 706.1), and head and neck (p. 708.1).

Multiple sclerosis. Results suggest that oral methotrexate 7.5 mg weekly may be of benefit[1] in slowing the progression of multiple sclerosis (p. 996.3). Although the results of studies of immunosuppressant therapy in this condition have tended to be disappointing, it has been pointed out that benefit was assessed differently in the methotrexate study,[2] which may have a bearing on its more favourable conclusions.

2. Whitaker JN, *et al.* Clinical outcomes and documentation of partial beneficial effects of immunotherapy for multiple sclerosis. *Ann Neurol* 1995; 37: 5–6.

Myasthenia gravis. Methotrexate has been tried in the management of myasthenia gravis (p. 684.1) in patients who require immunosuppression but are intolerant of or unresponsive to corticosteroids and azathioprine.

Organ and tissue transplantation. For reference to the use of methotrexate (usually with ciclosporin) in bone marrow transplantation, see Haematopoietic Stem Cell Transplantation, p. 1937.1.

Primary biliary cirrhosis. Like other drugs used for primary biliary cirrhosis (p. 2638.3) methotrexate has been associated with biochemical improvement but evidence of clinical and in particular histological improvement is harder to show, and the toxicity of immunosuppressants such as methotrexate is problematic. A randomised study comparing methotrexate with colchicine found a slightly lower survival with methotrexate after 10 years of treatment;[1] a systematic review[2] concluded that methotrexate had no effect on mortality or the need for liver transplantation in patients with primary biliary cirrhosis and that there was no evidence to support its use.

1. Kaplan MM, *et al.* A randomized controlled trial of colchicine plus ursodiol versus methotrexate plus ursodiol in primary biliary cirrhosis: ten-year results. *Hepatology* 2004; 39: 915–23.
2. Giljaca V, *et al.* Methotrexate for primary biliary cirrhosis. Available in The Cochrane Database of Systematic Reviews: Issue 5. Chichester: John Wiley; 2010 (accessed 07/07/10).

Psoriatic arthritis. Methotrexate may be useful for severe or progressive cases of psoriatic arthritis (see under Spondyloarthropathies, p. 14.3) when the arthritis is not controlled by physical therapy and NSAIDs, although toxicity may limit long-term use in some patients.

Retroperitoneal fibrosis. There are reports[1,2] of success with low-dose weekly methotrexate in the treatment of retroperitoneal fibrosis (p. 1612.1); corticosteroids were also given, but tapered off in one case.[1]

1. Scavalli AS, *et al.* Long-term follow-up of low-dose methotrexate therapy in one case of idiopathic retroperitoneal fibrosis. *Clin Rheumatol* 1995; 14: 481–4.

Rheumatoid arthritis. Therapy of rheumatoid arthritis (p. 13.2) is conventionally begun with an analgesic and an NSAID for symptomatic relief, to which a disease-modifying antirheumatic drug (DMARD) is subsequently added in an attempt to retard the disease process. It is now clear that irreversible joint damage commonly occurs in early disease and rheumatologists now generally add the DMARD shortly after rheumatoid arthritis has been diagnosed. Methotrexate is widely used,[1] and is the DMARD of first choice in many patients. Systematic review has confirmed that methotrexate has significant benefit in the short-term treatment of the disease.[2] Multinational recommendations for its use[3] produced by the 3E Initiative included beginning oral therapy at 10 to 15 mg weekly and increasing this dose by 5 mg every 2 to 4 weeks up to a maximum of 20 to 30 mg weekly (this is somewhat higher than the licensed doses recommended in Uses and Administration, p. 822.3); the Initiative also considered that at least 5 mg of folic acid weekly should be given as a supplement. These recommendations considered that monotherapy was preferable to combination of methotrexate with other DMARDs in DMARD-naive patients,[3] with methotrexate-based combinations used when monotherapy was ineffective. Methotrexate has been tried with ciclosporin, hydroxychloroquine and sulfasalazine, leflunomide, etanercept, and infliximab. Studies have shown improved responses to these combinations compared with methotrexate alone, but long-term efficacy and safety has not been studied.[4] For debate on the value of initial combination therapy versus monotherapy see p. 13.2. A randomised controlled study[5] found that subcutaneous methotrexate was significantly more effective than the same dose of oral methotrexate in patients with active rheumatoid arthritis.

Methotrexate may be of benefit[6-8] in juvenile idiopathic arthritis (p. 12.1): for doses, see Administration in Children, p. 823.1.

Methotrexate may also be of value in the management of associated uveitis (see p. 825.1).

Sarcoidosis. Where therapy is required for sarcoidosis (p. 1612.2) corticosteroids are the first choice of drug; methotrexate is one of the preferred second-line immunosuppressants.

Skin disorders, non-malignant. Methotrexate is widely used in the treatment of severe refractory psoriasis. As discussed on p. 1688.1 the aim of such therapy is to bring the disease under control, enabling a return to other therapy. For use in psoriatic arthritis see above. Methotrexate is also used with corticosteroids in the management of pemphigus and pemphigoid (p. 1687.1).

Termination of pregnancy. Methotrexate has been investigated as an alternative to mifepristone for use with misoprostol for the termination of early pregnancy (p. 2131.3). Intramuscular methotrexate followed 3 days later by intravaginal misoprostol was more effective than misoprostol alone for termination at 56 days or less;[1] the combination was reported to be less successful after 57 to 63 days of gestation.[2] Later studies[3,4] however found the combination to be safe and effective in terminating pregnancies up to 63 days of gestation; in these the misoprostol was given up to 7 days after the methotrexate. Oral methotrexate is also effective.[5-7] However, the efficacy of methotrexate followed by misoprostol does appear to diminish with increasing gestational age,[8] and the time to complete abortion generally takes longer with regimens using methotrexate compared with mifepristone.[9] The American College of Obstetricians and Gynecologists[10] recommends that methotrexate with misoprostol may be used in pregnancies of up to 49 days of gestation, the usual regimen being methotrexate, either 50 mg/m^2 intramuscularly or 50 mg orally, followed 3 to 7 days later by misoprostol 800 micrograms vaginally. The College also advises that it may take up to 4 weeks for complete abortion to occur in about 1% to 25% of women given such regimens.

For the role of methotrexate in the management of ectopic pregnancy, see p. 823.3.

Vasculitic syndromes. In giant cell arteritis (p. 1604.2), improved clinical response and a corticosteroid-sparing effect have been reported with the addition of methotrexate to corticosteroid therapy,[1] but other studies using different designs and dosages[2,3] have failed to find any benefit. Guidelines from the 3E Initiative[4] considered it effective and recommended its use as a corticosteroid-sparing agent in polymyalgia rheumatica and giant-cell arteritis. For the use of methotrexate in Takayasu's arteritis and Wegener's granulomatosis see p. 1614.3 and p. 1615.2, respectively.

Adverse Effects

For general discussions see Antineoplastics, p. 726.1.

The most common dose-related toxic effects of methotrexate are on the bone marrow and gastrointestinal tract. Bone-marrow depression can occur abruptly, and leucopenia, thrombocytopenia, and anaemia may all occur. The nadir of the platelet and white-blood cell counts is usually around 5 to 10 days after a bolus dose, with recovery between about 14 to 28 days, but some sources suggest that leucocytes may show an early fall and rise, followed by a second nadir and recovery, within this period. Ulceration of the mouth and gastrointestinal disturbances are also early signs of toxicity: stomatitis and diarrhoea during treatment indicate that it may need to be interrupted, otherwise haemorrhagic enteritis, intestinal perforation, and death may follow.

Methotrexate is associated with liver damage, both acute (notably after high doses) and, more seriously, chronic (generally after long-term use). Hepatic fibrosis and cirrhosis may develop without obvious signs of hepatotoxicity, and have led to eventual death.

Other adverse effects include renal failure and tubular necrosis after high doses, pulmonary reactions including life-threatening interstitial lung disease, skin reactions (sometimes severe), alopecia, and ocular irritation. Neurotoxicity may be seen: leukoencephalopathy, paresis, demyelination are associated particularly with intrathecal use and are more likely when cranial irradiation is also given. Intrathecal use may also produce arachnoiditis, an acute syndrome of headache, nuchal rigidity, back pain, and fever. Other rarer reactions may include megaloblastic anaemia, osteoporosis, precipitation of diabetes, arthralgias, necrosis of soft tissue and bone, and anaphylaxis.

Methotrexate may cause defective oogenesis and spermatogenesis, and fertility may be impaired (this may be reversible). Like other folate inhibitors it is teratogenic, and it has been associated with fetal deaths. Lymphomas (generally reversible on withdrawal of treatment) have occasionally been reported with methotrexate therapy, although the association has been questioned (see Carcinogenicity, below).

Carcinogenicity. There are reports of lymphomas associated with low-dose methotrexate therapy for rheumatic disorders,[1-4] which in some cases have been associated with concomitant Epstein-Barr virus infection.[2] Transitional cell bladder cancer has also been associated with such therapy.[5] However, a retrospective analysis involving 16 263 patients with rheumatoid arthritis found no evidence of a relationship between the use of methotrexate as an antirheumatic and the development of haematological malignancy.[6] Nonetheless, the spontaneous remission of lymphoma after withdrawal of methotrexate in some patients seems to support an association[7] A later prospective study[8] of all new cases of lymphoma, detected over 3 years in patients treated with methotrexate for rheumatoid arthritis, also found a higher incidence of Hodgkin's disease compared with the general population. An Australian cohort study[9] in rheumatoid arthritis patients treated with methotrexate found an overall increased incidence of malignancy with a fivefold increased risk of non-Hodgkin's lymphoma, a threefold increased risk of lung cancer, and a threefold increased risk of melanoma relative to the general population. Further investigation was considered necessary to determine whether the findings with respect to melanoma were unique to Australia and what role methotrexate, immunosuppression, and environmental factors such as exposure to UV radiation have in the development thereof. The carcinogenic risk with antimetabolites such as methotrexate has generally been considered less than with alkylating agents (p. 726.2).

Effects on the blood. Although serious and sometimes fatal blood dyscrasias are a well-known consequence of high-dose methotrexate therapy the UK CSM[1] stated in September 1997 that it was also aware of 83 reports of blood dyscrasias associated with low-dose methotrexate used to treat psoriasis or rheumatoid arthritis; there were 36 fatalities. Many of the cases had contributing factors such as advanced age, renal impairment, or use with interacting drugs.

1. CSM/MCA. Blood dyscrasias and other ADRs with low-dose methotrexate. *Current Problems* 1997; 23: 12. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023240&RevisionSelectionMethod=LatestReleased (accessed 03/04/06)

MEGALOBLASTIC ANAEMIA. Megaloblastic anaemia, usually with marked macrocytosis, has been reported in mainly elderly patients given long-term weekly methotrexate therapy.[1-3] It has been suggested that therapy should be withdrawn if the mean corpuscular volume exceeds 106 femtolitres.[1] Symptoms appear to be associated with folate depletion by methotrexate,[2,4,5] probably due to increased excretion,[6] and in one case megaloblastic anaemia developed after starting a weight-reducing diet poor in folate.[4] Folate supplementation, conversely, may permit continuation of methotrexate therapy with resolution of the anaemia.[5]

6. Duhra P, *et al.* Intestinal folate absorption in methotrexate treated psoriatic patients. *Br J Dermatol* 1988; 119: 327–32.

Effects on the gastrointestinal tract. Although gastrointestinal toxicity is well recognised as an effect of high-dose regimens, oral ulceration has also been reported after low-dose (weekly) methotrexate use.[1,2] In some instances it was related to overdosage; symptoms resolved upon correction of the dose and with folate supplementation.[1] Folate deficiency may increase the oral toxicity of methotrexate, and folate supplementation may also avoid the need to stop low-dose methotrexate.[2]

2. Kalantzis A, *et al.* Oral effects of low-dose methotrexate treatment. *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 2005; 100: 52–62.

Effects on the kidneys. High-dose methotrexate therapy can result in supersaturation of the urine with methotrexate and its metabolites leading to crystal formation.[1] These crystals can cause intrarenal obstruction and are a factor in the development of acute renal failure. Risk factors for crystal formation are acid urine, volume depletion, and renal impairment. Adequate hydration, and urinary alkalinisation with sodium bicarbonate or acetazolamide play an important role in minimising nephrotoxicity in high-dose methotrexate regimens. A study found that the incidence of severe toxicity was reduced in patients given greater hydration and alkalinisation. However, this more intensive hydration regimen also significantly lowered methotrexate plasma concentrations.[2] Glucarpidase, a recombinant glutamate carboxypeptidase, is used in the management of methotrexate-induced renal dysfunction when methotrexate concentrations are very high (see Treatment of Adverse Effects, p. 826.3).[3]

Effects on the liver. Methotrexate is well established as a cause of hepatotoxicity, including periportal fibrosis, when given in relatively high doses as an antineoplastic, and it has become clear that its long-term use in lower doses for disorders such as psoriasis and rheumatoid arthritis can also be associated with liver toxicity.[1,2] There has been some difficulty in these patients in distinguishing the effects of the drug from the effects of the disease, but there is good evidence that the risk is increased in patients given doses on a daily rather than a weekly regimen, and in those with a high alcohol intake.[1] Pre-existing liver disease, obesity (especially if associated with diabetes mellitus), renal impairment, and increasing total cumulative dose may also increase the risk of hepatotoxicity.[1] A lower incidence of hepatotoxicity in patients with rheumatoid arthritis (compared with older studies in patients with psoriasis) may be due to improved dosage regimens and greater awareness of the risks.[1]

In order to minimise the risks of serious liver damage various guidelines and recommendations have been issued for the use of methotrexate in psoriasis and rheumatoid arthritis, and the appropriate monitoring.

- For patients with *psoriasis*, 1988 US guidelines[3] recommended a liver biopsy at the beginning of treatment and after each cumulative dose of 1 to 1.5 g, with monitoring of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, bilirubin, and albumin. However, the need to repeat routine liver biopsies was questioned[4] and some[5] recommended omitting the baseline biopsy in patients with no risk factors. A 2009 consensus[6] suggests that patients being considered for methotrexate therapy be divided into 2 groups based on their risk factors for liver injury. Patients with a low risk for hepatotoxicity are monitored similarly to rheumatoid arthritis patients (see below), with an option for liver biopsy upon reaching a cumulative dose of 3.5 to 4 g. For those with one or more risk factors for hepatotoxicity, guidelines remain more stringent, with the first consideration being the feasibility of using another drug. If methotrexate is used, it is advisable that a liver biopsy be performed, at or near the start of therapy; since some patients will stop methotrexate after 2 to 6 months because of adverse effects or lack of efficacy, the liver biopsy may be postponed until after this period. A repeat biopsy should be performed after a cumulative dose of 1 to 1.5 g, and with every additional 1 to 1.5 g thereafter. Methotrexate should be stopped if liver changes are moderate to severe. Practice in the UK has focused on monitoring of the aminoterminal peptide of type III procollagen (PIIINP), a serological marker of hepatic fibrosis,[7] and this is recommended by the British Association of Dermatologists[8] as a safer alternative to liver biopsy. PIIINP values should be determined before starting methotrexate and then every 2 to 3 months during treatment. A liver biopsy may then be considered in those with persistently abnormal values. However, some[7] have said that larger studies of the value of PIIINP assays should be undertaken before definitive recommendations can be made.
- In patients with *rheumatoid arthritis* US guidelines[9,10] suggest an initial biopsy only in patients with a history of excessive alcohol consumption, persistently abnormal AST or ALT values or chronic hepatitis B or C infection. All patients should have liver function tests (LFTs) monitored monthly for the first 6 months and then every 1 to 2 months thereafter. For minor elevations in AST or ALT (less than twofold the upper limit of normal), LFTs are repeated in 2 to 4 weeks; for moderate elevations in AST or ALT (greater than twofold but less than threefold the upper limit of normal), close monitoring, repeat LFTs in 2 to 4 weeks, and reduction of the dose as needed are advocated. A biopsy should be performed if 5 of 9 (or 6 of 12) measurements of AST are elevated in a 12-month

interval or if there is a decline in serum albumin (with normal nutritional status) below the normal range; if liver changes are moderate to severe, methotrexate should be stopped. Options for patients with normal findings include continuing to follow the above guidelines without biopsy, or the first biopsy may be performed at a cumulative dose of 3.5 to 4 g of methotrexate, or methotrexate can be stopped after this cumulative dose, or patients switched to alternative therapy. However, some rheumatologists[11,12] consider that less stringent monitoring may be warranted, especially in those with no risk factors for hepatotoxicity. Similarly, although these guidelines have been widely adopted for use in children with juvenile idiopathic arthritis, some[13] consider that routine blood tests every 4 to 8 weeks are unnecessarily frequent.

The UK CSM advised in 1997 that LFTs (with blood count and renal-function testing) should be performed before beginning long-term low-dose methotrexate therapy and repeated weekly until therapy was stabilised, and thereafter every 2 to 3 months.[14]

Effects on the lungs. Pulmonary toxicity due to methotrexate has been well described.[1-3] A review[1] of over 120 reports of methotrexate pneumonitis found that onset usually occurred during treatment, presenting as dyspnoea, cough, and fever. Examination often found tachypnoea and crackles, eosinophilia, reduced pulmonary function, interstitial and alveolar infiltrates on chest radiography, and interstitial inflammation and fibrosis. The majority of cases were managed with cessation of methotrexate with or without corticosteroid therapy; most patients improved, but there were 16 deaths caused by respiratory disease. Methotrexate was restarted in 16 patients, and pneumonitis recurred in 4 of these.

Up to 25 April 2003, the UK CSM had received 90 reports of parenchymal lung disorders, including 52 reports of pneumonitis, 21 of pulmonary fibrosis, 5 of interstitial lung disease, and 3 of interstitial pneumonitis. The CSM has suggested that patients should seek medical attention if symptoms such as dyspnoea, dry, nonproductive cough, or fever develop; methotrexate should be stopped and corticosteroids given in the event of suspected pneumonitis.[4]

A multicentre case-control study[5] which examined 29 cases of methotrexate-induced lung injury among rheumatoid arthritis patients found that risk factors included age over 60 years, pleuropulmonary disease (or to a lesser extent other extra-articular disease), previous use of other disease-modifying antirheumatic drugs, and low serum-albumin; an association with smoking, nonsedentary occupations, and diabetes mellitus was also noted. The mechanisms of methotrexate-induced pulmonary inflammation have been investigated *in vitro*,[6] and suggested to be due to stimulation of the p38 mitogen-activated protein kinase pathway, with increased production of the pro-inflammatory cytokines interleukin-1β and interleukin-8, and inhibition of the anti-inflammatory interleukin-4.

Effects on mental function. Children who had received intrathecal methotrexate with cranial irradiation for the prophylaxis of CNS leukaemia, had a significant intellectual deficit compared with their siblings.[1] There was no corresponding significant reduction in IQ in a group of children who had received systemic chemotherapy and radiotherapy when compared with their sibling controls. The results suggest that intrathecal methotrexate and cranial irradiation cause intellectual problems, particularly on the higher, more complex and integrated intellectual functions, and that the repercussions are greater in younger children. Subsequent results in these patients indicated that although the lowering of IQ had persisted, it had not progressed since the original study.[2] A further study confirmed the adverse neurological effects of leukaemia treatment, and its effects on IQ, and did not find a reduced radiation dose to be any less toxic.[3] Neurotoxicity appeared to be greater when systemic therapy with intramuscular rather than oral methotrexate was given with CNS prophylaxis. A study[4] of children who underwent surgery, chemotherapy, and craniospinal radiotherapy for medulloblastoma also found that those patients who received intrathecal methotrexate had significantly worse cognitive deficits than those who did not, and all patients performed worse than a control group of cousins and siblings.

In a small study[5] of children treated for leukaemia with chemotherapy that included intrathecal methotrexate, but without irradiation, there were lower cognitive scores in some measures compared with a group of healthy controls, but overall no major cognitive impairment was found.

A study in 20 patients receiving intermittent oral methotrexate for psoriasis found no evidence of psychological impairment.[6]

Effects on the nervous system. Methotrexate has a cumulative toxic effect on the nervous system, and generalised and focal neurotoxic reactions are associated with intrathecal and high-dose intravenous use.[1] An immediate, usually transient, effect occurring within a day of high intravenous doses can cause nausea and vomiting, headache, somnolence, lethargy, confusion, disorientation, seizures, and increased intracranial pressure. Reversible acute meningitis can follow intrathecal use, with similar results.[1] Aseptic meningitis has also been reported after intramuscular methotrexate.[2] Spinal cord myelopathy resulting in transient or permanent paraplegia has also followed intrathecal methotrexate use, especially if other neurotoxic treatments have also been used. A subacute form of toxic reaction can occur up to several weeks after treatment. It is usually transient and characterised by seizures, varying degrees of paresis, aphasia, anaesthesia, blurred vision, and pseudobulbar palsy. A more delayed syndrome occurs weeks to months after treatment and is of variable severity, but can progress to lethargy, seizures, spasticity, paresis, drooling, and dementia. This condition is characterised by leukoencephalopathy and chronic calcification of brain tissue. It is dose-related, and more severe if the patient has also received radiotherapy.[1]

Effects on the skin. There are rare reports[1,2] of painful erythema of the hands and feet, particularly the fingertips, with progression to blistering and desquamation (palmar-plantar erythrodysesthesia syndrome, p. 730.1) after the use of high-dose intravenous methotrexate. Purpuric skin lesions due to vasculitis have occurred after both high-dose[3] and low-dose[4,5] methotrexate. Accelerated rheumatoid nodulosis has been reported[6,7] after the use of methotrexate in patients with rheumatoid arthritis. Erosion of psoriatic plaques, accompanied by pain and erythema, has been seen[8,9] after low-dose methotrexate therapy; blistering and necrosis consistent with toxic epidermal necrolysis has occurred.[8] Possible exacerbation of a photosensitivity reaction to ciprofloxacin has been described,[10] and reactivation of sunburn has also been reported[11] in several cases where methotrexate was given within 2 to 5 days after the initial sunburn.

Hypersensitivity. There are rare reports of anaphylactic reactions in patients given methotrexate. Reactions have usually occurred in patients who had previous exposure to methotrexate, but there are also reports of reaction during initial exposure to high-dose intravenous therapy.[1] Serious reactions have also been described after low-dose intravenous[2] and intrathecal[3] use. Desensitisation may be possible.[4] A 9-year-old patient with osteosarcoma who had previously tolerated 5 courses of high-dose methotrexate (12 g/m² over 4 hours) developed urticaria, repeated on rechallenge, but no oedema or respiratory symptoms during the sixth. She was successfully managed by premedication with diphenhydramine and corticosteroids, followed by 1/1000 of the total methotrexate dose over 90 minutes, 1/100 over 90 minutes, 1/10 over 6 hours, and the remainder over 18 hours.[4]

Treatment of Adverse Effects

For general guidelines, see p. 730.2.

Folinic acid neutralises the immediate toxic effects of methotrexate on the bone marrow. It is given as sodium or calcium folinate orally, intramuscularly, by intravenous bolus injection, or by infusion. When overdosage is suspected the dose of folinate should be at least as high as that of methotrexate and should be given as soon as possible; further doses are given as required preferably based on serum-methotrexate concentrations. Folinate should be continued until serum-methotrexate concentrations fall below 0.05 to 0.1 micromol/litre, which may necessitate prolonged treatment in patients with delayed elimination. Other dosage regimens, given intramuscularly or orally, may be appropriate for more modest toxicity associated with conventional doses of methotrexate. For details, see under Folinic Acid, p. 2067.1. After intrathecal overdose, the drainage of 30 mL of CSF within 15 minutes removes about 95% of methotrexate; but methotrexate rapidly enters the systemic circulation and folinic acid treatment should be based on serum-methotrexate concentrations.

Folinic acid is usually given with high-dose methotrexate regimens to prevent damage to normal tissue ('folinic acid rescue') and this is discussed in Uses and Administration, p. 822.3.

An adequate flow of alkaline urine should be maintained after high doses of methotrexate to prevent precipitation of methotrexate or its metabolites in the renal tubules; in addition to adequate hydration, the use of acetazolamide or sodium bicarbonate is recommended.

The recombinant glutamate carboxypeptidase glucarpidase (p. 1555.1) is used in addition to folinic acid in the management of methotrexate toxicity. It rapidly hydrolyses methotrexate to its inactive metabolites 4-deoxy-4-amino-N^{10}-methylpteroic acid and glutamate which are metabo-

lised by the liver thus providing a non-renal pathway for methotrexate elimination.

Desensitisation. For mention of desensitisation to the drug in a patient with methotrexate-induced anaphylaxis see Hypersensitivity, p. 826.3.

Folate supplementation. A discussion of the selection of the appropriate route for folinic acid rescue with *high-dose methotrexate* regimens.[1] The general objective is to give folinic acid (as folinate) at doses that maintain plasma concentrations of reduced folates at a level equivalent to or greater than the plasma-methotrexate concentration. In any clinical situation suggesting impaired gastrointestinal function calcium folinate should be given by injection. Although absorption of intramuscular doses is relatively complete and rapid the intravenous route is usually preferable for other reasons, such as a reduced risk of bleeding at injection sites. In the absence of impaired gastrointestinal function, and where there are no concomitant risk factors for methotrexate toxicity, the oral route may be used provided that methotrexate concentrations are expected to be less than 1 micromol/litre. For very high dose methotrexate regimens it is generally appropriate to begin folinic acid rescue intravenously to ensure adequate initial therapy, but the majority of the dosage regimen can generally be given orally.

There is no consensus on the use of folate supplementation in patients taking *low-dose methotrexate*,[2] although reviews have concluded that supplementation with either folic or folinic acid reduces adverse effects related to the liver function tests, gastrointestinal tract and oral mucosa.[2,3] However, a study found that while folate supplementation reduced the incidence of methotrexate-related liver enzyme elevations, it had no effect on incidence, severity, or duration of other adverse effects.[4] Effects of folate supplementation on the efficacy of methotrexate have been inconclusive;[3] some consider the effect to be small.[4,5] There is some suggestion that folinic acid, but not folic acid, may reduce the efficacy of methotrexate.[2] However, an analysis[6] of two studies found a reduction in efficacy with folic acid supplementation. The issue of supplementation remains controversial, with some recommending routine folic acid,[2,5,7] and others suggesting that folate only be added when demand for folate increases, such as during infection or with antibacterial use.[8]

Other drugs. Pretreatment with fluorouracil is reported to reduce the toxicity of methotrexate sufficiently to permit high-dose methotrexate without the need for folinic acid rescue.[1] Methotrexate has also been given before fluorouracil to modulate its activity (see Administration, in Fluorouracil, p. 796.1).

The acute neurotoxic effects of methotrexate have been reported to be relieved by intravenous aminophylline or oral theophylline in some children.[2]

Precautions

For general discussions see p. 732.2.

Methotrexate should be used with great care in patients with bone-marrow, hepatic, or renal impairment. It should also be used cautiously in ulcerative disorders of the gastrointestinal tract, and in the elderly and the very young. Pleural or ascitic effusions may act as a depot for methotrexate and produce enhanced toxicity, and should be drained before treatment.

Regular monitoring of haematological, renal, and hepatic function, and gastrointestinal toxicity is advisable. Treatment should be interrupted if myelosuppression, diarrhoea, or stomatitis occur. Dyspnoea or cough may be a sign of pulmonary toxicity and patients should be advised to contact their doctor if they develop these symptoms. Treatment should be withdrawn and the patient investigated to exclude infection. If methotrexate-induced lung disease is suspected corticosteroid therapy may be started and further treatment with methotrexate should not be given. Patients or their carers should report any symptoms or signs suggestive of infection, especially sore throat.

In patients receiving **low-dose methotrexate for psoriasis or rheumatoid arthritis** full blood counts and renal and liver function tests should be performed before starting treatment and repeated regularly thereafter (for discussion of guidelines for monitoring in these patients see Effects on the Liver, p. 825.3). Treatment should be interrupted if myelosuppression, stomatitis, or any abnormality of liver function is detected. Methotrexate should not be used to treat rheumatoid arthritis or psoriasis in patients with alcoholism, liver disease or persistent abnormal liver function tests, or in those with significant renal impairment, immunodeficiency, or blood disorders. A test dose has been recommended. Severe or fatal toxicity has resulted from overdosage when doses intended for a low-dose weekly regimen were mistakenly taken daily, and particular care should be taken to avoid confusion about dosage frequency.

With **high-dose regimens**, serum concentrations of methotrexate should be monitored. Maintenance of an adequate flow of alkaline urine is essential (see Treatment of Adverse Effects, p. 826.3).

Methotrexate is a potent teratogen and should be avoided in **pregnancy**. While some licensed product information includes advice that conception should be avoided for at least 6 months after therapy some considers 3 months adequate.

Blood products. Enhanced toxicity was seen in 2 of 14 patients receiving methotrexate by 24-hour infusion when packed red cells were transfused immediately after the methotrexate infusion.[1] Erythrocytes act as reservoirs for methotrexate and probably resulted in the prolonged high serum-methotrexate concentrations seen in these patients. Great care should be exercised whenever packed red blood cells and methotrexate are given concurrently.

1. Yap AKL, *et al.* Methotrexate toxicity coincident with packed red cell transfusions. *Lancet* 1986; ii: 641.

Breast feeding. Methotrexate has been detected in breast milk in low concentrations.[1] The American Academy of Pediatrics considers[2] that methotrexate may interfere with cellular metabolism, causing neutropenia and possibly immunosuppression in the nursing infant, and has unknown effects on growth, and an association with carcinogenesis.

1. Johns DG, *et al.* Secretion of methotrexate into human milk. *Am J Obstet Gynecol* 1972; 112: 978–80.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 30/06/04)

Handling and disposal. Care should be taken to avoid inhalation of methotrexate or contact with skin and mucous membranes. It may cause irritation of the eyes.

Methods have been published for the oxidative destruction of methotrexate *wastes* using potassium permanganate and sulfuric acid, aqueous alkaline potassium permanganate, or sodium hypochlorite.[1] The first method may also be used for dichloromethotrexate. Residues produced by the degradation of methotrexate by these methods showed no mutagenicity *in vitro*.

Urine and faeces produced for up to 72 hours and 7 days respectively after a dose of methotrexate should be handled wearing protective clothing.[2]

Hepatitis. Reactivation of hepatitis B infection, with the development of hepatocellular necrosis and fulminant hepatic failure requiring liver transplantation, developed on stopping low-dose methotrexate therapy in a patient with rheumatoid arthritis who was also an asymptomatic chronic hepatitis B carrier.[1] It was suggested that all patients being considered for low-dose methotrexate therapy should be screened for the presence of serum HBsAg before beginning therapy. However, a similar case of fatal reactivation has been reported[2] in a patient negative for HBsAg.

2. Gwak GY, *et al.* Fatal hepatic failure associated with hepatitis B virus reactivation in a hepatitis B surface antigen-negative patient with rheumatoid arthritis receiving low dose methotrexate. *Clin Exp Rheumatol* 2007; 25: 888–9.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies methotrexate as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pregnancy. The use of methotrexate in pregnancy is contra-indicated (see Precautions, above). There is a report of a healthy infant born to a woman who was treated with *intrathecal* methotrexate, see Pregnancy, under Teniposide, p. 867.2.

PUVA. Of a total of 94 patients with psoriasis and 38 with mycosis fungoides treated with PUVA therapy (methoxsalen and ultraviolet light) 2 of the former also given methotrexate developed skin cancers.[1] It was suggested that the combination of methotrexate and PUVA may be synergistic in inducing cutaneous malignancy. However, in a cohort study[2] of patients with severe psoriasis, exposure to methotrexate for at least 4 years was associated with an increase in risk of squamous cell carcinoma but not basal cell carcinoma, and no interaction was found between methotrexate and PUVA.

1. Fitzsimons CP, *et al.* Synergistic carcinogenic potential of methotrexate and PUVA in psoriasis. *Lancet* 1983; i: 235–6.
2. Stern RS, Laird N. The carcinogenic risk of treatments for severe psoriasis. *Cancer* 1994; 73: 2759–64.

Radiation. Analysis of neutrophil counts for 18 months in children with acute lymphoblastic leukaemia showed that methotrexate-induced neutropenia was significantly greater in patients given CNS irradiation and was considered to have contributed to 3 of 5 deaths during remission.[1]

For the effect of cranial irradiation and intrathecal methotrexate on intellectual development, see Effects on Mental Function, p. 826.2.

1. Report to the Medical Research Council of the Working Party on Leukaemia in Childhood. Analysis of treatment in childhood leukaemia: I—predisposition to methotrexate-induced neutropenia after craniospinal irradiation. *BMJ* 1975; 3: 563–6.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. The effects of methotrexate may be enhanced by drugs that decrease its renal excretion, such as NSAIDs and salicylates, probenecid, and some penicillins. Fatal toxicity has occurred in patients given NSAIDs with methotrexate (see p. 828.2). Severe toxicity has occurred rarely when co-trimoxazole or trimethoprim was given with methotrexate. Use with other myelotoxic, hepatotoxic, or nephrotoxic agents may increase the risk of toxicity. Folic acid and its derivatives may decrease the efficacy of methotrexate, although they are often used together to reduce methotrexate toxicity (see Treatment of Adverse Effects, p. 826.3).

Animal studies suggested methotrexate toxicity may be increased by chloramphenicol, para-aminobenzoic acid, and hypoglycaemics, but there does not appear to be any evidence of this clinically.

Antibacterials. The oral *aminoglycosides* neomycin[1] and paromomycin[2] have been reported to reduce the gastrointestinal absorption of methotrexate. Various *penicillins* have been reported to markedly decrease the clearance of methotrexate given intravenously for treatment of neoplasms,[3-6] although *ceftazidime* may not.[4] There have also been a few reports of penicillins possibly exacerbating the toxicity of low-dose methotrexate in patients being treated for psoriasis or rheumatoid arthritis, but a small study found that although fludoxacillin decreased methotrexate clearance slightly, this was not clinically significant.[7] Methotrexate toxicity has been reported in a patient receiving low-dose methotrexate after a course of *tetracycline*.[8] In a patient receiving high-dose methotrexate, giving *doxycycline* before the eleventh cycle was believed to be responsible for an exacerbation of methotrexate toxicity, with raised plasma concentrations and reduced clearance of methotrexate.[9] *Sulfonamides* such as sulfafurazole and sulfamethoxazole may displace methotrexate from binding sites[10] and reduce renal clearance.[11] Megaloblastic pancytopenia has been reported on several occasions when methotrexate was given with *co-trimoxazole*[12-14] or *trimethoprim*;[13,15,16] possible mechanisms involved include an addi-

tive antifolate effect, in addition to the effect of the sulfamethoxazole component in the case of co-trimoxazole.

Antiepileptics. For mention of the reduction in serum-*valproate* concentration produced by methotrexate see p. 557.3.

Antineoplastics. Enhanced methotrexate toxicity might be expected with nephrotoxic agents (such as *cisplatin*) that can reduce methotrexate excretion by impairing renal function. Sequential use of methotrexate and *fluorouracil* may result in synergistic enhancement of effect (see Administration, in Fluorouracil, p. 796.1), and equally, fluorouracil before methotrexate may reduce its toxicity (see Other Drugs, under Treatment of Adverse Effects, p. 827.1), but if *asparaginase* (p. 744.3) is given before methotrexate the cytotoxic effect of methotrexate may be reduced.

Methotrexate may increase the bioavailability of *mercaptopurine*, probably by interference with first-pass metabolism (see p. 821.3).

Colestyramine. Serum-methotrexate concentrations were markedly reduced in 3 patients given colestyramine to treat methotrexate toxicity.[1,2] Colestyramine appears to bind methotrexate and reduce its enterohepatic recirculation.

1. Ertmann R, Landbeck G. Effect of oral cholestyramine on the elimination of high-dose methotrexate. *J Cancer Res Clin Oncol* 1985; 110: 48–50.
2. Shinozaki T, *et al.* Successful rescue by oral cholestyramine of a patient with methotrexate nephrotoxicity: nonrenal excretion of serum methotrexate. *Med Pediatr Oncol* 2000; 34: 226–8.

Dantrolene. Dantrolene was considered to have caused methotrexate toxicity in a patient given high-dose methotrexate.[1]

1. André N, *et al.* Can dantrolene contribute to methotrexate toxicity? *Ann Pharmacother* 2006; 40: 1695–6.

Gastrointestinal drugs. Elevated serum concentrations of methotrexate were reported when it was given to 2 patients also receiving *omeprazole*.[1,2] The effect was not seen with subsequent cycles of methotrexate therapy once omeprazole had been stopped. In another case[3] however, raised methotrexate concentrations were thought to be due to an interaction with omeprazole, but were identical during a second cycle after omeprazole had been withdrawn. Severe generalised myalgia and bone pain were reported in a patient who received methotrexate and *pantoprazole*.[4] The same reaction occurred on rechallenge with the combination, but not with methotrexate alone. Although methotrexate concentrations were unchanged, concentrations of the metabolite 7-hydroxymethotrexate were raised suggesting an interaction with its renal elimination. *Lansoprazole* has been reported not to affect the pharmacokinetics of methotrexate.[5] A Japanese study found that use of proton pump inhibitors (including omeprazole, lansoprazole, and *rabeprazole*) was associated with delayed plasma elimination of methotrexate in patients given high-dose methotrexate therapy.[6]

6. Suzuki K, *et al.* Co-administration of proton pump inhibitors delays elimination of plasma methotrexate in high-dose methotrexate therapy. *Br J Clin Pharmacol* 2009; 67: 44–9.

Glutamine. Drugs with the potential to lower urinary pH, such as glutamine, may decrease clearance of methotrexate and cause it to precipitate in the renal tubules. Acute nephrotoxicity[1] followed failure to adjust urinary pH during high-dose methotrexate infusion in a patient also taking glutamine. Urinary pH should be continually checked in patients receiving both drugs and adjusted with bicarbonate if necessary.

1. Marín Pozo JF, *et al.* Hazards of concomitant administration of methotrexate and glutamine. *Am J Health-Syst Pharm* 2010; 67: 601–2.

Immunosuppressants. For reports of enhanced toxicity with *ciclosporin* in patients who have received methotrexate see p. 1957.2.

Leflunomide. For a report of the effect of methotrexate in patients receiving leflunomide, see p. 82.3.

Nitrous oxide. Severe unpredictable myelosuppression and stomatitis have been attributed to the use of nitrous oxide anaesthesia in patients receiving methotrexate, potentiating the effects of methotrexate on folate metabolism.[1] The effect could be reduced by the use of folinic acid rescue.

1. Goldhirsch A, *et al.* Methotrexate/nitrous-oxide toxic interaction in perioperative chemotherapy for early breast cancer. *Lancet* 1987; ii: 151.

NSAIDs. Severe, and in some cases fatal, aggravation of methotrexate toxicity has been reported when it was given with various NSAIDs including *aspirin* and other *salicylates*,[1,2] *azapropazone*,[3] *diclofenac*,[4] *indometacin*,[4,5] and *ketoprofen*.[6] The mechanism is uncertain but may include both displacement of methotrexate from protein-binding sites or an effect of NSAIDs on the kidney resulting in reduced methotrexate excretion.[6,7] *Naproxen* has been reported not to affect the pharmacokinetics of methotrexate,[8,9] but a fatal interaction has nonetheless been reported.[10] Despite the risks, some commentators have pointed out that methotrexate and NSAIDs are frequently used together in the treatment of rheumatoid arthritis,[11,12] and that provided this is done with caution, in low doses, and patients are appropriately monitored and cautioned to avoid additional 'over-the-counter' analgesics, such combinations need not be contra-indicated. A study in patients receiving low-dose methotrexate for rheumatoid arthritis suggested that *flurbiprofen*, *ketoprofen*, or *piroxicam* did not influence methotrexate clearance.[13] A case of methotrexate toxicity has nevertheless been described[14] in an elderly woman when flurbiprofen was added to low-dose methotrexate therapy.

Manufacturers of methotrexate generally contra-indicate the use of NSAIDs with high-dose methotrexate.

Probenecid. Probenecid can produce two- to fourfold increases in serum-methotrexate concentrations,[1-3] presumably by inhibiting renal excretion of methotrexate. Although probenecid has been shown to reduce protein binding of methotrexate,[4] usual doses of probenecid are unlikely to significantly affect methotrexate elimination by this mechanism. A woman receiving low-dose weekly methotrexate for rheumatoid arthritis developed severe pancytopenia when probenecid was given for asymptomatic hyperuricaemia.[5]

5. Basin KS, *et al.* Severe pancytopenia in a patient taking low dose methotrexate and probenecid. *J Rheumatol* 1991; 18: 609–10.

Retinoids. An increased risk of hepatotoxicity has been reported when methotrexate and *etretinate* are given together,[1] possibly due to increased plasma concentrations of methotrexate.[2,3]

1. Zachariae H. Dangers of methotrexate/etretinate combination therapy. *Lancet* 1988; i: 422.

3. Larsen FG, *et al.* Interaction of etretinate with methotrexate pharmacokinetics in psoriatic patients. *J Clin Pharmacol* 1990; 30: 802–7.

Xanthines. For mention of the effect of methotrexate on the clearance of theophylline, see Antineoplastics, under Interactions of Theophylline, p. 1235.2.

Pharmacokinetics

When given in low doses, methotrexate is rapidly absorbed from the gastrointestinal tract, but higher doses are less well absorbed. It is also rapidly and completely absorbed after intramuscular doses. Peak serum concentrations occur to 2 hours after an oral dose, and 30 to 60 minutes after an intramuscular one.

Methotrexate is distributed to tissues and extracellular fluid with a steady-state volume of distribution of 0.4 to 0.8 litres/kg; it penetrates ascitic fluid and effusions, which may act as a depot and thus enhance toxicity. Clearance from plasma is reported to be triphasic, with a terminal elimination half-life of between 3 and 10 hours after doses less than 30 mg/m^2 or 8 to 15 hours after high-dose parenteral therapy. It is about 50% bound to plasma protein. Methotrexate enters the cells in part by an active transport mechanism and is bound as polyglutamate conjugates: bound drug may remain in the body for several months, particularly in the liver.

Only small or insignificant amounts cross the blood-brain barrier and enter the CSF after oral or parenteral doses, although this may be increased by giving higher doses; however, after intrathecal doses there is significant passage into the systemic circulation.

Methotrexate has been detected in very small amounts in saliva and breast milk. It crosses the placenta.

Methotrexate does not appear to undergo significant metabolism at low doses; after high-dose therapy the 7-hydroxy metabolite has been detected. Methotrexate may be partly metabolised by the intestinal flora after oral doses. It is excreted mainly in the urine, by glomerular filtration and active tubular secretion. Small amounts are excreted in bile and found in faeces; there is some evidence for enterohepatic recirculation.

Considerable interindividual variation exists in the pharmacokinetics of methotrexate: those patients in whom clearance is delayed are at increased risk of toxicity.

Pharmacopoeial Preparations

BP 2014: Methotrexate Injection; Methotrexate Tablets;
USP 36: Methotrexate for Injection; Methotrexate Injection; Methotrexate Tablets.

2-Methoxyoestradiol

2-ME2; 2-Methoxyestradiol; NSC-659853; 2-Метоксиэстрадиол.
(17β)-2-Methoxyestra-1,3,5(10)-triene-3,17-diol.
$C_{19}H_{26}O_3$=302.4
CAS — 362-07-2.
UNII — 6I2QW73SR5.

NOTE. The names Panzem and PulmoLAR have been used as trade marks for 2-methoxyoestradiol.

Profile

2-Methoxyoestradiol is a metabolite of oestradiol (p. 2271.1). It does not have direct oestrogenic activity, but works through multiple cellular pathways to produce antineoplastic effects, including inhibition of angiogenesis and induction of apoptosis. 2-Methoxyoestradiol is under investigation in the treatment of various diseases, including glioblastoma, multiple myeloma, carcinoid tumours, as well as ovarian, prostate, breast, and renal cell cancers. It is also under investigation for pulmonary arterial hypertension and rheumatoid arthritis.

Midostaurin *(USAN, rINN)*

Benzoylstaurosporine; CGP-41251; Midostaurina; Midostaurine; Midostaurinum; PKC-412; Мидостаурин.
N-[(9*S*,10*R*,11*R*,13*R*)-2,3,10,11,12,13-Hexahydro-10-methoxy-9-methyl-1-oxo-9,13-epoxy-1*H*,9*H*-diindolo[1,2,3-*gh*:3′,2′,1′-*lm*]pyrrolo[3,4-*j*][1,7]benzodiazonin-11-yl]-*N*-methylbenzamide.
$C_{35}H_{30}N_4O_4$=570.6
CAS — 120685-11-2.
UNII — ID912S5VON.

Profile

Midostaurin is a multikinase inhibitor effective against tyrosine kinase and protein kinase C, and those of receptors for growth factors including vascular endothelial growth factor and platelet-derived growth factor. It is under investigation for the treatment of acute myeloid leukaemia, myelodysplastic syndrome, and systemic mastocytosis.

Mifamurtide *(BAN, rINN)*

Mifamurtida; Mifamurtidum; MTP-PE; Muramyl Tripeptide Phosphatidyl Ethanolamine; Muramyl Tripeptide Phosphatidyl Monoethanolamine; Мифамуртид.
2-[(*N*-[(2*R*)-[(2-Acetamido-2,3-dideoxy-D-glucopyranos-3-yl)oxy]propanoyl]-L-alanyl-D-isoglutaminyl-L-alanyl)amino]ethyl (2*R*)-2,3-bis(hexadecanoyloxy)propyl hydrogen phosphate.
$C_{59}H_{109}N_6O_{19}P$=1237.5
CAS — 83461-56-7.
ATC — L03AX15.
ATC Vet — QL03AX15.
UNII — 1LM890Q4FY.

NOTE. The name Mifamurtide has been used for both the base and the sodium salt. The name Junovan has been used as a trade mark for mifamurtide.

Mifamurtide Sodium *(rINNM)*

CGP-19835A; L-MTP-PE (liposomal mifamurtide sodium); Mifamurtida sódica; Mifamurtide (USAN); Mifamurtide Sodique; Mifamurtidum Natricum; Мифамуртид Натрий.
2-[(*N*-[(2*R*)-2-[(3*R*,4*R*,5*S*,6*R*)-3-(Acetylamino)-2,5-dihydroxy-6-(hydroxymethyl)tetrahydro-2*H*-pyran-4-yloxy]propanoyl]-L-alanyl-D-isoglutaminyl-L-alanyl)amino]ethyl (2*R*)-2,3-bis(hexanoyloxy)propyl sodium phosphate hydrate.
$C_{59}H_{108}N_6NaO_{19}P.xH_2O$=1259.5 (anhydrous)
CAS — 838853-48-8.

NOTE. The name Mifamurtide has been used for both the base and the sodium salt.

Uses and Administration

Mifamurtide is an immunomodulator that activates monocytes and macrophages to increase their capacity to destroy cancer cells. A liposomal formulation of mifamurtide is used with other chemotherapy to treat non-metastatic, resected osteosarcoma in patients from 2 to 30 years of age. The reconstituted suspension is filtered then diluted in 50 mL sodium chloride 0.9% and given by intravenous infusion over 1 hour. Mifamurtide 2 mg/m² is given twice weekly (at least 3 days apart) for 12 weeks, followed by once weekly for an additional 24 weeks. A total of 48 infusions is given in 36 weeks.

3. Chou AJ, *et al.* Addition of muramyl tripeptide to chemotherapy for patients with newly diagnosed metastatic osteosarcoma: a report from the Children's Oncology Group. *Cancer* 2009; 115: 5339–48.

Administration in children. Mifamurtide is given in a liposomal formulation to children aged from 2 years with osteosarcoma; see above for dosage details.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Common adverse effects with mifamurtide include blood disorders such as anaemia, thrombocytopenia, granulocytopenia, transient neutropenia, and leucopenia; CNS disorders such as headache, dizziness, paraesthesia, hypoaesthesia, somnolence or insomnia, tremor, fatigue, confusion, depression, and anxiety; musculoskeletal disorders such as pain, spasm, arthralgia, and myalgia; and skin disorders such as rash, pruritus, dry skin, alopecia, and hyperhidrosis. Gastrointestinal disturbances such as nausea, vomiting, diarrhoea or constipation, abdominal pain, and anorexia are very common.

Other adverse effects that occur commonly during treatment include infusion-site reactions, phlebitis, flushing, dehydration, hypokalaemia, vertigo, tinnitus, hearing loss, blurred vision, hepatic pain, dysmenorrhoea, haematuria, dysuria, pollakiuria, fever, chills, and oedema.

Common respiratory disorders include dyspnoea or tachypnoea, cough, haemoptysis, epistaxis, sinus or nasal congestion, pleural effusion, or pharyngolaryngeal pain. Respiratory distress has been reported occasionally in patients with pre-existing asthma; mifamurtide therapy should be stopped if a severe respiratory reaction occurs. Prophylactic bronchodilators may be considered in those with a history of reversible airways obstruction.

Cardiac disorders such as tachycardia and hypertension or hypotension are common. Subacute thrombosis has been reported very rarely. Patients with a history of venous thrombosis, vasculitis, or unstable cardiovascular disease should be closely monitored, and treatment delayed or stopped if symptoms are persistent or worsening. Clotting parameters should be monitored after the first dose and again after several doses.

Mifamurtide has occasionally been associated with an inflammatory response, including pericarditis and pleuritis, and it should be used with caution in those with a history of auto-immune disorders, inflammatory disease, or other collagen vascular diseases. Patients should be monitored for signs of uncontrolled inflammatory reactions such as arthritis or synovitis. Allergic reactions also have occurred occasionally with mifamurtide; symptoms include rash, dyspnoea, and severe hypertension.

Caution is required in patients with hepatic or renal impairment due to a lack of data; hepatic and renal function should be monitored until treatment is complete.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Mifamurtide modulates the immune system and its use is not recommended with calcineurin inhibitors or with regular use of corticosteroids. The use of mifamurtide with high-dose NSAIDs is also not recommended as *in vitro* studies have shown that high-dose NSAIDs can block the macrophage-activating action of mifamurtide.

Licensed product information suggests liposomal mifamurtide should not be administered at the same time as other lipophilic formulations.

Pharmacokinetics

Mifamurtide is rapidly cleared from the plasma after intravenous injection and is distributed into the liver, spleen, nasopharynx, thyroid, and to a lesser extent, into the lungs. The cells of the reticuloendothelial system clear mifamurtide liposomes by phagocytosis. The mean half-life is biphasic, that for the initial phase being about 15 minutes while the terminal half-life is about 18 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Austria*: Mepact; *Cz.*: Mepact; *Denm.*: Mepact; *Ger.*: Mepact; *Gr.*: Mepact; *Irl.*: Mepact; *Israel*: Mepact; *Ital.*: Mepact; *Neth.*: Mepact; *Norw.*: Mepact; *Pol.*: Mepact; *Port.*: Mepact; *Spain*: Mepact; *Swed.*: Mepact; *Switz.*: Mepact; *UK*: Mepact.

Milatuzumab *(USAN, rINN)*

Immu-115; Milatuzumabum; Милатузумаб.
Immunoglobulin G1, anti-(human class II antigen invariant chain) (human-mouse monoclonal hLL1 heavy chain), disulfide with human-mouse monoclonal hLL1 κ-chain, dimer.
CAS — 899796-83-9.
UNII — 2OP4E0GC6V.

Profile

Milatuzumab is a humanised monoclonal antibody directed against the CD74 antigen. It is under investigation for the treatment of multiple myeloma, chronic lymphocytic leukaemia, and non-Hodgkin's lymphoma. Milatuzumab conjugated to doxorubicin (p. 782.3) is also being studied for multiple myeloma treatment.

Miltefosine *(BAN, rINN)*

D-18506; HDPC; Hexadecilfosfocolina; Hexadecylphosphocholine; Miltefosiini; Miltefosin; Miltefosina; Miltéfosine; Miltefosinum; Мильтефозин.
[2-(Trimethylammonio)ethyl][hexadecyloxyphosphonate].
$C_{21}H_{46}NO_4P$=407.6
CAS — 58066-85-6.
ATC — L01XX09.
ATC Vet — QL01XX09.
UNII — 53EY29W7EC.

Profile

Miltefosine is a phospholipid derivative that is structurally related to the phospholipid components of the cell membrane and is thought to exert its antineoplastic actions by disruption of cell-membrane function. A 6% solution is applied once or twice daily as a topical antineoplastic agent for skin metastases of breast cancer. Topical miltefosine is also being investigated for the treatment of cutaneous T-cell lymphoma and *Acanthamoeba* keratitis (p. 919.3); topical and oral formulations have been tried for disseminated amoebic infections (p. 920.1). Systemic miltefosine is being investigated for urticaria. Oral miltefosine is used for the treatment of visceral and cutaneous leishmaniasis in a dose of 1.5 to 2.5 mg/kg daily (maximum daily dose 150 mg) for 28 days.

Acanthamoeba infections. References[1,2] to the potential value of miltefosine against *Acanthamoeba* infections (p. 920.1).

2. Walochnik J, *et al.* Anti-acanthamoeba efficacy and toxicity of miltefosine in an organotypic skin equivalent. *J Antimicrob Chemother* 2009; 64: 539–45.

Leishmaniasis. Miltefosine, given orally in doses of 50 to 150 mg daily, or about 2.5 mg/kg daily, for 28 days, appears to be of benefit[1-7] in the treatment of visceral leishmaniasis (p. 923.1), and has been licensed for this purpose in India and Germany. Benefit has also been reported in patients given similar doses for New World cutaneous leishmaniasis,[8] (p. 922.1) and it has also been licensed in some South American countries, but success may depend on the infecting *Leishmania* species.[9] A small

study[10] in Iran found oral miltefosine to be at least as good as intramuscular meglumine antimonate for the treatment of infections caused by *L. major*. Another retrospective, observational study[11] reported successful treatment with oral miltefosine in 30 of 34 patients (most of whom had not responded to initial treatment with intralesional antimony alone or with cryotherapy) for *L. major* infection acquired in northern Afghanistan. A further 4 patients were cured after receiving additional doses of either intralesional or intravenous antimony. The use of longer courses of miltefosine in the treatment of patients with both leishmaniasis and HIV infection has been reported.[12]

After recovery from visceral leishmaniasis caused by *L. donovani* patients may develop post-kala-azar dermal leishmaniasis; further treatment is needed in these patients as they represent a human reservoir for the disease. A small study[13] of 24 patients in Bihar, India reported that an oral dose of miltefosine 50 mg three times daily for 60 days (or 50 mg twice daily for 90 days in those who had intolerable adverse effects) achieved a cure in 96% of the patients. There were no relapses at 1-year follow-up.

Miriplatin *(rINN)*

Miriplatine; Miriplatino; Miriplatinum; SM-11355; Мириплатин.
(SP-4-2)-[(1*R*,2*R*)-Cyclohexane-1,2-diamine-*N*,*N*']bis(tetradecanoato-*O*)platinum.
$C_{34}H_{68}N_2O_4Pt$=764.0
CAS — 141977-79-9.

Miriplatin Hydrate *(rINNM)*

D-06294; Miriplatine, Hydrate de; Miriplatini Hydratum; Miriplatino hidratada; Мириплатина Гидрат.
$C_{34}H_{68}N_2O_4Pt.H_2O$=782.0
CAS — 250159-48-9.

Profile

Miriplatin is a platinum derivative used as an antineoplastic in the treatment of hepatocellular carcinoma. It is given as the hydrate but doses are expressed as the base; 1 mg of miriplatin hydrate is equivalent to about 1.02 mg of miriplatin. A usual dose of 70 mg is given once daily by hepatic intra-arterial injection. Hepatic dysfunction, hepatobiliary disorders, and hepatic failure can occur.

Mitobronitol *(BAN, rINN)*

DBM; Dibromomannitol; Mitobronitolum; NSC-94100; R-54; WR-220057; Митобронитол.
1,6-Dibromo-1,6-dideoxy-D-mannitol.
$C_6H_{12}Br_2O_4$=308.0
CAS — 488-41-5.
ATC — L01AX01.
ATC Vet — QL01AX01.
UNII — 5UP30YED7N.

Pharmacopoeias. In *Br.*

BP 2014: (Mitobronitol). A white or almost white crystalline solid. Slightly soluble in water, in alcohol, and in acetone; practically insoluble in chloroform. Protect from light.

Profile

Mitobronitol is an antineoplastic that appears to act as an alkylating agent, perhaps by epoxide formation. It has been used in the management of thrombocythaemia, both primary, and secondary to chronic myeloid leukaemia or polycythaemia vera.

The usual oral dose is 250 mg daily until the platelet count falls to acceptable levels. Intermittent dosage has been given for maintenance therapy, adjusted according to the blood count. Frequent examination of the blood should be performed during treatment. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Mitobronitol is well absorbed from the gastrointestinal tract and is excreted through the liver into the bile, with reabsorption from the small intestine. It is eliminated as unchanged drug and some bromine-containing metabolites in the urine over several days.

Carcinogenicity. Long-term follow-up of a cooperative study[1] involving 350 patients with polycythaemia vera and treated with mitobronitol was thought to indicate that mitobronitol was less likely than phosphorus-32 or busulfan to induce acute myeloid leukaemia.

For a discussion of the usual management of polycythaemia vera, see p. 695.2.

Mitoguazone Dihydrochloride *(rINNM)*

Dihidrocloruro de mitoguazona; Methyl-GAG; Methylglyoxal Bisguanylhydrazone (mitoguazone); MGBG; Mitoguazona, dihidrocloruro de; Mitoguazone, Dichlorhydrate de; Mitoguazoni Dihydrochloridum; NSC-32946; Митогуазона Дигидрохлорид.
1,1'-[(Methylethanediylidene)dinitrilo]diguanidine dihydrochloride.
$C_5H_{12}N_8.2HCl$=257.1
CAS — 459-86-9 (mitoguazone); 7059-23-6 (mitoguazone dihydrochloride).
ATC — L01XX16.
ATC Vet — QL01XX16.
UNII — NNI098FX5Q.

Profile

Mitoguazone is an antineoplastic that may exert its cytotoxic effects by its ability to inhibit polyamine biosynthesis. It has been tried as the dihydrochloride monohydrate or the acetate, in the treatment of leukaemias, lymphomas, and some solid tumours.

Mitoguazone may produce hypoglycaemia and should be given dissolved in glucose-containing infusion fluids; sugar may be taken orally if hypoglycaemia develops during infusion. Granulocytopenia and thrombocytopenia are generally mild and reversible on stopping treatment. Gastrointestinal effects frequently occur.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Fr.***: Methyl-Gag†.

Mitolactol *(rINN)*

DBD; Dibromodulcitol; Mitolactolum; NSC-104800; WR-138743; Митолактол.
1,6-Dibromo-1,6-dideoxy-D-galactitol.
$C_6H_{12}Br_2O_4$=308.0
CAS — 10318-26-0.
UNII — LJ2P1SIK8Y.

Profile

Mitolactol is an antineoplastic that may act by alkylation, probably as epoxide metabolites including dianhydrogalactitol. It has been given orally in the treatment of metastatic breast and cervical carcinoma, although other drugs are usually preferred, and has also been tried in other malignant neoplasms, notably those of the brain. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

In addition to myelosuppression, which is usually dose-limiting, and manifests chiefly as leucopenia and thrombocytopenia, adverse effects include gastrointestinal disturbances, skin rashes, grey pigmentation of the skin, transient disturbances of hepatic function, elevated blood-urea nitrogen (BUN), and hypersensitivity reactions. Blood counts should be taken regularly during treatment and mitolactol withdrawn if bone-marrow depression occurs.

Mitomycin *(BAN, USAN, rINN)*

Mitomicina; Mitomicina C; Mitomicinas; Mitomicinum; Mitomisin; Mitomycin C; Mitomycine; Mitomycine C; Mitomycinum; Mitomysiini; NSC-26980; Митомицин.
6-Amino-1,1a,2,8,8a,8b-hexahydro-8-hydroxymethyl-8a-methoxy-5-methylazirino[2',3':3,4]pyrrolo[1,2-*a*]indole-4,7-dione carbamate; (1*S*,2*S*,9*S*,9a*R*)-7-Amino-2,3,5,8,9,9a-hexahydro-9a-methoxy-6-methyl-5,8-dioxo-1,2-epimino-1-*H*-pyrrolo[1,2-*a*]indol-9-ylmethyl carbamate.
$C_{15}H_{18}N_4O_5$=334.3
CAS — 50-07-7.
ATC — L01DC03.
ATC Vet — QL01DC03.
UNII — 50SG953SK6.

Description. Mitomycin is an antineoplastic antibiotic produced by the growth of *Streptomyces caespitosus*.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Mitomycin). A substance produced by a strain of *Streptomyces caespitosus*. Blue-violet crystals or crystalline powder. Slightly soluble in water and in acetone; freely soluble in dimethylacetamide; sparingly soluble in methyl alcohol. A 0.1% solution in water has a pH of 5.5 to 7.5. Protect from light.

USP 36: (Mitomycin). A blue-violet crystalline powder. It has a potency of not less than 970 micrograms/mg. Slightly soluble in water; soluble in acetone, in butyl acetate, in cyclohexanone, and in methyl alcohol. A 0.5% suspension in water has a pH of 6.0 to 7.5. Store in airtight containers at a temperature of 25 degrees, excursions permitted between 15 degrees and 30 degrees. Protect from light.

Incompatibility. Mitomycin may be incompatible with drugs that are acid in solution—for a report of incompatibility with topotecan, see p. 872.3.

Stability. Mitomycin undergoes degradation in acid solution,[1] and two studies[2,3] suggested that mitomycin was much less stable in glucose 5% injection than in sodium chloride 0.9%. These findings were queried by a manufacturer (*Bristol, USA*) whose own results suggested[4] that mitomycin was stable for 48 hours in glucose injection 5% at 25 degrees, and it is uncertain whether different manufacturers' formulations differ in stability, or, as has been suggested, that an unsuitable assay was used by the manufacturer to measure stability.[5]

Uses and Administration

Mitomycin is a highly toxic antibiotic with antineoplastic properties. It acts as an alkylating agent after activation *in vivo* and suppresses the synthesis of nucleic acids. It is a cell-cycle non-specific agent, but is most active in the late G_1 and early S phases.

Mitomycin is used, with other antineoplastic agents, in the treatment of many solid tumours including those of the bladder, breast, cervix, eye, stomach, and prostate as indicated by the cross-references given below. Mitomycin has been tried in other neoplasms including those of the gastrointestinal tract, head and neck, pancreas, in melanoma, sarcomas, and in leukaemias.

Dosage regimens include an initial dose of 10 to 20 mg/m² intravenously; subsequent doses are repeated at intervals of 6 to 8 weeks if blood counts permit, and should be reduced according to the previous haematological response. Usual doses in other regimens range from 4 to 10 mg (60 to 150 micrograms/kg) given at 1- to 6-week intervals. Other regimens may be used, particularly in combination.

Doses are adjusted according to the effect on bone marrow and treatment should not be repeated until the leucocyte and platelet counts are above acceptable levels (see also Bone-marrow Depression, p. 730.3).

Mitomycin is also used as a bladder instillation: 20 to 40 mg is instilled once weekly or three times a week for a total of 20 doses in the treatment of superficial bladder tumours. These doses are usually given in 20 to 40 mL of water for injection. The solution should be retained in the bladder for at least 1 hour. For the prevention of recurrent bladder tumours 20 mg may be instilled every 2 weeks, or 40 mg monthly or 3-monthly. Alternatively 4 to 10 mg has been instilled once weekly or three times a week.

Mitomycin has been given by the intra-arterial route in the treatment of liver tumours, sometimes as an infusion of microcapsules designed to produce localised embolisation.

Mitomycin is used for its effect on fibroblasts to improve outcomes and reduce scarring in certain types of surgery, notably in glaucoma (see below).

Mitomycin is also used topically in the form of 0.02% or 0.04% eye drops to treat conjunctival or corneal squamous cell carcinoma.

Glaucoma. Mitomycin, like fluorouracil, is effective in improving the outcome of glaucoma filtering surgery in selected patients when used as an adjunct to prevent the formation of scar tissue (see p. 1999.1). Fluorouracil is usually given as a regimen of multiple injections but mitomycin given as a single intra-operative topical application in usual concentrations ranging from 200 to 500 micrograms/mL appears to be of similar efficacy.[1,2] A systematic review of 11 studies concluded that intra-operative mitomycin reduced the chances of failure in high-risk patients, and in those having their first trabeculectomy.[3] However it was noted that the nature of the data might have led to overestimation of the effect and that there was some evidence of an increased risk of cataract with mitomycin. Late hypotony is also a problem.[4] For other potential complications see Effects on the Eye, below.

Keratectomy. Mitomycin has been used as an adjunct to laser keratectomy (photorefractive or phototherapeutic keratectomy) to prevent the subsequent formation of corneal haze due to fibroblast proliferation. Although earlier studies used brief intraoperative local application of a 0.02% solution, a lower dose solution (0.002%) also appears to be effective, and may reduce the risk of adverse effects.

Malignant neoplasms. Mitomycin is used in the prevention of recurrent bladder cancer (p. 700.2), in the palliative therapy of advanced breast cancer (p. 702.1), in malignancies of the cervix (p. 704.2), eye (p. 705.1), and stomach and anus (p. 706.1 and p. 708.1), and has been tried in advanced prostatic cancer (see p. 712.3).

Pterygium. Pterygium is a degenerative condition of subconjunctival tissues that results in a vascularised overgrowth of the conjunctiva and cornea. It is cosmetically unappealing but does not usually require treatment. However, if it affects the pupillary area it can be treated surgically. Pterygium often recurs after removal and methods used to prevent recurrence include radiotherapy or the topical application of mitomycin or thiotepa.[1]

Thiotepa has been applied postoperatively as 0.05% eye drops for several weeks, but pterygium may still recur[2] and adverse effects include conjunctival injection, granuloma, hypertrophic conjunctiva, and black deposits in the conjunctival fornix.[1] Depigmentation of the eyelids may also be a problem, so patients should avoid direct sunlight during thiotepa use.[1]

Mitomycin has been applied topically to the surgical site, or given as eye drops postoperatively.[1] The optimal intraoperative exposure time and concentration are uncertain: concentrations of 0.02 or 0.04% have been applied for up to 5 minutes,[1,3] and low-dose treatment with mitomycin 0.02% for 30 seconds has been reported to be effective with few complications.[4] Postoperative treatment has generally been given as 0.02, 0.04, or 0.1% eye drops for up to 2 weeks, but the higher concentrations and longer treatment periods have been associated with more adverse effects,[1] some of which may be severe and sight-threatening (see also Effects on the Eyes, below). Comparisons of intraoperative with postoperative use suggest that pterygium recurrence rates are similar.[1,5]

A range of β-irradiation doses and fractionation methods have been used. Long-term complications include posterior subcapsular changes of the lens, atrophy and ulceration of the sclera, and scleral necrosis leading to endophthalmitis.[1] In one retrospective study,[6] intra-operative use of 0.04% mitomycin was more effective than β-irradiation in preventing recurrence after surgery. In another study,[7] postoperative mitomycin 0.02% for one week was less effective than radiation therapy.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The main adverse effect of mitomycin is delayed cumulative bone-marrow suppression. Profound leucopenia and thrombocytopenia occurs after about 4 weeks with recovery in about 8 to 10 weeks after a dose. Therapy should be withheld until platelets and white blood cells recover to at least 100 000 cells/mm³ and 4000 cells/mm³, respectively. Blood counts may not recover in about one-quarter of patients. Other serious adverse effects include renal damage and pulmonary toxicity; a potentially fatal haemolytic-uraemic syndrome has been reported in some patients. US licensed product information states that the degree of renal impairment does not appear to be related to dose or duration of therapy although it has been suggested that the risk of renal toxicity is low with cumulative doses less than 50 mg/m², but increases with higher cumulative doses (see also Effects on the Kidneys, below). Gastrointestinal toxicity, dermatitis, alopecia, fever, malaise, and rarely cardiotoxicity may also occur. Local tissue necrosis, ulceration, and cellulitis may follow extravasation. Intra-arterial use can cause skin disorders such as pain, redness, erythema, blisters, erosion, and ulceration; skin and/or muscle necrosis may develop. Injection into the hepatic artery can cause liver and biliary tract disorders such as cholecystitis, cholangitis, and bile duct necrosis.

Mitomycin is contra-indicated in patients with impaired renal function or coagulation disorders. Renal function should be tested before beginning treatment and after each course.

Effects on the bladder. Intravesical instillation of mitomycin after resection of superficial bladder tumours has led to the development of indolent asymptomatic ulcers at the resection site which may persist for months, and must be distinguished from persistent infiltrating bladder cancer.[1,2] Persistent ulceration, inflammation, necrosis, and pain has also occurred, possibly because of mitomycin extravasation at the resection site.[3] Fistula formation has also been described.[4] There are also a few reports[5] of eosinophilic cystitis, in which eosinophilic infiltration of the mucosa and muscle were accompanied by oedema, inflammation, muscle necrosis and fibrosis. Severe bladder contracture is a rare, and often irreversible, complication of intravesical mitomycin;[6] urinary diversion may be required in cases of intolerable urinary frequency.[7] Formation of papillary-like calcifications at the resection site,[8] and calcification of the bladder wall have also been described after the use of mitomycin for superficial transitional cell carcinoma of the bladder.

Effects on the eyes. Early complications after the topical use of mitomycin with glaucoma filtering surgery (see Glaucoma, above) include hypotony, shallow anterior chamber, cataract formation, choroidal effusions, hypotonous maculopathy, and suprachoroidal haemorrhage.[1] Late complications include bleb leak, blebitis, and endophthalmitis.[2] Complications from the topical use of mitomycin with or after pterygium surgery (see Pterygium, above) commonly include irritation and photophobia. Other effects include delayed epithelial healing, avascularity of the sclera and cornea, scleral calcification and ulceration, necrotising scleritis, corneal or scleral perforation, iridocyclitis, cataract formation, glaucoma, and symblepharon.[1] Some of these effects may be severe and sight-threatening, and require further surgery.[3] Complications most commonly reported after the use of topical mitomycin in ocular surface neoplasia were hypersensitivity reactions and epiphora (an overflow of tears) secondary to stenosis of the lachrymal punctum.[4]

Effects on the kidneys. A syndrome of thrombotic microangiopathy resembling the haemolytic-uraemic syndrome has been seen in patients receiving mitomycin, either alone[1] or more often with other drugs, particularly fluorouracil[2] or tamoxifen.[3,4] The syndrome is characterised by haemolytic anaemia, thrombocytopenia, and progressive renal failure, and may be accompanied by hypertension, pulmonary oedema, and neurological effects including confusion, headache, and seizures.[1,2] Onset is usually delayed, sometimes occurring several months after the end of a course of mitomycin.[1,2]

There is some uncertainty as to whether mitomycin dose is significant, but one study[1] found that all of 25 cases they

reported had received total doses of 70 mg or more, and another[2] reported that 74 of 83 cases had received 60 mg or more.

Symptoms may be exacerbated by blood transfusions.[2] The use of erythropoietin allowed the cessation of blood transfusion, with subsequent haematological improvement and slower progression of chronic renal failure in one case report.[3] Plasma exchange has been suggested as possibly helpful,[1] although only a minority of patients may benefit from this treatment.[2] Extracorporeal protein A immunoadsorption has also been tried.[6] Captopril therapy may also be useful.[7]

7. Schiebe ME, *et al.* Mitomycin C-related hemolytic uremic syndrome in cancer patients. *Anticancer Drugs* 1998; 9: 433–5.

Effects on the liver. Hepatic veno-occlusive disease developed in 6 of 29 patients given intensive mitomycin therapy and autologous bone marrow transplantation.[1] The effect was manifest as abdominal pain, hepatomegaly, and ascites, and liver failure was progressive and fatal in 3. A further patient, who had no symptoms, was found to have veno-occlusive disease at post mortem.

1. Lazarus HM, *et al.* Veno-occlusive disease of the liver after high-dose mitomycin C therapy and autologous bone marrow transplantation. *Cancer* 1982; 49: 1789–95.

Effects on respiratory function. Mitomycin-induced pulmonary toxicity has been reviewed.[1,2] There have been reports of toxicity at total dosages as low as 20 mg/m² of mitomycin,[2] although others report[1] that the average cumulative dose associated with toxicity is 78 mg. Premedication with corticosteroids may reduce the incidence of lung toxicity.[2] Interstitial lung disease associated with intravesical mitomycin has also been described.[3]

Effects on the skin. Severe eczema of the hands and feet and generalised rash have been reported in patients receiving intravesical mitomycin.[1,2] These symptoms appear to be due to a delayed hypersensitivity (type IV) reaction,[1,2] which is probably also responsible for the bladder irritation and cystitis that may follow intravesical mitomycin[1] (see p. 831.3). Leucocytoclastic vasculitis caused by an immune-complex mediated (type III) reaction and presenting as purpuric papules has also been described.[2]

2. Kunkeler L, *et al.* Type III and type IV hypersensitivity reactions due to mitomycin C. *Contact Dermatitis* 2000; 42: 74–6.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies mitomycin as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Antineoplastics. Cardiotoxicity developed in 14 of 91 patients who received mitomycin therapy as second-line treatment for breast cancer after the failure of *doxorubicin*-containing regimens, compared with 3 of 89 similar patients whose second-line treatment did not include mitomycin.[1]

For reports of acute bronchospasm after injection of a *vinca alkaloid* in patients pretreated with mitomycin see Vinblastine Sulfate, p. 882.2. For the increased risk of haemolytic-uraemic syndrome that may occur if mitomycin is given with *fluorouracil* or *tamoxifen* see under Effects on the Kidneys, p. 831.3.

1. Buzdar AU, *et al.* Adriamycin and mitomycin C: possible synergistic cardiotoxicity. *Cancer Treat Rep* 1978; 62: 1005–8.

Pharmacokinetics

Mitomycin disappears rapidly from the blood after intravenous injection with an initial (distribution) half-life of 17 minutes. It is widely distributed but does not appear to cross the blood-brain barrier. Mitomycin is metabolised mainly but not exclusively in the liver. The terminal half-life is about 50 minutes. After normal doses about 10% of a dose is excreted unchanged in the urine; small amounts are also present in bile and faeces. With increasing doses metabolic pathways are saturated, and more drug is excreted unchanged in the urine.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Asomutan; Crisofimina; Maximiton; Mitocyna; Mitokebir; Mitonovag; Mitotie; Sintemicina; Vetio; *Braz.*: Baxmicin†; Mitocin; *Fin.*: Mitostat; *Fr.*: Ametycine; *Ger.*: Ametycine; Mitem; Mito-extra; Mito-medac; *India*: Almito; Mitocin; Mitodus; Mitonco; Oncocin; *Mex.*: Mitocin-C†; Mitolem; Mitotie; Mixandex; *Philipp.*: Mytoxid; *Thai.*: Mitocin; Vesimycin; *USA*: Mitosol; Mitozytrex†; Mutamycin†.

Pharmacopoeias. In *US.*

USP 36: (Mitotane). A white crystalline powder with a slight aromatic odour. M.p. is between 75 degrees and 81 degrees. Practically insoluble in water; soluble in alcohol, in ether, in petroleum spirit, and in fixed oils and fats. Store in airtight containers. Protect from light.

Uses and Administration

Mitotane is an oral antineoplastic that directly suppresses the adrenal cortex. It may also modify peripheral steroid metabolism. It is given in the treatment of advanced adrenocortical tumours. Dosing schedules vary. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

In the UK, mitotane is given in an initial oral dose of 2 to 3 g daily in patients with adrenocortical tumours, increased at 2-week intervals until plasma mitotane concentrations reach the target range of 14 to 20 micrograms/mL. For rapid control of Cushing's symptoms in these patients, an initial oral dose of 4 to 6 g daily may be necessary, and can be increased as often as every week to achieve the target concentration range. The total daily dose is given in 2 or 3 divided doses with meals containing fat-rich foods. Corticosteroid therapy may also be required for adrenal insufficiency, see Precautions, below. Mitotane plasma concentrations should be measured at frequent intervals (after each dose adjustment) until the target concentration range is reached, usually within 3 to 5 months. Regular monitoring of plasma concentrations should continue once the maintenance dose is established. If severe toxicity occurs, mitotane treatment should be withheld and restarted when plasma concentrations are within the target range. For mild toxicity the dose should be reduced until the maximum tolerated dose is reached. Mitotane treatment may be continued for as long as there is benefit. If there is no benefit after 3 months at an optimal dose, treatment should be stopped. For doses in children, see below.

In the USA, the usual initial oral dosage is 2 to 6 g daily in 3 or 4 divided doses. Doses are usually increased to 9 to 10 g daily, unless adverse effects necessitate dose reduction. The maximum tolerated dose ranges from about 2 to 16 g daily.

Administration in children. Mitotane is used in children and adolescents for the treatment of advanced adrenocortical tumours. In the UK, an initial oral dose of 1.5 to 3.5 g/m² daily can be increased up to a target dose of 4 g/m² daily. The total daily dose is given in 2 or 3 divided doses with meals containing fat-rich foods. Plasma concentrations of mitotane should be monitored as for adults, see above; a sharp increase in mitotane concentration may be seen when 10 micrograms/mL is reached. The dose may be reduced after 2 or 3 months depending on mitotane concentrations or toxicity.

Malignant neoplasms of the adrenal gland. Adrenocortical carcinoma is a rare and aggressive malignancy, and there are few prospective studies of its treatment. Surgery is the treatment of choice and the only curative option for localised disease.[1] Retrospective studies of adjuvant mitotane after resection with curative intent have shown mixed results. Some investigators found that mitotane had no effect on survival[2] or recurrence rate,[3] while others reported significantly improved recurrence-free survival.[4] Nevertheless, mitotane is often suggested as adjuvant therapy because of the high risk of recurrence, although it might be considered unnecessary following complete resection of localised small tumours.[1,5]

Mitotane has been reported to be of benefit in patients undergoing palliative surgery,[2] and is the drug of choice when the tumour cannot be completely removed surgically[1,5] although tumour reduction may be minimal.[3] Response rates range from 13 to 30% in metastatic disease, but most are of limited duration and complete response is rare.[1] It is also used in metastatic disease to control symptoms but adverse effects can limit its use. Mitotane has also been tried with cytotoxic chemotherapy, and various regimens are under investigation.[1]

Adverse Effects

Almost all patients given mitotane have anorexia, nausea and vomiting, and sometimes diarrhoea, and about 40% suffer some central toxicity with dizziness, vertigo, sedation, lethargy, ataxia, and paraesthesia. Brain damage and impaired function can occur after prolonged use of high doses. Other common adverse effects include leucopenia, thrombocytopenia, anaemia, hypercholesterolaemia, hypertriglyceridaemia, mucositis, gynaecomastia, and headache. Bleeding time may be prolonged, but the mechanism of this effect is unknown. Ocular adverse effects may occur including blurred vision, diplopia, lenticular opacities, maculopathy, and retinopathy. Other adverse effects include hypersensitivity reactions, rashes, fever, myalgia, myasthenia, haemorrhagic cystitis, haematuria, albuminuria, flushing, hypertension, orthostatic hypotension, and hypersalivation. Liver enzymes are commonly increased with mitotane, and there have been reports of auto-immune hepatitis and cholestatic hepatitis. Hypothyroidism has occurred.

Precautions

Mitotane inhibits the adrenal cortex and adrenocortical insufficiency may develop during treatment; corticosteroid therapy is often required. In trauma, infection, or shock the drug should be temporarily withdrawn and corticosteroids should be given systemically. Mitotane should be given with care to patients with renal or hepatic impairment. Before mitotane therapy is begun, all possible tumour tissue from large metastases should be surgically removed, in order to minimise possible infarction or haemorrhage in the tumour. Patients should not drive or operate machinery. Behavioural and neurological assessments should be carried out regularly in patients who have been receiving treatment for 2 years or more, especially when mitotane plasma concentrations exceed 20 micrograms/mL. Plasma concentrations should be monitored to guide dosage; the therapeutic window lies between 14 and 20 micrograms/ml (see also Therapeutic Drug Monitoring, p. 833.1). Fetal adrenal abnormalities have been reported after exposure during pregnancy.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies mitotane as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

Mitotane can induce hepatic microsomal enzymes such as cytochrome P450 isoenzymes. This may enhance the

metabolism of some other drugs, including coumarin anticoagulants.

Spironolactone. Mitotane in a dose of up to 3 g daily in a 65-year-old patient with Cushing's syndrome appeared to be ineffective and did not produce the usual adverse effects associated with mitotane while the patient was also receiving spironolactone.[1]

1. Wortsman J, Soler NG. Mitotane: spironolactone antagonism in Cushing's syndrome. *JAMA* 1977; 238: 2527.

Pharmacokinetics

Up to 40% of a dose of mitotane is absorbed from the gastrointestinal tract; absorption increases with food. After daily doses of 5 to 15 g, concentrations in the blood of 7 to 90 micrograms/mL of unchanged drug and 29 to 54 micrograms/mL of metabolite have been reported. It is widely distributed and appears to be stored mainly in fatty tissues. It is metabolised in the liver and other tissues and excreted as metabolites in urine and bile. From 10 to 25% of a dose has been recovered in the urine as a water-soluble metabolite. As it is slowly released from storage sites, terminal plasma half-lives ranging from 18 to 159 days have been reported. In most patients mitotane is no longer detected in plasma about 6 to 9 weeks after stopping therapy.

Therapeutic drug monitoring. Monitoring of mitotane and its major metabolite *o,p'*-DDE in 2 patients receiving mitotane in low doses for Cushing's disease found that there is a prolonged lag time in the plasma concentration changes in response to alterations in dosage,[1] presumably because of the lipophilicity of both compounds which leads to accumulation in adipose tissue. A study[2] in adrenal carcinoma found that mitotane is preferentially distributed into the very-low-density lipoprotein (VLDL) fraction of the serum of patients with hypertriglyceridaemia, whereas under normolipidaemic conditions, it is bound to high-density lipoproteins and albumin. Because VLDL is not incorporated into the human adrenal cells, mitotane's lipophilicity has implications for treatment and monitoring in patients with hypertriglyceridaemia. In some studies[3,4] tumour responses were seen only in those patients with a serum concentration of mitotane above 14 micrograms/mL, and a small prospective study[5] found that therapeutic concentrations (defined as between 14 and 20 micrograms/mL) could be reached by sustained low doses (1 to 3 g daily), thus limiting adverse effects.

Mitoxantrone Hydrochloride

(BANM, USAN, rINNM)

CL-232315; DHAD; Dihydroxyanthracenedione Dihydrochloride; Hidrocloruro de mitoxantrona; Mitoksantron Hidroklorür; Mitoksantronihydroklorid; Mitoksantrono hidrochloridas; Mitoxantron dihydrochlorid; Mitoxantrona, hidrocloruro de; Mitoxantrone, Chlorhydrate de; Mitoxantronhidroklorid; Mitoxantronhydrochlorid; Mitoxantronhydroklorid; Mitoxantroni Dihydrochloridum; Mitoxantron hydrochloridum; Mitozantrón Hidroklorür; Mitozantrone Hydrochloride; NSC-301739; Митоксантрона Гидрохлорид.

1,4-Dihydroxy-5,8-bis[2-(2-hydroxyethylamino)ethylamino] anthraquinone dihydrochloride.

$C_{22}H_{28}N_4O_6.2HCl$=517.4

CAS — 65271-80-9 (mitoxantrone); 70476-82-3 (mitoxantrone hydrochloride).

ATC — L01DB07.

ATC Vet — QL01DB07.

UNII — U6USW86RDQ.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US.*

Ph. Eur. 8: (Mitoxantrone Hydrochloride). A dark-blue, electrostatic, hygroscopic powder. Sparingly soluble in water; practically insoluble in acetone; slightly soluble in methyl alcohol. Store in airtight containers.

USP 36: (Mitoxantrone Hydrochloride). A dark-blue powder. Sparingly soluble in water; practically insoluble in acetone, in acetonitrile, and in chloroform; slightly soluble in methyl alcohol. Store in airtight containers.

Uses and Administration

Mitoxantrone is an anthracenedione antineoplastic structurally related to doxorubicin (p. 782.3). It inhibits topoisomerase II and causes DNA strand breakage, as well as intercalating with DNA. It is cell-cycle non-specific but is most active against cells in the late *S* phase.

It is used in the treatment of metastatic breast cancer (p. 702.1), and of non-Hodgkin's lymphomas (p. 696.3), alone or with other agents. It may also be given to treat adult acute myeloid leukaemias (p. 693.1). Mitoxantrone has also been used in patients with hormone-refractory prostate cancer (p. 712.3), liver cancer (p. 709.3), and ovarian cancer (p. 711.2).

In addition, mitoxantrone is used in the management of secondary progressive or relapsing multiple sclerosis (see below), to reduce neurological disability or the frequency of relapses.

Mitoxantrone is given as the hydrochloride, but doses are expressed in terms of the base; 1.2 mg of the hydrochloride is equivalent to about 1 mg of mitoxantrone. In the treatment of breast cancer, prostate cancer, liver cancer, and lymphomas, a dose equivalent to mitoxantrone 14 mg/m^2 is given initially, then repeated every 3 weeks. It is diluted to at least 50 mL in sodium chloride 0.9% or glucose 5% and injected over at least 3 minutes into a freely-running intravenous infusion of either. Subsequent doses may be adjusted according to the degree of myelosuppression produced. Initial dosage may need to be reduced to 12 mg/m^2 in debilitated patients or those who have had previous chemotherapy. Doses should also probably be reduced when mitoxantrone is given as part of a combination regimen; initial doses should generally be reduced by 2 to 4 mg/m^2 below those recommended for single-agent use.

In the treatment of patients with acute myeloid leukaemia an intravenous dose of 12 mg/m^2 daily for 5 days may be given as monotherapy to induce remission; alternatively 10 to 12 mg/m^2 may be given for 3 days with a 7-day course of cytarabine.

All patients should have cardiac function assessed before starting therapy, including left ventricular ejection fraction (LVEF) evaluation. Regular cardiac examinations are recommended in all patients at increased risk of cardiotoxicity and in those who receive a cumulative dose of mitoxantrone greater than 160 mg/m^2. Regular blood counts should be performed during treatment and courses should not be repeated until blood counts have recovered (see also Bone-marrow Depression, p. 730.3).

In the management of **multiple sclerosis**, the recommended dose is the equivalent of mitoxantrone 12 mg/m^2 by intravenous infusion over 5 to 15 minutes. This dose may be given once every 3 months initially provided that neutrophil counts are above 1500 cells/mm^3 and that LVEF is greater than 50%. Blood counts and liver function should be monitored before each dose. LVEF should be evaluated before beginning mitoxantrone therapy and before all subsequent doses; a total cumulative dose in excess of 140 mg/m^2 should be avoided. LVEF should also be measured if signs or symptoms of heart failure develop.

Multiple sclerosis. Mitoxantrone has produced clinical benefit[1-4] in terms of reduced relapse rate and a slowing of disease progression in patients with multiple sclerosis (p. 996.3). It has been given intravenously in doses of 5 or 12 mg/m^2 every 3 months, or 8 mg/m^2 every month. Patients with progressive relapsing disease may benefit from rapid induction with 12 mg/m^2 monthly for 3 months.[5] Benefit has also been found when used with corticosteroids,[6] although the combination was not compared with mitoxantrone alone. However, cardiotoxicity limits the dose that can be given[7,8] (see Uses and Administration, above). Because of this and other adverse effects, such as possible secondary malignancy or potentially permanent amenorrhoea, some consider the use of mitoxantrone in multiple sclerosis to be unproven[9] and others have cautioned[10] that alternative immunomodulators have less severe toxicities. A systematic review[11] concluded that mitoxantrone was moderately effective in the short-term treatment of multiple sclerosis, but that information on its long-term effects was lacking; use should be limited to patients with worsening relapsing-remitting or secondary progressive disease with evidence of worsening disability.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin, p. 784.1. Mitoxantrone is reported to be better tolerated than doxorubicin. The nadir of the white cell count usually occurs about 10 days after a dose, with recovery by day 21. Elevation in liver enzyme values may occur; there are occasional reports of severe hepatic impairment in patients with leukaemia, in whom doses are generally higher and adverse effects of mitoxantrone may be more frequent and severe.

Transient blue-green coloration of the urine, and occasionally the sclerae, may occur. Blue discoloration of the skin (which can also occur after extravasation) and nails have been reported. Nail dystrophy and onycholysis can occur.

Severe neurotoxicity has resulted from erroneous intrathecal dosage; local or regional neuropathy has followed intra-arterial injection. Care is required in patients with pre-existing heart disease, or who have had prior anthracycline treatment or radiotherapy to the chest, as they are at increased risk of cardiotoxicity; regular cardiac examinations, including left ventricular ejection fraction (LVEF) evaluation, should be performed in these patients from the start of therapy. All patients should be assessed for cardiac signs and symptoms; multiple sclerosis patients with a baseline LVEF below the lower limit of normal should not be treated with mitoxantrone. UK licensed product information states that cardiac monitoring should also be performed in patients without identifiable cardiac risk factors who receive a total cumulative dose of mitoxantrone in excess of 160 mg/m^2; US licensed product information states that the risk of symptomatic congestive heart failure is higher after a cumulative dose of 140 mg/m^2 and that multiple sclerosis patients should not receive a total cumulative dose greater than this. Care is also required in patients with hepatic impairment. Regular blood counts should be performed during treatment. Treatment with mitoxantrone, either alone or with other antineoplastics and/or radiotherapy, has been associated with an increased risk of development of secondary acute myeloid leukaemia.

Alopecia. Two patients receiving therapy with mitoxantrone developed selective alopecia of white but not of dark hair.[1]

1. Arlin ZA, *et al.* Selective alopecia with mitoxantrone. *N Engl J Med* 1984; 310: 1464.

Breast feeding. Mitoxantrone was detected in the breast milk of a woman with acute promyelocytic leukaemia in remission who was given consolidation chemotherapy that included mitoxantrone 6 mg/m^2 on days 1 to 3. Concentrations were 120 nanograms/mL just after the third dose and 18 nanograms/mL 28 days after treatment. Although she breast fed her neonate from 3 weeks after the completion of the course of treatment and no adverse effects were seen, the authors recommended that women treated with mitoxantrone should not breast feed.[1]

1. Azuno Y, *et al.* Mitoxantrone and etoposide in breast milk. *Am J Hematol* 1995; 48: 131–2.

Effects on the heart. Data from over 4000 patients treated with mitoxantrone included 172 reports of cardiac events, including 42 cases of congestive heart failure and 66 of

decreased ejection fraction.[1] Previous anthracycline therapy increased the risk, and congestive heart failure seemed to be more likely in patients exposed to a cumulative mitoxantrone dose of 160 mg/m², or 100 mg/m² in those already given anthracyclines. The risk of symptomatic congestive heart failure in cancer patients has been estimated to be 2.6% for patients receiving a cumulative dose of up to 140 mg/m²; the US manufacturer recommended that patients with multiple sclerosis should not receive a total cumulative dose greater than this.[2] In a further 78 patients,[3] clinical heart failure developed in 2 after cumulative doses of 174 and 243 mg/m². Four of 9 other patients given mitoxantrone in doses above 100 mg/m² showed signs of cardiotoxicity, and a further patient previously given doxorubicin 313 mg/m² had a fall in stress ejection fraction after only 47 mg/m² of mitoxantrone. However, cardiotoxicity has also been seen after lower doses; sinus bradycardia occurred[4] in 2 previously untreated patients after starting continuous infusions of mitoxantrone 10 mg/m², and severe acute heart failure[5] in a patient with multiple sclerosis, 2 months after a second dose of mitoxantrone 12 mg/m² was given. Late cardiotoxicity can also occur; dilated cardiomyopathy, with a left ventricular ejection fraction of 20%, developed[6] in a patient with multiple sclerosis 2 years after a course of mitoxantrone with a cumulative dose of 72 mg/m². For information on the cardiotoxicity of anthracyclines, to which mitoxantrone is structurally related, see under Adverse Effects and Treatment of Doxorubicin, p. 784.1.

Handling and disposal. *Urine and faeces* produced for up to 7 days after a dose of mitoxantrone should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Hypersensitivity. In a report of 3 patients, allergic-type reactions to mitoxantrone included vasculitis, facial oedema and skin rashes, and in one, breathlessness, tachypnoea, cyanosis, and unrecordable pulse and blood pressure.[1] Allergic reactions to the drug appear to be rare.

1. Taylor WB, *et al.* Allergic reactions to mitoxantrone. *Lancet* 1986; i: 1439.

Pregnancy. For a report of a fetal sinusoidal heart rate pattern and neonatal pancytopenia after a woman was given combination chemotherapy including mitoxantrone, see Pregnancy, under Etoposide, p. 791.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies mitoxantrone as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

For a report of the effect of ciclosporin in patients receiving mitoxantrone and etoposide, see p. 792.1.

Pharmacokinetics

After intravenous doses mitoxantrone is rapidly and extensively distributed to body tissues, and slowly excreted in urine and bile as unchanged drug and metabolites. The elimination half-life is reported to range from 5 to 18 days. Between 6 and 11% of a dose has been recovered from urine, and 13 to 25% in faeces, within 5 days. It does not appear to cross the blood-brain barrier, but it is distributed into breast milk.

Mogamulizumab *(USAN, rINN)*

AMG-761; KM-8761; KW-0761; Mogamulizumabum; Могамулизумаб.

Immunoglobulin G1, anti-(CC chemokine receptor CCR4) (human-mouse monoclonal KW-0761 heavy chain), disulfide with human-mouse monoclonal KW-0761 κ-chain, dimer.

CAS — 1159266-37-1.
UNII — YI437801BE.

Profile

Mogamulizumab is a humanised monoclonal antibody directed against the CCR4 chemokine receptor. It is used in the treatment of relapsed or refractory adult T-cell leukaemia/lymphoma. It is also under investigation for the treatment of asthma.

Motesanib *(USAN, rINN)*

AMG-706; Motésanib; Motesanibum; Мотезаниб.

N-(3,3-Dimethyl-2,3-dihydro-1*H*-indol-6-yl)-2-[(pyridine-4-ylmethyl)amino]pyridine-3-carboxamide.

$C_{22}H_{23}N_5O$=373.5

CAS — 453562-69-1.
UNII — U1JK633AYI.

Motesanib Diphosphate *(USAN, rINN)*

AMG-706; Difosfato de motesanib; Motésanib, Diphosphate de; Motesanibi Diphosphas; Мотезаниба Дифосфат.

Motesanib phosphate (1:2).

$C_{22}H_{23}N_5O,2H_3O_4P$=569.4

CAS — 857876-30-3.
UNII — T6Q3060U91.

Profile

Motesanib is a tyrosine kinase inhibitor that targets the receptors of vascular endothelial growth factor, platelet-derived growth factor, and other growth factors, thereby inhibiting angiogenesis. It is under investigation for the treatment of solid malignancies such as non-squamous non-small cell lung cancer and breast cancer.

Muparfostat

PI-88.

CAS — 185077-23-0.

Profile

Muparfostat is a heparanase inhibitor derived from the yeast *Pichia holstii* that is under investigation for the treatment of malignancies such as liver cancer and advanced melanoma.

Naptumomab Estafenatox *(rINN)*

ABR-217620; Naptumomab Estafénatox; Naptumomabum Estafenatoxum; Наптумомаб Эстафенатокс.

Immunoglobulin fragment, anti-[trophoblast glycoprotein (TPBG, 5T4)] monoclonal 5T4 gamma1 heavy chain fragment fusion protein [*Mus musculus* VH (5T4V14: H41>P, S44>G, I69>T, V113>G)-IGHG1_CH1] - [Glycyl-Glycyl-Prolyl] -superantigen SEA/E-120 (synthetic), non-disulfide linked with monoclonal 5T4 kappa light chain [*Mus musculus* V-KAPPA (5T4V18: F10>S, T45>K, I63>S, F73>L, T77>S, L78>V, L83>A)-IGKC].

CAS — 676258-98-3.
UNII — 93T929W6LC.

Profile

Naptumomab estafenatox is a murine monoclonal antibody conjugated with a bacterial superantigen, a modified variant of staphylococcal enterotoxin A that acts as a target for T-cell activation. The antibody is directed against a tumour-specific antigen 5T4. Naptumomab estafenatox is under investigation for the treatment of renal cell carcinoma.

Nedaplatin *(rINN)*

Nédaplatine; Nedaplatino; Nedaplatinum; NSC-375101O; 254-S; Недаплатин.

cis-Diammine(glycolato-*O*¹,*O*²)platinum.

$C_2H_8N_2O_3Pt$=303.2

CAS — 95734-82-0.
UNII — 8UQ3W6JXAN.

Profile

Nedaplatin is a platinum derivative with general properties similar to those of cisplatin (p. 766.1) although it may be associated with less nephrotoxicity. It is used in the treatment of a variety of malignant neoplasms. It is given by intravenous infusion over 1 hour or more, dissolved in at least 300 mL of an appropriate infusion solution, in doses of 80 to 100 mg/m². The infusion should be followed by infusion of at least 1 litre of fluid to ensure adequate hydration and reduce the risk of renal damage.

Nelarabine *(BAN, USAN, rINN)*

506U; 506U78; GW-506U; GW-506U78; MAY; Nelarabin; Nélarabine; Nelarabinum; Nelzarabine; Неларабин.

2-Amino-9-β-D-arabinofuranosyl-6-methoxy-9*H*-purine.

$C_{11}H_{15}N_5O_5$=297.3

CAS — 121032-29-9.
ATC — L01BB07.
ATC Vet — QL01BB07.
UNII — 60158CV180.

Uses and Administration

Nelarabine is a prodrug of ara-G, a purine nucleoside analogue that is used as an antimetabolite antineoplastic in the treatment of relapsed or refractory T-cell acute lymphoblastic leukaemia and lymphoma. A dose of 1.5 g/m² is given undiluted by intravenous infusion over 2 hours in adults, on days 1, 3, and 5 of a 21-day cycle. For doses in children, see below.

Nelarabine should be stopped at the first sign of moderate to severe neurological toxicity. Dosage may be delayed for other toxicities, including haematological toxicity.

References.

Administration in children. Nelarabine is given to children for the treatment of relapsed or refractory T-cell acute lymphoblastic leukaemia and lymphoma. It is given undiluted by intravenous infusion over 1 hour, at a dose of 650 mg/m² daily for 5 consecutive days, and repeated every 21 days.

UK licensed product information recommends the above dose for those aged 21 years and younger, and the adult dose (see Uses and Administration, above) in those aged 16 years and older; in studies, for those patients in the age range of 16 to 21 years either dose has been used.

Adverse Effects, Treatment, and Precautions

Neurotoxicity is common with nelarabine and may be dose-limiting. Signs and symptoms include somnolence, confusion, convulsions, ataxia, paraesthesias, and hypoaesthesia. Severe toxicity can manifest as coma, status epilepticus (which may be fatal), craniospinal demyelination, or ascending neuropathy. Risk of neurotoxicity is increased by previous or current intrathecal chemotherapy or previous radiation to the spine or brain. Leucopenia, thrombocytopenia, anaemia, and neutropenia are common, especially in children. Full blood counts should be regularly monitored. Other common adverse events include fatigue, gastrointestinal disorders, respiratory disorders, pyrexia, headache, hypokalaemia, hypoalbuminaemia, hyperbilirubinaemia, and increased liver enzyme values. Fatal cerebral haemorrhage has been reported. Appropriate measures to avoid hyperuricaemia (especially in patients considered at risk for tumour lysis syndrome) include adequate hydration, urinary alkalinisation, and possible prophylaxis with allopurinol.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies nelarabine as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pharmacokinetics

In adult patients with leukaemia or lymphoma, nelarabine is rapidly eliminated from the plasma, with a half-life of about 30 minutes; no data are available for paediatric patients although the mean clearance is reported to be about 30% higher in children. Nelarabine is rapidly and extensively demethylated via the enzyme adenosine deaminase to the active metabolite 9-β-D-arabinofuranosylguanine (ara-G; arabinosylguanine; arabinofuranosylguanine; guanine arabinoside); both nelarabine and ara-G are widely distributed throughout the body. Ara-G has an elimination half-life from plasma of about 3 hours. Plasma protein binding is not significant. Nelarabine also undergoes hydrolysis to form methylguanine. Both methylguanine and ara-G undergo further metabolism to guanine, which is deaminated to form xanthine, itself further oxidised to uric acid. Nelarabine and ara-G are partially eliminated by the kidneys; mean apparent clearance is lower in patients with mild to moderate renal impairment.

Neratinib *(USAN, rINN)*

HKI-272; Neratinib; Neratinibum; Нератиниб.
(2*E*)-*N*-[4-({3-Chloro-4-[(pyridine-2-yl)methoxy]phenyl}amino)-3-cyano-7-ethoxyquinolin-6-yl]-4-(dimethylamino)but-2-enamide.
$C_{30}H_{29}ClN_6O_3$=557.1
CAS — 698387-09-6.
UNII — JJH94R3PWB.

Profile

Neratinib is an orally active tyrosine kinase inhibitor of the epidermal growth factor receptor (EGFR) family, including HER1, HER2 and HER4. It is under investigation for the treatment of breast cancer and other solid tumours.

CAS — 923288-90-8.
ATC — L01XE08.
ATC Vet — QL01XE08.
UNII — K37N7BYX3X (anhydrous nilotinib hydrochloride); 5JHU0N1R6K (nilotinib hydrochloride monohydrate).

Uses and Administration

Nilotinib is a potent inhibitor of BCR-ABL tyrosine kinase. Nilotinib is used for the treatment of adults with Philadelphia chromosome-positive chronic myeloid leukaemia (CML; p. 694.2), both as first-line treatment of chronic phase, and in the treatment of chronic or accelerated phase in those who are resistant to, or intolerant of, previous imatinib-based treatment. Nilotinib is given orally as the hydrochloride, but doses are expressed in terms of the base; 100 mg of nilotinib is equivalent to about 110 mg of nilotinib hydrochloride monohydrate. Doses are given at least 1 hour before or 2 hours after food. Capsules should usually be swallowed whole, but if patients have difficulty swallowing then capsules can be opened and the contents dispersed in one teaspoon of apple sauce; the mixture should be taken immediately (within 15 minutes). *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

For first-line treatment of chronic phase CML, nilotinib hydrochloride is given in an oral dose equivalent to nilotinib 300 mg twice daily. In the treatment of patients with chronic or accelerated phase CML resistant to prior treatment or where there has been intolerance to therapy, a dose equivalent to nilotinib 400 mg twice daily is used. If a dose is missed, no catch-up dose is recommended; the next dose should be taken as usual. Treatment may be continued until disease progression. Doses may need to be adjusted or treatment withheld for toxicity, see below. For doses in hepatic impairment, see below.

Nilotinib is mainly metabolised by the cytochrome P450 isoenzyme CYP3A4. Use with strong CYP3A4 inhibitors or inducers should be avoided. If a strong CYP3A4 inhibitor is required, nilotinib treatment should be interrupted. If a strong CYP3A4 inhibitor must be used with nilotinib, US licensed product information suggests reducing the dose of nilotinib as follows:

- In first-line treatment of chronic phase CML, consider a dose reduction to 200 mg once daily
- In the treatment of patients with chronic or accelerated phase CML resistant to prior treatment or where there has been intolerance to therapy, consider a dose reduction to 300 mg once daily

Once the inhibitor is stopped, a washout period should be allowed before nilotinib is increased to the original dose.

Increasing the dose of nilotinib is considered unlikely to compensate for the loss of nilotinib exposure when strong CYP3A4 inducers are used, and their use together is not recommended.

Nilotinib has been investigated for the treatment of gastrointestinal stromal tumours.

Administration in hepatic impairment. Exposure to nilotinib is increased in hepatic impairment and US licensed product information recommends a lower initial dose in patients with impairment at baseline. For first-line treatment of chronic phase chronic myeloid leukaemia (CML), those with mild, moderate, or severe impairment (Child-Pugh classes A, B, and C, respectively) are given an initial oral dose equivalent to nilotinib 200 mg twice daily which can be increased up to the usual dose of 300 mg twice daily if tolerated. In the treatment of patients with chronic or accelerated phase CML resistant to prior treatment or where there has been intolerance to therapy, those with mild or moderate impairment are given an initial oral dose equivalent to nilotinib 300 mg twice daily which can be increased up to the usual dose of 400 mg twice daily if tolerated; those with severe impairment are given an initial oral dose equivalent to nilotinib 200 mg twice daily which can be increased up to 300 mg twice daily, and then 400 mg twice daily, as tolerated.

UK licensed product information states that dose adjustments of nilotinib are not necessary in hepatic impairment, although caution is advised.

Dose adjustments may also be required if liver function deteriorates during treatment, see Administration in Toxicity, below.

Administration in toxicity. Nilotinib should be withheld or the dose reduced if haematological toxicity that is not related to the underlying leukemia occurs during treatment of chronic myeloid leukaemia (CML). In chronic phase CML (either when nilotinib is used first-line or when there has been resistance to or intolerance of prior treatment), nilotinib should be withheld when the absolute neutrophil count (ANC) falls to < 1000 cells/mm³ and/or platelets to $< 50\,000$ cells/mm³. If values increase above these levels within 2 weeks, treatment may be resumed using the previous oral dose, but if blood counts remain low for more than 2 weeks, a dose reduction to 400 mg once daily may be required.

Accelerated phase CML in patients that are resistant to or intolerant of prior treatment is managed as for chronic phase in the USA (see above). However, in the UK, nilotinib is withheld when the ANC falls to < 500 cells/mm³ and/or platelets to $< 10\,000$ cells/mm³. If the ANC increases to > 1000 cells/mm³ and/or platelets increase to $> 20\,000$ cells/mm³ within 2 weeks, treatment may be

resumed using the previous dose, but if blood counts remain low for more than 2 weeks, a dose reduction to 400 mg once daily may be required.

Nilotinib treatment may need to be withheld or the dose reduced to 400 mg once daily for increases (grade 3 or above) in serum lipase or amylase, bilirubin, and/or liver enzymes; if withheld, treatment may be restarted at 400 mg once daily when values return to grade 1 or below. Similarly, for other moderate to severe non-haematological toxicity, nilotinib should be withheld, and treatment restarted at 400 mg once daily when toxicity has resolved; if appropriate the dose may be increased back up to the usual recommended dose (see Uses and Administration, p. 835.2).

Nilotinib can prolong the QT interval and US licensed product information recommends withholding treatment for a corrected QT (QTcF) of > 480 milliseconds. If the QTcF interval returns to < 450 milliseconds and to within 20 milliseconds of the baseline value within 2 weeks, nilotinib can be restarted at the previous dose. If the QTcF interval is between 450 and 480 milliseconds after 2 weeks, the dose should be restarted at a lower dose of 400 mg once daily, and treatment stopped if the QTcF increases again to > 480 milliseconds. An ECG should be carried out about 7 days after any dose adjustment.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The most common adverse effects of nilotinib are rash, pruritus, fatigue, headache, and gastrointestinal disturbances. Other common adverse effects include fever, alopecia, asthenia, muscle spasms, myalgia, arthralgia, pain including musculoskeletal or chest pain, oedema, folliculitis, papilloma, insomnia, anxiety, dizziness, paraesthesia, conjunctivitis, dry eye, vertigo, flushing, dyspnoea, cough, hyperhidrosis, dry skin, urticaria, and acne. Myelosuppression occurs (commonly thrombocytopenia, neutropenia, and anaemia), but is generally reversible and can be managed by withholding therapy or dose reduction, see Administration in Toxicity, p. 835.3. Complete blood counts should be performed every fortnight for the first 2 months and monthly thereafter. Nilotinib can prolong the QT interval, which may result in ventricular tachycardia (torsade de pointes), causing syncope, seizures, and/or death; treatment may be withheld or the dose reduced (p. 835.3). Nilotinib should not be used in patients at high risk of developing QT prolongation such as those with hypokalaemia or hypomagnesaemia, congenital long QT syndrome, uncontrolled or significant cardiac disease, or those taking other medicines that prolong the QT interval. Taking nilotinib with substances that increase the concentration of nilotinib, such as food or inhibitors of the cytochrome P450 isoenzyme CYP3A4, may increase the risk of QT prolongation, see Interactions, below. ECGs should be obtained at baseline, 1 week after starting nilotinib, and periodically thereafter including after dose adjustments. Other cardiac adverse effects include arrhythmias, palpitations, angina, hypertension, cardiac failure, pericarditis,and myocardial infarction. Sudden death has occurred rarely and may be related to ventricular repolarisation abnormalities. Thrombotic disorders or haemorrhage have been reported.

Tumour lysis syndrome has occurred rarely, and adequate hydration and treatment of elevated uric acid concentrations are recommended before starting nilotinib. Electrolyte abnormalities can occur and electrolytes should be monitored during therapy. Hepatotoxicity has been reported. Pancreatitis can occur and serum lipase should be monitored; caution is recommended in patients with a history of pancreatitis. Other adverse effects that have been reported include pleural or pericardial effusion, interstitial lung disease, mucosal ulceration or inflammation, hypersensitivity, thyroid and/or parathyroid disorders, dyslipidaemia, hyperglycaemia or hypoglycaemia, gout, depression, amnesia, tremor, peripheral neuropathy, chorioretinopathy, tinnitus, visual or hearing impairment, epistaxis, urinary disorders, erectile dysfunction, gynaecomastia, menorrhagia, erythema multiforme, erythema nodosum, palmar-plantar erythrodysesthesia, photosensitivity, and skin changes such as discoloration, hyperpigmentation, exfoliation, hypertrophy, or atrophy.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies nilotinib as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/09/11)

Interactions

Nilotinib is mainly metabolised by the cytochrome P450 isoenzyme CYP3A4, and use with strong inhibitors or inducers of CYP3A4 should be avoided. If strong CYP3A4 inhibitors must be used, dose adjustments may be required (see Uses and Administration, p. 835.2). Grapefruit juice may increase plasma concentrations of nilotinib and should be avoided. St John's wort should also be avoided. *In vitro*, nilotinib is a relatively strong inhibitor of CYP3A4, CYP2C8, CYP2C9, CYP2D6, and of the uridine diphosphate glucuronosyltransferase isoenzyme UGT1A1; exposure to substrates of these enzymes may be altered by nilotinib. Nilotinib is a substrate for P-glycoprotein and exposure may be affected by drugs that modulate P-glycoprotein. Nilotinib should not be given with drugs that prolong the QT interval.

The solubility of nilotinib is affected by pH, with a reduced solubility at higher pH, and drugs that suppress gastric acid may lead to lower exposure to nilotinib. However, nilotinib absorption was only modestly decreased by esomeprazole despite a marked increase in gastric pH, and nilotinib may be used with esomeprazole or other proton pump inhibitors.

References.

1. Yin OQP, *et al.* Effect of the proton pump inhibitor esomeprazole on the oral absorption and pharmacokinetics of nilotinib. *J Clin Pharmacol* 2010; **50**: 960–7.
2. Tanaka C, *et al.* Effects of rifampin and ketoconazole on the pharmacokinetics of nilotinib in healthy participants. *J Clin Pharmacol* 2011; **51**: 75–83.

Pharmacokinetics

Peak plasma concentrations occur about 3 hours after an oral dose of nilotinib. Bioavailability is about 30% and is increased almost twofold when given with food. Plasma protein binding is about 98%. The apparent elimination half-life is about 17 hours. It is metabolised in the liver via oxidation and hydroxylation, in which cytochrome P450 isoenzyme CYP3A4 plays an important role. Most of an oral dose is eliminated unchanged in the faeces within 7 days.

ATC — L02BB02.

ATC Vet — QL02BB02.

UNII — 51G6I88902.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Nilutamide). A white or almost white powder. Very slightly soluble in water; freely soluble in acetone; soluble in anhydrous ethanol. Protect from light.

Uses and Administration

Nilutamide is a nonsteroidal anti-androgen that is used similarly to flutamide (p. 798.2) in the treatment of prostatic carcinoma (p. 712.3). It is given orally in a dose of 300 mg daily, usually starting on the same day as orchidectomy or starting treatment with a gonadorelin analogue. Dosage may be reduced to 150 mg daily after 1 month.

4. Nakabayashi M, *et al.* Efficacy of nilutamide as secondary hormonal therapy in androgen-independent prostate cancer. *BJU Int* 2005; **96**: 783–6.

Adverse Effects and Precautions

As for Flutamide, p. 798.3. Interstitial pneumonitis has occurred in patients receiving nilutamide, and the drug is contra-indicated in those with severe respiratory insufficiency.

Effects on the eyes. Reversible visual disturbances, particularly delayed dark adaptation, have been associated with nilutamide.[1-3] Although some consider such visual disturbances to be mild and generally well tolerated,[4] others suggest that these, together with alcohol intolerance and, more seriously, effects on the lung, mean that other nonsteroidal anti-androgens should be preferred.[5]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies nilutamide as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Interactions

Patients receiving nilutamide may exhibit intolerance to alcohol.

Pharmacokinetics

Nilutamide is rapidly and completely absorbed from the gastrointestinal tract. It is extensively metabolised although it may inhibit its own metabolism to some extent after multiple doses. About 60% of an oral dose of nilutamide is eliminated in the urine and less than 10% in the faeces, with an elimination half-life of 41 to 49 hours.

CAS — 828933-51-3.

Profile

Nimotuzumab is a humanised monoclonal antibody that binds to the epidermal growth factor receptor (EGFR). It may be used in some countries for the treatment of glioma and cancers of the head and neck. It is also under investigation for pancreatic cancer, non-small cell lung cancer, oesophageal cancer, and gastric cancer.

ATC — L01AD06.

ATC Vet — QL01AD06.

UNII — DFR965WKBU.

Profile

Nimustine is a nitrosourea antineoplastic with actions and uses similar to those of carmustine (p. 761.2). It is licensed for use in the treatment of malignant glioma. Nimustine hydrochloride is given in doses of 2 to 3 mg/kg or 90 to

100 mg/m² as a single dose by slow intravenous injection, repeated at intervals of 6 weeks depending on haematological response.

$C_{172}H_{204}N_{62}Na_{17}O_{91}P_{17}S_{17}$=6058.3

CAS — 190977-41-4.

UNII — SH55B0RQ9K.

NOTE. The name Genasense has been used as a trade mark for oblimersen sodium.

Profile

Oblimersen sodium is an antisense oligonucleotide that blocks the production of BCL-2, a mitochondrial protein that prevents apoptosis. It is under investigation for the treatment of various malignant neoplasms, including leukaemias and malignant melanoma.

Ofatumumab *(BAN, USAN, rINN)*

2F2; GSK-1841157; HuMax-CD20; Ofatumumabum; Офатумумаб.

Immunoglobulin G1, anti-(human CD20 (antigen))(human monoclonal HuMax-CD20 heavy chain), disulfide with human monoclonal HuMax-CD20 κ-chain, dimer.

CAS — 679818-59-8.

ATC — L01XC10.

ATC Vet — QL01XC10.

UNII — M95KG522R0.

Uses and Administration

Ofatumumab is a human anti-CD20 monoclonal antibody that is used in the treatment of refractory chronic lymphocytic leukaemia (p. 693.3) in patients refractory to fludarabine and alemtuzumab. An initial intravenous infusion of ofatumumab 300 mg is given for the first dose, followed after 1 week by 2 g once weekly for a further 7 doses. After a 4- or 5-week interval, 2 g is given every 4 weeks for a further 4 doses. The drug is given via an infusion pump and an in-line 0.2-micrometre filter, and is diluted in 1 litre of sodium chloride 0.9% (giving a concentration of 0.3 mg/mL for the first infusion and 2 mg/mL for subsequent infusions). An initial infusion rate of 12 mL/hour is recommended for the first 2 infusions; this rate can be doubled every 30 minutes until a rate of 200 mL/hour is reached, providing no infusion reactions occur. Subsequent doses may be begun at a rate of 25 mL/hour, and doubled every 30 minutes to a maximum of 400 mL/hour. The infusion rate should be reduced if infusion reactions occur, and premedication with a corticosteroid, analgesic, and an antihistamine is recommended, see Adverse Effects below.

It is also under investigation for non-Hodgkin's lymphoma, rheumatoid arthritis, and multiple sclerosis.

Adverse Effects, Treatment, and Precautions

As for Rituximab, see p. 854.1. Premedication with an intravenous corticosteroid, an oral analgesic, and an oral or intravenous antihistamine is recommended 30 to 120 minutes before every ofatumumab infusion; the corticosteroid dose may be reduced for later infusions if a severe infusion reaction did not occur with the previous dose. If an infusion-related adverse effect does occur, treatment should be interrupted until the patient is stable. After a mild or moderate reaction, the infusion should be restarted either at half the infusion rate being used at the time of the reaction, or the usual initial rate (12 mL/hour) if this was being used at the time of the reaction. For severe reactions, treatment should either be restarted at 12 mL/hour, regardless of the rate being used before (US recommendation for grade 3 reactions and UK recommendation), or treatment stopped (US recommendation for grade 4 reactions). If restarted, infusion rates can then be increased as usual, according to tolerance (see Uses and Administration, above).

Other adverse effects that have occurred with ofatumumab include agranulocytosis, red cell aplasia, coagulopathy, and hyperhidrosis.

Pharmacokinetics

Peak plasma concentrations of ofatumumab occur at or shortly after the end of the infusion. Ofatumumab is eliminated by proteolytic enzymes and via binding to B-cells. There is a rapid and sustained depletion of CD20 B-cells after the first infusion, leaving a reduced number for binding at subsequent infusions. As a result, clearance and half-life decrease with repeated dosing, and there is increased exposure to ofatumumab, although there is considerable interindividual variation. The mean half-life is reported to be about 1.3 days after the first infusion, and about 14 days after the twelfth.

CAS — 26833-87-4.

ATC — L01XX40.

ATC Vet — QL01XX40.

UNII — 6FG804155B.

NOTE. The name Ceflatonin has been used as a trade mark for omacetaxine mepesuccinate.

Pharmacopoeias. In *Chin.*

Uses and Administration

Omacetaxine mepesuccinate is a semisynthetic formulation of homoharringtonine, which is an alkaloid derived from the tree *Cephalotaxus harringtonia*, and related species. It is thought to induce apoptosis by inhibition of protein synthesis.

It is used for the treatment of chronic myeloid leukaemia (p. 694.2) when there is resistance or intolerance to tyrosine kinase inhibitors. The recommended starting dose of omacetaxine mepesuccinate is 1.25 mg/m² twice daily, by subcutaneous injection, for 14 consecutive days of a 28-day cycle. Cycles should be repeated every 28 days until there is a haematological response. The maintenance dose should be 1.25 mg/m² twice daily for 7 consecutive days of a 28-day cycle, repeated as long as there is clinical benefit. Complete blood counts should be performed weekly during induction and initial maintenance therapy, and every two weeks or as needed after initial maintenance cycles; the dose should be adjusted when toxicity occurs (see Administration in Subsequent Cycles, p. 838.1).

Omacetaxine mepesuccinate has also been tried in the treatment of acute leukaemias and other neoplastic disorders. The related compounds harringtonine, isoharringtonine, and deoxyharringtonine have also been investigated.

5. Kim TD, *et al.* Omacetaxine mepesuccinate for the treatment of leukemia. *Expert Opin Pharmacother* 2011; 12: 2381–92.

Administration in subsequent cycles. If the absolute neutrophil count (ANC) falls to < 500 cells/mm³ or the platelet count falls to < 50 000 cells/mm³ during treatment with omacetaxine mepesuccinate, then the next cycle should be delayed until the ANC is ≥ 1000 cells/mm³ and the platelet count ≥ 50 000 cells/mm³. The number of dosing days should also be reduced by 2 days for the next cycle.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Omacetaxine mepesuccinate causes myelosuppression, resulting in thrombocytopenia, neutropenia, and anaemia in a significant proportion of patients. Severe thrombocytopenia has resulted in gastrointestinal haemorrhage and cases of fatal cerebral haemorrhage. Other common adverse effects include diarrhoea, nausea, fatigue, asthenia, arthralgia, headache, alopecia, rash, and convulsions. Glucose intolerance and severe hyperglycaemia have been reported. Injection site reactions can occur.

Complete blood counts should be monitored regularly. Blood-glucose should also be monitored, particularly in patients with diabetes or risk factors for diabetes.

Pharmacokinetics

Peak plasma concentrations of omacetaxine mepesuccinate occur about 30 minutes after subcutaneous injection. Plasma protein binding is less than or equal to 50%. Omacetaxine mepesuccinate is hydrolysed by plasma esterases, but the major elimination route is unknown. The mean elimination half-life after subcutaneous use is about 6 hours.

$C_8H_{14}N_2O_4Pt$=397.3.

CAS — 61825-94-3.

ATC — L01XA03.

ATC Vet — QL01XA03.

UNII — 04ZR38536J.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Oxaliplatin). A white or almost white, crystalline powder. Slightly soluble in water; practically insoluble in dehydrated alcohol; very slightly soluble in methyl alcohol.

USP 36: (Oxaliplatin). A white to off-white crystalline powder. Slightly soluble in water; practically insoluble in alcohol; very slightly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Incompatibility. Licensed product information states that oxaliplatin should not be mixed with chloride-containing solutions (including sodium chloride) or alkaline drugs or solutions. In particular, oxaliplatin should not be mixed with fluorouracil or any trometamol salts. While oxaliplatin may be infused through a Y-site with folinic acid (in glucose 5% solution), they may not be mixed in the same infusion bag, and folinic acid must not contain trometamol as an excipient. The infusion line should be flushed with glucose 5% before giving any other medication. Oxaliplatin may degrade on contact with aluminium, and injection equipment containing aluminium should not be used.

Stability. UK licensed product information states that oxaliplatin must be diluted in glucose 5% to give a concentration not less than 200 micrograms/mL. From a microbiological point of view, the infusion preparation should be used immediately; the infusion should not be stored for longer than 24 hours at 2 degrees to 8 degrees unless it has been prepared in controlled and validated aseptic conditions. Chemical and physical stability has been shown for 48 hours at 2 degrees to 8 degrees, and for 24 hours at 25 degrees. US licensed product information states that, after dilution in 250 to 500 mL of glucose 5%, oxaliplatin infusion solutions have a shelf-life of 6 hours at room temperature (20 degrees to 25 degrees) and up to 24 hours when refrigerated (2 degrees to 8 degrees), and that protection from light is not required.

A study[1] found that oxaliplatin solutions at 700 micrograms/mL in polyolefin infusion bags of glucose 5% were chemically stable for at least 30 days at both 3 degrees to 7 degrees and 20 degrees to 24 degrees without regard to light. Another study[2] found that oxaliplatin solutions at 250 micrograms/mL in 5% glucose, in polyolefin bags, were stable at 4 degrees as well as at room temperature (either protected or unprotected from light) for 90 days. Additionally, oxaliplatin solutions diluted to 200 micrograms/mL and 1.3 mg/mL in glucose 5% were found to be stable in PVC, polyethylene, and polypropylene infusion bags for at least 14 days at both 4 degrees and 20 degrees, either protected or unprotected from light.[3]

Uses and Administration

Oxaliplatin is a platinum-containing complex similar to cisplatin (see p. 766.1). It is given with fluorouracil and folinic acid in the treatment of metastatic colorectal cancer and in the adjuvant treatment of stage III (Dukes C) colon cancer (p. 706.3). The recommended dose is 85 mg/m² by intravenous infusion over 2 to 6 hours, dissolved in 250 to 500 mL of glucose 5%. The dose may be repeated at intervals of 2 weeks if toxicity permits, reduced according to tolerance. In the adjuvant setting, oxaliplatin is given for 12 cycles. After persistent neurotoxicity or recovery from severe adverse effects licensed product information recommends an initial reduction to 65 mg/m² in metastatic colorectal cancer, and to 75 mg/m² when given as adjuvant treatment. Oxaliplatin should always be given before fluoropyrimidines.

Oxaliplatin is under investigation for the treatment of ovarian and lung cancer. A liposomal formulation of oxaliplatin is in development.

Administration in the elderly. A review[1] concluded that there are no data to support dose reduction of oxaliplatin based on age alone, other than any dosage adjustment considered necessary for renal impairment (see Administration in Renal Impairment, below).

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; 25: 1832–43.

Administration in renal impairment. The primary route of platinum elimination is renal, and clearance of platinum is decreased in patients with renal impairment. However, a study determined that increased platinum exposure in patients with renal impairment was not associated with increased oxaliplatin toxicity. Dose reduction was not considered to be necessary in patients with mild to moderate renal impairment (as defined by creatinine clearance of 20 mL/minute or more).[1] UK licensed product information concurs that no dose adjustment is necessary in mild to moderate renal impairment, but contra-indicates the use of oxaliplatin in severe renal impairment (defined as creatinine clearance of less than 30 mL/minute), due to lack of data.

1. Takimoto CH, *et al.* Dose-escalating and pharmacological study of oxaliplatin in adult cancer patients with impaired renal function: a National Cancer Institute organ dysfunction working group study. *J Clin Oncol* 2003; 21: 2664–72.

Adverse Effects and Precautions

The adverse effects of oxaliplatin are similar to those of cisplatin (p. 767.1) but nausea and vomiting, nephrotoxicity, and myelosuppression, seem to be less marked. Raised liver enzyme values may occur. Neurotoxicity can be dose-limiting. Peripheral neuropathy occurs in 85 to 95% of patients given oxaliplatin; pain, functional impairment, and loss of tendon reflexes may develop. Pulmonary fibrosis, potentially fatal, has also been reported. Extravasation of oxaliplatin can cause local pain and inflammation; complications may sometimes be severe, including necrosis.

Neurological examinations should be carried out at regular intervals during treatment and the dose should be reduced if symptoms are prolonged or severe. Regular blood counts should be performed during treatment and courses should not be repeated until blood counts have recovered (see also Bone-marrow Depression, p. 730.3). Oxaliplatin should not be given to patients with pre-existing sensory neuropathies or myelosuppression, nor to those with severe renal impairment. Renal function and toxicity should be carefully monitored in those with more moderate degrees of renal impairment.

Patients are recommended to use appropriate contraceptive measures during treatment and for 6 months after stopping treatment for men and for 4 months for women.

Effects on the blood. Acute haemolysis, with[1-3] and without[4] anaemia, has been reported with the use of oxaliplatin. The reactions were considered to be immune-mediated. Evan's syndrome (immune-mediated thrombocytopenia and haemolytic anaemia) has also been reported,[7] as has sudden onset of pancytopenia with resultant intracranial haemorrhage.[8]

8. Teng CJ, *et al.* Sudden-onset pancytopenia with intracranial hemorrhage after oxaliplatin treatment: a case report and literature review. *Jpn J Clin Oncol* 2011; 41: 125–9.

Effects on the liver. The development of ascites, portal hypertension, and hepatic lesions in a patient with colorectal cancer was considered to be due to oxaliplatin; metastatic or recurrent cancer had been originally suspected.[1]

1. Tisman G, *et al.* Oxaliplatin toxicity masquerading as recurrent colon cancer. *J Clin Oncol* 2004; 22: 3202–4.

Effects on the nervous system. Neurological toxicity is the principal dose-limiting adverse effect with oxaliplatin.[1-4] The toxicity is biphasic:

- acute paraesthesias or dysaesthesias of the extremities, triggered or exacerbated by cold, are seen in 85 to 95% of patients within hours of infusion, but are normally mild and resolve within hours or days. Some patients also

have distressing laryngopharyngeal symptoms, such as difficulty in breathing or swallowing.
- with increasing cumulative dose, peripheral sensory symptoms increase in duration and intensity. Symptoms are sometimes associated with pain and cramps, and may progress to functional impairment (loss of fine sensorimotor coordination). Dosage reduction may be required, but in clinical practice the onset of functional impairment often occurs after the maximum response to therapy has been attained. Cumulative neurotoxicity is reversible in most cases, and about 80% of patients exhibit symptom regression within 4 to 6 months.

The incidence of neurotoxicity may be higher when oxaliplatin is given with fluorouracil. There is some evidence that more prolonged infusion of oxaliplatin can reduce acute toxicity, particularly laryngopharyngeal symptoms. Antiepileptics such as carbamazepine (see Neuropathic Pain, p. 513.2) or gabapentin have been investigated in the management of oxaliplatin-induced neurotoxicity, although results have been inconclusive.[5] Other drugs that have been tried include amifostine, glutathione, acetylcarnitine, thioctic acid, celecoxib, and ginkgo biloba extract.[5] Initial results have been promising for some of these substances,[5] but, similarly to cisplatin (see p. 767.3), conclusive data are lacking for most interventions. Intravenous calcium gluconate and magnesium chloride infusions have been used to prevent acute oxaliplatin neuropathy with good initial results; similarly, intravenous calcium gluconate and magnesium sulfate have been reported to dramatically improve oxaliplatin-associated neuropathy.[6-8] However, a study designed to evaluate potential reduction of cumulative neurotoxicity associated with oxaliplatin, using calcium and magnesium salts, was terminated after those patients receiving calcium and magnesium reported a significantly lower response to chemotherapy (which consisted of oxaliplatin, folinic acid, fluorouracil, and bevacizumab). Although these results need confirmation, the possibility that calcium and magnesium may reduce the activity of certain drugs in the treatment of colorectal cancer should be considered.[9] Others[10,11] have contended that calcium and magnesium therapy does not affect the antitumour efficacy of oxaliplatin-containing regimens; further studies are planned.

REVERSIBLE POSTERIOR LEUKOENCEPHALOPATHY SYNDROME. Reversible posterior leukoencephalopathy syndrome (RPLS) was diagnosed in a woman given oxaliplatin with bevacizumab, and capecitabine. She tolerated further therapy with bevacizumab and irinotecan with no complications. The authors attributed the RPLS to oxaliplatin.[1]

Extravasation. Although oxaliplatin was originally considered to be non-vesicant, there have been reports of extravasation causing inflammation, sclerosis, or, in some cases, severe necrosis.[1-4] Some consider it to be a vesicant drug,[1,2] although others state oxaliplatin extravasation to be less harmful than that of more classic vesicants.[4]

For discussion of the management of extravasation, see under Treatment of the Adverse Effects of Antineoplastics, p. 731.3.

Hypersensitivity. Hypersensitivity reactions, including anaphylaxis, have been reported with oxaliplatin,[1-18] usually after several cycles of treatment. Symptoms include hypotension, tachycardia, dyspnoea, burning sensations, pruritus, erythema, sweating, and dizziness.[1,2,7,8] Rashes have also been reported[5,6,12] as have fever and chills.[9,10] While the mechanism of hypersensitivity to oxaliplatin is not clear, it has been suggested that reactions are characterised by development of symptoms during or shortly after the infusion, and are possibly due to a type I IgE-mediated reaction.[7,10] Idiosyncratic or infusional reactions, which are delayed until hours after the infusion,[6,10] are considered to be associated with cytokine release.[7,10] Cases have generally resolved on stopping oxaliplatin and giving appropriate treatment. Acute thrombocytopenia, occurring after the onset of hypersensitivity, has been reported in 2 patients,[15] both of whom were found to have oxaliplatin-dependent IgG platelet antibodies; see also Effects on the Blood, p. 838.3.

Prophylaxis before further oxaliplatin therapy, with corticosteroids and/or antihistamines, has shown variable efficacy.[4-7,9,10] Desensitisation protocols using dilute solutions and longer infusion times have been reported to be successful.[10,11,13,14] For the successful use of cisplatin in a patient hypersensitive to oxaliplatin see p. 768.1.

Intradermal skin testing has been used to identify patients with suspected hypersensitivity to oxaliplatin; however, in some patients with negative skin tests, reactions have occurred upon rechallenge.[6,8]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies oxaliplatin as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/08/11)

Interactions

For reference to the effect of oxaliplatin on fluorouracil, see Antineoplastics, p. 797.3.

Pharmacokinetics

After intravenous doses, oxaliplatin is widely distributed throughout the body. It binds irreversibly to red blood cells, which can prolong the half-life of the drug. The mean terminal half-life has been variously stated to be 273 hours and 391 hours.

Oxaliplatin is extensively metabolised to both inactive and active compounds and is mainly excreted in the urine.

Pharmacopoeial Preparations

USP 36: Oxaliplatin for Injection; Oxaliplatin Injection.

Paclitaxel *(BAN, USAN, rINN)*

BMS-181339-01; NSC-125973; Paclitaxelum; Paklitakseeli; Paklitaksel; Paklitaxel; Taxol; Taxol A; Паклитаксел.

(2*S*,5*R*,7*S*,10*R*,13*S*)-10,20-Bis(acetoxy)-2-benzoyloxy-1,7-dihydroxy-9-oxo-5,20-epoxytax-11-en-13-yl (3*S*)-3-benzoylamino-3-phenyl-o-lactate.

$C_{47}H_{51}NO_{14}$=853.9

CAS — 33069-62-4.

ATC — L01CD01.

ATC Vet — QL01CD01.

UNII — P88XT4IS4D.

NOTE. Paclitaxel was formerly referred to as taxol, but the use of this name is now limited, as Taxol is a trademark.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Paclitaxel). Isolated from natural sources or produced by fermentation or by a semisynthetic process. A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in dichloromethane; soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 36: (Paclitaxel). A white to off-white powder. Insoluble in water; soluble in alcohol. Store in airtight containers at a temperature between 20 degrees and 25 degrees. Protect from light.

Incompatibility. The vehicle for conventional paclitaxel injection, which contains alcohol and polyoxl castor oil, was found to leach the plasticiser diethylhexyl phthalate (DEHP) from some plastic giving sets.[1,2] Consequently, licensed product information recommends the use of non-PVC containers and giving sets; the use of filter devices which incorporate short inlet and/or short outlet plasticised PVC tubing has not resulted in significant leaching of DEHP.

Paclitaxel was found to be compatible with doxorubicin for at least 24 hours, but microcrystalline precipitation of paclitaxel occurred after 3 to 5 days.[3] For mention of the incompatibility of paclitaxel and cisplatin see p. 766.1.

Uses and Administration

Paclitaxel is a taxane originally derived from the bark of the Pacific yew tree *Taxus brevifolia* (Taxaceae), and now obtained semisynthetically from a taxane precursor derived from the needles of the European yew, *Taxus baccata*. Paclitaxel's antineoplastic action arises from induction of microtubule formation and stabilisation of microtubules, thereby disrupting normal cell division in the G_2 and M phases of the cell cycle.

Paclitaxel is used for the primary treatment of advanced ovarian cancer (p. 711.2) with cisplatin or carboplatin, and for secondary treatment, usually after failure of standard platinum-containing therapy. In the treatment of node-positive breast cancer (p. 702.1), paclitaxel is used for adjuvant therapy after anthracycline-containing chemotherapy. In locally advanced or metastatic breast cancer, it is used first-line with an anthracycline, or as a second-line single-agent, usually after failure of anthracycline-based therapy. In patients with locally advanced or metastatic disease who overexpress HER2 (human epidermal growth receptor 2) it may be used with trastuzumab as initial therapy. Paclitaxel is used with cisplatin or carboplatin, for the primary treatment of non-small cell lung cancer (p. 710.2) in patients who are not candidates for potentially curative surgery and/or radiotherapy. In metastatic adenocarcinoma of the pancreas (p. 712.1) it is used first-line with gemcitabine. It may be used for the second-line treatment of AIDS-related Kaposi's sarcoma (p. 718.1), and has been tried in other neoplasms including cancers of the head and neck, and relapsed germ-cell tumours.

The conventional formulation of paclitaxel with polyoxyl castor oil and alcohol is usually given intravenously. It is diluted, usually with sodium chloride 0.9% or glucose 5%, to a final concentration of 0.3 to 1.2 mg/mL, in a non-PVC container and given through an in-line filter (of not greater than 0.22 micrometres). In licensed regimens it is generally given at 3-week intervals although there is increasing evidence that use at smaller intervals of 1 week may be advantageous (see Administration, below). An injectable suspension of albumin-bound paclitaxel nanoparticles (*Abraxane; Celgene, UK and USA;* ABI-007) is also available. It is usually given intravenously over 30 minutes. PVC or non-PVC containers may be used; an in-line filter is not necessary.

The recommended dose of conventional paclitaxel for the primary treatment of **ovarian cancer** is 135 mg/m^2 infused over 24 hours, followed by cisplatin, and repeated at 3-week intervals. Alternatively 175 mg/m^2 may be infused over 3 hours, followed by cisplatin, every 3 weeks. For the secondary treatment of ovarian cancer, the suggested dose as a single agent is 135 or 175 mg/m^2 infused over 3 hours once every 3 weeks.

Paclitaxel has also been given intraperitoneally for the treatment of ovarian cancer.

For **breast cancer**, an intravenous dose of conventional paclitaxel 175 mg/m^2 infused over 3 hours once every 3 weeks is recommended for adjuvant treatment (for 4 courses), for second-line monotherapy, and for first-line treatment with trastuzumab; paclitaxel is given the day after the first dose of trastuzumab, or immediately after subsequent doses if well-tolerated. When used first-line with doxorubicin, paclitaxel 220 mg/m^2 is infused over 3 hours once every 3 weeks; the dose is given 24 hours after doxorubicin.

Albumin-bound paclitaxel nanoparticles are also used for the treatment of refractory or relapsed metastatic breast cancer. The dose is 260 mg/m^2 given intravenously over 30 minutes every 3 weeks.

In **non-small cell lung cancer**, the recommended dose of conventional paclitaxel is 135 mg/m^2 over 24 hours, or 175 mg/m^2 over 3 hours, followed by cisplatin, and repeated at 3-week intervals.

Albumin-bound paclitaxel nanoparticles may also be used with carboplatin as a first-line option for locally advanced or metastatic non-small cell lung cancer. A dose of 100 mg/m^2 is infused intravenously over 30 minutes on days 1, 8, and 15 of a 21-day cycle.

For the first-line treatment of metastatic **pancreatic adenocarcinoma**, albumin-bound paclitaxel nanoparticles are given in a dose of 125 mg/m^2 infused intravenously over 30 to 40 minutes, and followed immediately after by gemcitabine, on days 1, 8, and 15 of a 28-day cycle.

A dose of conventional paclitaxel 135 mg/m^2 over 3 hours once every 3 weeks has been suggested for AIDS-related **Kaposi's sarcoma**. Alternatively, 100 mg/m^2 over 3 hours every 2 weeks may be given, especially in patients with poor performance status.

Regular blood counts should be performed, and dosage should not be given or repeated until the neutrophil and platelet counts are at acceptable levels; see Administration in Subsequent Cycles, below. Pretreatment with corticosteroids, antihistamines, and histamine H_2-antagonists is needed for the conventional formulation of paclitaxel, but not for the albumin-bound nanoparticle formulation.

The dose of paclitaxel may need to be reduced in patients with hepatic impairment (see below).

Various formulations have been developed to avoid the use of polyoxyl castor oil and improve the efficacy and safety of paclitaxel. In addition to the albumin-bound formulation referred to above, formulations in development include paclitaxel linked to docosahexaenoic acid (DHA-paclitaxel) or biodegradable polymers (such as paclitaxel poliglumex, CT-2103), micellar and liposomal formulations, and an oral dosage form. An injectable gel containing a modified-release formulation of paclitaxel is also under investigation, for direct injection into tumours.

Paclitaxel-releasing stents may be used to reduce restenosis after coronary artery stent placement.

Administration. Although many of the original studies of conventional paclitaxel employed a 24-hour infusion regimen, the use of *3-hour infusions* has subsequently become widespread. A systematic review[1] noted that although it was difficult to compare efficacy in studies of unlike malignancies there was no conclusive evidence of a difference in efficacy with differing length of infusion; however, there were differences in the adverse effect profile, neutropenia being much less marked with the shorter infusion, although neurotoxic effects were reduced with 24-hour administration. (Note that albumin-bound paclitaxel can be given over 30 minutes, see p. 839.3).

There has also been considerable interest in evaluating the use of conventional paclitaxel in reduced-dose *weekly* schedules.[2-14] Various dosage regimens have been tried: most have found that doses of between 50 and about 100 mg/m^2 weekly, usually by infusion over 1 hour rather than a conventional 3-hour infusion, can be given with relatively modest toxicity. Although higher doses have been tried, neurotoxicity and myelosuppression become problematic and tend to limit dose intensity. Several studies have addressed the use of weekly paclitaxel with other antineoplastics, for example with trastuzumab in breast cancer, estramustine in prostate cancer, and with platinum compounds or gemcitabine in other solid tumours such as those of the ovary or lung. In a randomised controlled study[13] in patients with metastatic breast cancer, weekly paclitaxel (80 mg/m^2) with or without trastuzumab nearly doubled time to progression from 5 to 9 months compared with a 3-weekly regimen, and had better response rates and overall survival. Neuropathy was the main toxicity (see also Effects on the Nervous System, p. 841.3). A meta-analysis[14] of weekly versus 3-weekly taxane regimens in advanced breast cancer found that although the objective response rate was better with a 3-week regimen of paclitaxel, giving the drug weekly produced higher overall survival and was associated with fewer serious adverse effects. There appeared to be little difference between a weekly and a 3-weekly regimen for docetaxel, but it was impossible to come to firm conclusions because of scanty data.

The use of weekly paclitaxel with radiotherapy is also under investigation in the management of lung cancer and glioblastoma multiforme.

For the suggestion that inhibitors of P-glycoprotein (such as ciclosporin) might be used to boost bioavailability and allow the use of *oral* paclitaxel see Immunosuppressants, under Interactions of Docetaxel, p. 782.2.

Administration in the elderly. A review[1] stated that data are conflicting regarding the impact of age on paclitaxel clearance. However, studies indicate that both weekly and 3-weekly dosing regimens are feasible in elderly patients, and no dose reduction of paclitaxel is needed on the basis of age alone.

Administration in hepatic impairment. Total bilirubin has been shown to be a good predictor of paclitaxel elimination capacity and of individual susceptibility to paclitaxel-related myelosuppression.[1]

UK licensed product information for the conventional formulation of paclitaxel states that there are inadequate data available to recommend dose adjustment in mild to moderate hepatic impairment. Paclitaxel is not recommended in patients with severe hepatic impairment. US licensed product information makes recommendations for initial dosage adjustment of some paclitaxel regimens in patients with hepatic impairment, according to transaminase and bilirubin concentrations. They suggest the conventional formulation of paclitaxel should not be given if transaminase values are > 10 times the upper limit of normal (ULN), or if bilirubin is > 7.5 mg per 100 mL or 5 times the ULN.

In US licensed product information for the albumin-bound paclitaxel nanoparticle formulation recommendations vary depending on the indication and the degree of hepatic impairment; in patients with aspartate aminotransferase (AST/SGOT) < 10 times ULN and the following bilirubin concentrations:

- bilirubin > ULN to 1.25 times ULN (mild impairment): usual initial dose (see Uses and Administration, p. 839.3)
- 1.26 to 2 times ULN (moderate impairment): an initial dose of 200 mg/m^2 in breast cancer and 75 mg/m^2 in non-small cell lung cancer (NSCLC); not recommended for pancreatic adenocarcinoma
- 2.01 to 5 times ULN (severe impairment): an initial dose of 130 mg/m^2 in breast cancer and 50 mg/m^2 in NSCLC; not recommended for pancreatic adenocarcinoma

Treatment with the albumin-bound formulation is not recommended in any patients with AST/SGOT > 10 times ULN or bilirubin > 5 times ULN. Further dose adjustments in subsequent cycles are based on individual tolerance; in severe impairment, an increase up to 200 mg/m^2 in breast cancer and 75 mg/m^2 in NSCLC can be considered if the initial dose is tolerated.

UK licensed product information for this formulation states that a dose reduction must be considered in patients with bilirubin concentrations more than twice the ULN; patients with bilirubin > 5 times the ULN or with transaminase concentrations > 10 times the ULN should not be treated, due to a lack of data.

1. Joerger M, *et al.* Safety and pharmacology of paclitaxel in patients with impaired liver function: a population pharmacokinetic-pharmacodynamic study. *Br J Clin Pharmacol* 2007; 64: 622–33.

Administration in subsequent cycles. In general, if toxicity occurs paclitaxel doses are withheld until the patient has recovered or symptoms have improved; treatment may be restarted at a reduced dose. If the toxicity is persistent despite dose reductions treatment should be stopped.

Conventional paclitaxel should not be given to patients with baseline neutrophil counts < 1500 cells/mm^3; some manufacturers also contra-indicate use in patients with platelets < 100 000 cells/mm^3. In patients with Kaposi's sarcoma, conventional paclitaxel should not be given if baseline neutrophil counts are < 1000 cells/mm^3 or platelets are < 75 000 cells/mm^3. Subsequent doses should not be given until the neutrophil and platelet counts reach these values or greater. Patients who have severe neutropenia (< 500 cells/mm^3 for a minimum of 7 days) or severe peripheral neuropathy should receive a dose reduction of 20% for subsequent courses; for patients with Kaposi's sarcoma, a dose reduction of 25% is recommended.

Albumin-bound paclitaxel should also not be given to patients with baseline neutrophil counts < 1500 cells/mm^3.

- In patients with **breast cancer**, treatment is modified if severe neutropenia or severe sensory neuropathy occur. Doses are reduced in steps of 40 mg/m².
- In patients with **non-small cell lung cancer** treatment is modified for neutropenia, thrombocytopenia, or severe sensory neuropathy. Doses are reduced in steps of 25 mg/m².
- In patients with **pancreatic adenocarcinoma** treatment is modified for neutropenia, thrombocytopenia, severe peripheral neuropathy, grade 2 or 3 cutaneous toxicity, or grade 3 mucositis or diarrhoea. Doses are reduced in steps of 25 mg/m².

Reperfusion and revascularisation procedures. Restenosis is a particular problem after percutaneous coronary revascularisation procedures (p. 1259.2) and various drugs have been tried for its prevention. Coronary stents that elute paclitaxel effectively reduce restenosis and have been widely used, although there is some suggestion that sirolimus-eluting stents may be superior to paclitaxel-eluting stents in terms of clinical outcome and rates of restenosis.[1-3] In a study compared with bare metal stents, paclitaxel-releasing stents reduced the risk of restenosis and the need for repeat revascularisation procedures, although the follow-up rates of death from cardiac causes or myocardial infarction were not significantly reduced at 9 months[4] and 1 year.[5] However, between 9 months and 1 year, major cardiac adverse events were significantly reduced in the paclitaxel-releasing stent group compared with controls.[5] A larger multicentre study[6] in patients with acute myocardial infarction confirmed the reduced risk of restenosis and recurrent ischaemia with paclitaxel-releasing as against bare-metal stents; no evidence of differences in mortality or stent thrombosis was seen at 1 year of follow-up. A review[7] of various stent designs concluded that safety of paclitaxel-releasing stents was independent of design, dose-density, or presence or absence of a polymer carrier system; however, those without a polymer carrier were unable to show a positive effect on clinical outcome in patients with de novo coronary lesions. However, in a paclitaxel-releasing stent system, failure of the stent-delivery balloon to deflate has been associated with serious injuries and 1 fatality.[8] The risk of late stent thrombosis may also be increased with drug eluting stents,[9] although the evidence is controversial,[10] and their role in complex interventions is not yet established.[11,12]

Positive effects on restenosis have also been reported[13] with use of a paclitaxel-coated angioplasty balloon.

Adverse Effects, Treatment, and Precautions

Paclitaxel is available as two formulations: a conventional formulation and an albumin-bound form. The two formulations are not interchangeable and one cannot be substituted for the other. While adverse effects are similar, the frequency of these effects can vary between formulations.

Conventional paclitaxel commonly produces severe dose-limiting myelosuppression, mainly neutropenia. The nadir of the white cell count usually occurs after about 11 days, with recovery usually by day 15 to 21 after a dose. Neutropenia may be less frequent when infusions are given over 3 rather than 24 hours. Blood counts should be monitored frequently.

Peripheral neuropathy can also be severe, and occasionally dose-limiting. Neurotoxicity appears to be more frequent and more severe when infusions are given over 3 hours rather than 24 hours. Hypersensitivity reactions, with flushing, rash, chills, dyspnoea, hypotension (or hypertension), chest pain, back pain, tachycardia, generalised urticaria, and angioedema may occur; anaphylaxis has been reported. All patients should be given initial premedication with corticosteroids, antihistamines, and histamine H_2-antagonists. Mild hypersensitivity reactions do not require interruption of therapy, but serious reactions (which may be fatal, and can occur despite premedication) require treatment to be stopped; patients who have serious reactions should not be re-treated with paclitaxel. Conventional paclitaxel is formulated in polyoxyl castor oil and it should be avoided in patients hypersensitive to this substance.

Cardiac disorders include bradycardia, arrhythmias, myocardial infarction, and heart failure; severe cardiac conduction disorders occur rarely and require continuous cardiac monitoring.

Common adverse effects include alopecia, arthralgia and myalgia, gastrointestinal disturbances, transient mild nail and skin changes, and elevation of liver enzyme values. Infections are also common, and fatalities have been reported. Injection site reactions and mucositis may occur more frequently with the 24-hour infusion than the 3-hour infusion. Manifestations include localised oedema, pain, erythema, and induration; extravasation may result in tissue damage.

Rare adverse events include febrile neutropenia, motor or autonomic neuropathy (which can result in paralytic ileus and orthostatic hypotension), seizures, encephalopathy, dizziness, headache, ataxia, severe thrombotic events, optic nerve and/or visual disturbances (especially at high doses), ototoxicity, bowel obstruction or perforation, pancreatitis, interstitial pneumonia, and pseudomembranous colitis. There are reports of hepatic necrosis and hepatic encephalopathy, some of which have been fatal. Increases in bilirubin and blood creatinine have been reported. Severe skin disorders include Stevens-Johnson syndrome, epidermal necrolysis, erythema multiforme, and exfoliative dermatitis.

Albumin-bound paclitaxel also causes myelosuppression, mainly neutropenia which is rapidly reversible and dose-dependent. Febrile neutropenia is common. Sensory neuropathy occurs frequently, but is usually mild and does not generally require dose modification. Hypersensitivity is uncommon, and premedication is not required. Patients who have a severe hypersensitivity reaction to paclitaxel should not be given the drug again. Tachycardia and arrhythmias occur commonly; bradycardia, cardiac arrest, congestive heart failure, and left ventricular dysfunction are rare, but cardiac monitoring may be required, especially if patients have underlying cardiac disease or previous exposure to anthracyclines.

As with conventional paclitaxel, adverse effects such as alopecia, arthralgia, myalgia, gastrointestinal disturbances, nail and skin disorders, infections, and increases in liver enzyme values are common. Other common adverse effects include anorexia, hypokalaemia, stomatitis, flushing, hypertension, oedema (including lymphoedema), dyspnoea, epistaxis, cough, rhinitis, rhinorrhoea, fatigue, eye disorders, vertigo, and pain. Headache, ataxia, dizziness, dysgeusia, insomnia or somnolence, depression, and anxiety are also common.

Rare adverse effects include hypotension, thrombotic events, injection site reactions, and interstitial pneumonia. Other uncommon adverse effects include glucose and electrolyte disturbances, increases in bilirubin and blood creatinine, and urinary disorders. There have been rare reports of stroke and transient ischaemic attacks, cranial nerve palsies, and vocal cord paresis.

Both conventional and albumin-bound paclitaxel should be used with caution in patients with hepatic impairment (see Administration in Hepatic Impairment, p. 840.3).

Alcohol intoxication. Acute alcohol intoxication resulting from high-dose paclitaxel infusion has been reported;[1] it was calculated that the dose used (348 mg/m²) supplied 50 mL of alcohol, or the equivalent of about 3 drinks (half a bottle of wine).

1. Wilson DB, *et al.* Paclitaxel formulation as a cause of ethanol intoxication. *Ann Pharmacother* 1997; 31: 873–5.

Effects on the eyes. Optic neuritis has occurred with paclitaxel. There is a report of glaucoma possibly related to the use of docetaxel and paclitaxel in a patient also receiving corticosteroids.[1]

1. Fabre-Guillevin E, *et al.* Taxane-induced glaucoma. *Lancet* 1999; 354: 1181–2.

Effects on the heart. Infusion of paclitaxel has been associated with sinus bradycardia, atrial arrhythmias, ventricular tachycardia, heart block, myocardial infarction, and sudden death.[1,2] Symptoms of heart failure have been reported.[3] In another report sudden death 7 days after paclitaxel treatment raised the question of whether paclitaxel might have had a delayed effect.[4] There is some evidence of cellular damage to the myocardium of a patient with paclitaxel-associated cardiac symptoms.[3] Licensed product information notes that severe cardiovascular events have been seen more frequently after the use of paclitaxel in patients with non-small cell lung cancer than in those with breast or ovarian carcinoma.

Effects on the musculoskeletal system. For discussion of paclitaxel-induced arthralgia and myalgia (also referred to as paclitaxel-acute pain syndrome), and its association with neuropathic pain, see Effects on the Nervous System, below.

Effects on the nervous system. Neurotoxicity, usually manifesting as cumulative sensory peripheral neuropathy, is the most important non-haematological toxicity associated with use of paclitaxel, particularly when given in weekly dose-dense regimens,[1] where it is often dose-limiting (see also Administration, p. 840.2). The risk appears to be greater in older patients, those with diabetes, and those with co-existing alcohol abuse. Motor neuropathy is much less common than sensory symptoms, which may include numbness, paraesthesia, and burning sensations in a symmetric glove-and-stocking pattern that usually affects the lower limbs first. Orthostatic hypotension, arrhythmias, and ileus have sometimes been reported as possible signs of autonomic neuropathy. Although mild sensory neuropathy is generally reversible within a few months, more severe cases may persist much longer. Treatment options are lacking and close monitoring of patients to avoid the development of severe symptoms is important.[1]

Paclitaxel-acute pain syndrome (also called paclitaxel-induced arthralgia and myalgia), has been described as a diffuse aching discomfort that is most often felt in the legs, hips, and lower back. Symptoms usually develop over 1 to 4 days of treatment and resolve over a similar timeframe. It has been noted that the intensity of pain felt with the first paclitaxel infusion appeared to predict the later severity of sensory-predominant peripheral neuropathy (particularly shooting or burning pain) that gradually developed over a 12-week course of therapy, supporting the hypothesis that paclitaxel-acute pain syndrome is a form of neurotoxicity.[2,3] Gabapentin has been reported to be of benefit in the management of taxane-induced arthralgia and myalgia.[4,5]

Acute encephalopathy, manifesting between 5 hours and 16 days after infusion, has also been reported rarely in patients given paclitaxel.[6] Symptoms have included disorientation, mood disorders, language disorders, delirium, hallucinations, and coma.

Effects on the respiratory system. Acute bilateral interstitial pneumonitis has been reported rarely in patients receiving paclitaxel, despite premedication with corticosteroids and histamine antagonists.[1] Symptoms resolved on treatment with parenteral corticosteroids.

1. Khan A, *et al.* Paclitaxel-induced acute bilateral pneumonitis. *Ann Pharmacother* 1997; 31: 1471–4.

Effects on the skin, hair, and nails. Nail changes, noted as pigmentation or discoloration of the nail-bed, may occur with paclitaxel. Onycholysis (separation of the nail from the nail-bed) has also been reported.[1] Discoloration and onycholysis can also occur after docetaxel use, and there are reports of subungual hyperkeratosis and haemorrhage.[2-4]

Localised oedema evolving into skin sclerosis, mimicking systemic sclerosis, has been reported after taxane use.[5,6] In most patients, the sclerosis developed mainly on the extremities, and especially the lower extremities. Joint contracture may occur. The total cumulative dose of the taxane may contribute to the onset.[5]

Severe and irreversible alopecia has been reported after use of docetaxel or paclitaxel in patients with breast cancer.[7]

Hypersensitivity. Despite premedication with corticosteroids, antihistamines, and H_2-antagonists, hypersensitivity reactions are common in patients given conventional paclitaxel; up to about 40% of patients may have a mild reaction and about 2% a severe reaction. Fatalities have been reported. There are rare reports of delayed hypersensitivity reactions with paclitaxel; necrotic ulceration has occurred, without evidence of extravasation.[1] Some consider the cause to be the polyoxyl castor oil diluent for paclitaxel, and docetaxel has been suggested as a suitable alternative.[2] However, hypersensitivity reactions have also occurred with docetaxel and taxane cross-reactivity has been reported.[3,4] Although the manufacturers of both drugs consider further use to be contra-indicated after a severe reaction, strategies for continuation of treatment and desensitisation have been described.[5,6]

Hypersensitivity reactions to paclitaxel-eluting stents have also been reported;[7] however, the incidence is low, and some consider the polymer coating of the stent to be the likely cause.[8]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies paclitaxel as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Pregnancy. Paclitaxel has been shown to be embryotoxic and fetotoxic in *animal* studies, but, although the use of potentially teratogenic drugs would normally be avoided during pregnancy, the risk to the mother of inadequate treatment may outweigh whatever risks exist of abnormality in the fetus. A retrospective study[1] of 15 women who were given taxane chemotherapy for breast and ovarian cancer during the second and third trimesters of pregnancy found no differences in birth-weight, gestational age at delivery, rate of growth restriction, congenital anomalies and incidence of maternal and neonatal neutropenia for taxanes when compared with conventional chemotherapy. A systematic review[2] of taxane use for ovarian cancer during 12 pregnancies (11 for paclitaxel and 1 for docetaxel) found that in 92% of cases a healthy child was born; in 6 out of 8 cases with survival data, the mother was alive and disease free at the end of follow-up (median 20 months, and ranging from 9.75 to 45 months). The authors concluded that taxanes may be valuable for treatment of ovarian cancer during the second and third trimesters, but use in early pregnancy is associated with an increased risk of abortion or congenital abnormalities.

Oligohydramnios has been reported[3] with paclitaxel in a pregnant woman with breast cancer. From 24 weeks of gestation the patient received four cycles of doxorubicin and cyclophosphamide and was then started on a weekly regimen of paclitaxel; growth factor support was given throughout chemotherapy. Oligohydramnios was noted after the fourth week of paclitaxel. A healthy infant was delivered at 36 weeks of gestation.

Sickle-cell disease. A patient with previously undiagnosed sickle-cell disease had a painful crisis after being given conventional paclitaxel as part of a chemotherapy regimen for breast cancer.[1] It was unclear if the reaction was due to paclitaxel or its vehicle, and whether an alternative taxane or albumin-bound paclitaxel would cause a similar effect.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Pretreatment with cisplatin may reduce the clearance of paclitaxel, resulting in increased toxicity, and when both drugs are given, paclitaxel should be given first.

Paclitaxel is metabolised by the cytochrome P450 isoenzymes CYP2C8 and CYP3A4. No clinically relevant interactions with other CYP2C8 substrates are likely. While use with ketoconazole (a potent inhibitor of CYP3A4) does not affect paclitaxel elimination, data are limited on use with other CYP3A4 inhibitors or inducers, and caution is advised when paclitaxel is used with these drugs.

Antineoplastics. For reference to enhanced cardiotoxicity when paclitaxel was given with *doxorubicin*, see p. 785.2. For the pharmacokinetic changes reported when paclitaxel was given with *gemcitabine*, see p. 802.1.

Pretreatment with *fluorouracil* has been reported to inhibit paclitaxel's cytotoxic action, possibly by preventing tumour cells from entering the G_2-M phases of the cell cycle.[1] The effect also occurred when the 2 drugs were given simultaneously, suggesting that combination therapy might not be appropriate.

Valspodar inhibits P-glycoprotein, and a pharmacokinetic study[2] found that it decreased clearance of paclitaxel and prolonged the terminal half-life, increasing exposure to paclitaxel and myelosuppressive effects. The authors suggested that the dose of paclitaxel may need to be reduced by about 60%.

Variable effects on paclitaxel pharmacokinetics have been seen when it has been given with *carboplatin* plus *sorafenib*; see under Interactions of Sorafenib, p. 858.2.

2. Advani R, *et al.* A phase I trial of doxorubicin, paclitaxel, and valspodar (PSC 833), a modulator of multidrug resistance. *Clin Cancer Res* 2001; 7: 1221–9.

Antiretrovirals. In a patient given various antiretrovirals during paclitaxel treatment for Kaposi's sarcoma, pharmacokinetic parameters of paclitaxel were not significantly different when compared with historical controls.[1] The first course of therapy combined paclitaxel with *lamivudine, stavudine,* and the HIV-protease inhibitors *ritonavir* and *saquinavir*. In subsequent courses, paclitaxel was given with *nevirapine,* and the final course consisted of paclitaxel given with ritonavir and *indinavir*.

However, licensed product information for paclitaxel states that studies suggest that systemic clearance of paclitaxel was significantly lower in the presence of *nelfinavir* and ritonavir, but not indinavir, and that paclitaxel should be given with caution to patients taking HIV-protease inhibitors. HIV-protease inhibitors are metabolised by the cytochrome P450 isoenzyme CYP3A4, but are also reported to inhibit CYP3A activity. This may lead to increased adverse effects when given with taxanes; the combination of *delavirdine* and saquinavir has been reported to cause serious mucositis, severe myalgia, alopecia, and leucopenia when given with paclitaxel.[2] In other case reports, one patient tolerated *lopinavir*, ritonavir, delavirdine, and *didanosine* without complications until the addition of paclitaxel caused fatal toxicity. In another patient taking indinavir, ritonavir, stavudine, and lamivudine, the addition of paclitaxel caused profound cytopenia and total body alopecia; further courses of paclitaxel were given at a reduced dose with no sequelae.[3]

Immunosuppressants. For the effect of ciclosporin on the oral absorption of paclitaxel, see Immunosuppressants, under Interactions of Docetaxel, p. 782.2.

For the effects of *valspodar* (an analogue of ciclosporin) on paclitaxel, see Antineoplastics, above.

Pharmacokinetics

Intravenous paclitaxel exhibits a biphasic decline in plasma concentrations, with a mean terminal half-life of anywhere between about 3 and 50 hours. The pharmacokinetics are non-linear. The steady-state volume of distribution is reported to range from 200 to 700 litres/m², indicating extensive extravascular distribution, tissue binding, or both. Paclitaxel is 89% or more bound to plasma protein *in vitro*. The elimination of paclitaxel has not been fully elucidated; only about 1 to 12% of a dose is reported to be excreted in urine, as unchanged drug, indicating extensive non-renal clearance. Paclitaxel is metabolised in the liver, with the major metabolic pathway apparently mediated by the cytochrome P450 isoenzyme CYP2C8, although CYP3A4 may play a minor role. Metabolites are excreted in the faeces via the bile, the primary metabolite being 6α-hydroxypaclitaxel.

The clearance and volume of distribution of albumin-bound paclitaxel nanoparticles are reported to be markedly greater (by about 45 and 55% respectively) than those from conventional formulations. In addition, the fraction of free (unbound) paclitaxel in the blood has been reported to be higher than with conventional paclitaxel.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Asotax; Clitaxel; Dalys; Drifen; Erioxal; Paclikebir; Pacliteva; Paklitaxfil; Panataxel; Tarvexol; Taxocris; Taxol; Taycovit; ***Austral.***: Abraxane; Anzatax; Taxol; ***Austria***: Ebetaxel; Taxol; ***Belg.***: Paclitaxin; Paxene†; Taxol; ***Braz.***: Biopaxel; Evotaxel; Ontax; Onxel; Paclitax; Pantium; Parexel; Tarvexol; Taxilan; Taxol; Tevapacli; ***Cana.***: Abraxane; Taxol; ***Chile***: Britaxol; Oncoplaxel†; Praxel; Taxodiol; ***China***: Anzatax (安素泰); Li Pu Su (力扑素); Medaxol (紫舒); Taxol (泰素); Te Su (特素); ***Cz.***: Abraxane; Anzatax; Brevitax; Egilitax; Eucol; OncoTax; Onxol†; Paclimedac; Pacline; Paxene†; Taxol; ***Denm.***: Abraxane; Cantaxel†; Paclimedac; Taxli; ***Fin.***: Paclitaxin; Taxol†; ***Fr.***: Abraxane; Paxene†; Taxol; ***Ger.***: Abraxane; Axitaxel; Bendatax; celltaxel; NeoTaxan†; Paclit; Ribotax; Taxol†; Taxomedac; ***Gr.***: Abraxane; Biotaxel; Cedol; Oncotaxen; Ovapac; Pacline; Paclit; Paclitaxin; Paclitol; Paclixel; Pataxel; Paxene; Paxital; Ribotal; Taxogen; Taxol; Taxoprol; Xenius; ***Hong Kong***: Anzatax; Ebetaxel; Intaxel†; Sindaxel; Taxol; ***Hung.***: Genexol; Intaxel†; Paxene†; Taxol†; ***Indi.***: Abraxane; Altaxel; Betaxel; Cansure; Cantaxel; Celtax; Cytrax; Dutaxel; Intaxel; Mitotax; Nanoxel; Napro-Tax; Neotaxl; Oncotaxel; Paclicad; Pacliron; Paclitax; Paclitec; Paclitrust; Petaxel; ***Indon.***: Anzatax; Ebetaxel; Paxus; Sindaxel; Taxol†; ***Irl.***: Abraxane; Cantaxel; Ebetaxel; Palat; Paxene†; Taxol†; ***Israel***: Biotax†; Ebetaxel; Medixel; Paclavenir; ***Ital.***: Anzatax; Taxol; ***Jpn***: Taxol; ***Malaysia***: Anzatax; Formoxol; Mitotax; Taxol; ***Mex.***: Aclixel†; Acoexcel; Asotax; BrisTaxol; Cryoxet; Daburex; Ifaxol†; Paclisan; Praxel; ***Neth.***: Abraxane; Paclitaxin; Paxene†; Taxol; ***Norw.***: Abraxane; ***NZ***: Abraxane; Anzatax; Taxol; ***Philipp.***: Intaxel; Nanoxel; Napro-Tax; Paclitaxin; Palitax; Paxol; Taxol†; Unitaxel; ***Pol.***: Abraxane; Poltaxel†; Sindaxel; Taxol; ***Port.***: Abraxane; Paxene†; Taxobine; Taxol; ***Rus.***: Abitaxel (Абитаксел); Intaxel (Интаксел); Mitotax (Митотакс); Paclitax (Паклитакс); Paclitera (Паклитера); Paxene (Паксен); Sindaxel (Синдаксел); Taxacad (Таксакад); Taxol (Таксол); ***S.Afr.***: Anzatax; Biolyse; Ebetaxel; Paxitas; Paxitas; Taxol; ***Singapore***: Aclipak; Anzatax; Ebetaxel; Genexol; Mitotax; Paclitaxin; Taxol; ***Spain***: Abraxane; Paxene†; Taxol; ***Swed.***: Abraxane; Paxene†; Taxol†; ***Switz.***: Taxol; ***Thai.***: Anzatax; Genetaxyl; Inoxel; Intaxel; Oncotaxel†; Paclitaxin; Paxoll; Praxel; Sindaxel; Taxol; ***Turk.***: Anzatax; Ebetaxel; Taksen; Taxol; Vitax; ***UK***: Abraxane; Paxene†; ***Ukr.***: Mitotax (Митотакс); ***USA***: Abraxane; Onxol†; Taxol†; ***Venez.***: Clitaxel; Intaxel; Paclitax.

Pharmacopoeial Preparations

USP 36: Paclitaxel Injection.

Palifosfamide *(USAN, rINN)*

IPM; Palifosfamida; Palifosfamidum; ZIO-201; Палифосфамид.

N,N'-Bis(2-chloroethyl)phosphorodiamidic acid.

$C_4H_{11}Cl_2N_2O_2P$=221.0

CAS — 31645-39-3.

UNII — 6A4U6NN813.

Profile

Palifosfamide is an active metabolite of ifosfamide (p. 806.1) that is under investigation for the treatment of soft-tissue sarcoma.

Panitumumab *(BAN, USAN, rINN)*

ABX-EGF; E7.6.3; Panitumumabum; rHuMAb-EGFr; Панитумумаб.

Immunoglobulin, anti-(human epidermal growth factor receptor) (human monoclonal ABX-EGF heavy chain), disulfide with human monoclonal ABX-EGF light chain, dimer.

CAS — 339177-26-3.
ATC — L01XC08.
ATC Vet — QL01XC08.
UNII — 6A901E312A.

Stability. Panitumumab was physically stable when stored for 14 days at 4 degrees in either PVC infusion bags at a concentration of 2.5 mg/mL in sodium chloride 0.9%, or the opened original glass vial at a concentration of 20 mg/mL.[1]

1. Ikesue H, *et al.* Stability of cetuximab and panitumumab in glass vials and polyvinyl chloride bags. *Am J Health-Syst Pharm* 2010; 67: 223–6.

Uses and Administration

Panitumumab is a recombinant human monoclonal antibody that binds to the epidermal growth factor receptor (EGFR). Like cetuximab (p. 762.3), panitumumab can therefore affect cell growth regulation and angiogenesis in patients with wild-type (non-mutated) *RAS* (rat sarcoma) oncogene but it is ineffective in patients who have *RAS* gene mutations. It is used in the treatment of EGFR-expressing, *RAS* wild type, metastatic colorectal cancer (p. 706.3) either with fluoropyrimidine-containing chemotherapy as first- or second-line therapy, or as monotherapy in patients with disease progression after fluoropyrimidine-, oxaliplatin-, or irinotecan-containing regimens.

The recommended dose is 6 mg/kg given as an intravenous infusion every 14 days. Doses up to and including 1 g are given in 100 mL sodium chloride 0.9% over 60 minutes whereas doses above 1 g are diluted in 150 mL and given over 90 minutes; the final concentration of the infusion should not exceed 10 mg/mL. The infusion should be given via an infusion pump using a low-protein-binding 0.2 or 0.22 micrometre in-line filter. It may be given through a peripheral line or indwelling catheter; the line should be flushed with sodium chloride 0.9% before and after giving panitumumab. The infusion rate should be reduced by 50% in patients who have a mild to moderate infusion reaction, and stopped immediately and permanently if a severe reaction occurs.

Panitumumab should be withheld if severe dermatological toxicity develops, and permanently stopped if toxicity does not improve within 1 month. If toxicity improves after withholding no more than 2 doses of panitumumab, treatment may be restarted, either at the same dose or at a reduced dose; recommendations for dose modifications vary between countries.

Adverse Effects, Treatment, and Precautions

As for Cetuximab, p. 763.1, although the use of premedication for prevention of infusion reactions with panitumumab has not been standardised. The infusion rate should be reduced by 50% in patients who have mild to moderate infusion reactions and this lower rate should be maintained for subsequent infusions. If a severe reaction occurs, the drug should be stopped immediately and permanently. Fatal angioedema has been reported. In patients who developed skin reactions, infectious complications including abscesses and sepsis, also in some cases fatal, have been reported. Fatigue is very common, as is paronychia; the latter may be severe enough to require stoppage of therapy. Panitumumab should not be used in patients with interstitial pneumonitis or pulmonary fibrosis, and therapy should be permanently stopped in patients who develop interstitial lung disease, pneumonitis, or lung infiltrates; fatalities have been reported. Eye disorders are common and include conjunctivitis, ocular hyperaemia, increased lachrymation, dry eye, eye pruritus, and eyelash growth. There are rare reports of keratitis and ulcerative keratitis with panitumumab, and therapy should be interrupted or stopped if this occurs; contact lens use is a risk factor for development of keratitis and ulceration.

Wild-type *RAS* (rat sarcoma oncogene) status should be confirmed before starting treatment as panitumumab is ineffective in patients who have *RAS* mutations. Panitumumab should not be used with some chemotherapy regimens; for details of the adverse effects associated with such combinations, see Interactions, below.

Effects on the skin, hair, and nails. For reference to cutaneous adverse effects of epidermal growth factor receptor inhibitors, including panitumumab, see under Cetuximab, p. 763.2.

Hypersensitivity. Although infusion reactions and hypersensitivity have been reported with panitumumab (see above) there is evidence from a limited number of patients that there is no cross-sensitivity between panitumumab and cetuximab,[1-4] and that therefore the former can be used in those with severe reactions to the latter. Successful use of cetuximab in those with reactions to panitumumab has also been reported.[5] Despite this, fatal hypersensitivity reactions have occurred after panitumumab; one was in a patient who had previously reacted to cetuximab.[6]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies panitumumab as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

Panitumumab should not be used with some chemotherapy regimens. A high incidence of severe diarrhoea occurred in patients given panitumumab with fluorouracil, folinic acid, and irinotecan (the IFL regimen, see Table I, Common Chemotherapy Regimens for Malignant Disease, p. 719). Increased toxicity and risk of death occurred when panitumumab was given with bevacizumab. A reduced survival-time was reported in patients with tumours expressing *RAS* gene mutations or with unknown *RAS* status who were given panitumumab with oxaliplatin-based chemotherapy for metastatic colorectal cancer.

Pharmacokinetics

The pharmacokinetics of panitumumab are reported to be non-linear. Steady-state concentrations were reached by the third infusion with the recommended dose regimen. The elimination half-life was about 7.5 days.

Panobinostat *(USAN, rINN)*

LBH-589; Panobinostatum; Панобиностат.

(2*E*)-*N*-Hydroxy-3-[4-({[2-(2-methyl-1*H*-indol-3-yl)ethyl]amino}methyl)phenyl]prop-2-enamide.

$C_{21}H_{23}N_3O_2$=349.4

CAS — 404950-80-7.
UNII — 9647FM7Y3Z.

Profile

Panobinostat is a histone deacetylase inhibitor that is under investigation as an antineoplastic for the treatment of malignancies such as cutaneous T-cell lymphoma.

Patupilone *(rINN)*

EPO-906; Epothilone B; Patupilona; Patupilonum; Патупильон.

(1*S*,3*S*,7*S*,10*R*,11*S*,12*S*,16*R*)-7,11-Dihydroxy-8,8,10,12,16-pentamethyl-3-{(1*E*)-1-(2-methyl-1,3-thiazol-4-yl)prop-1-en-2-yl}-4,17-dioxabicyclo[14.1.0]heptadecane-5,9-dione.

$C_{27}H_{41}NO_5S$=507.7

CAS — 152044-54-7.
UNII — UEC0H0URSE.

Profile

Patupilone is a metabolite isolated from the bacterium *Sorangium cellulosum*, with microtubule stabilising activity similar to that of the taxanes. It is under investigation as an antineoplastic for the treatment of malignancies such as ovarian cancer.

Pazopanib Hydrochloride

(BANM, USAN, rINNM)

GW-786034B; Hidrocloruro de pazopanib; Pazopanib, Chlorhydrate de; Pazopanibi Hydrochloridum; Пазопаниба Гидрохлорид.

5-{[4-[(2,3-Dimethyl-2*H*-indazol-6-yl)methylamino]pyrimidin-2-yl]amino}-2-methylbenzenesulfonamide hydrochloride.

$C_{21}H_{23}N_7O_2S.HCl$=474.0

CAS — 444731-52-6 (pazopanib); 635702-64-6 (pazopanib hydrochloride).
ATC — L01XE11.
ATC Vet — QL01XE11.
UNII — 33Y9ANM545.

Uses and Administration

Pazopanib hydrochloride is an inhibitor of multiple tyrosine kinases including those associated with the vascular epidermal growth factor receptor (VEGFR). It is used in the treatment of advanced renal cell carcinoma (p. 708.3). It may also be used in advanced soft-tissue sarcoma (p. 718.2), although efficacy in adipocytic soft-tissue sarcoma or gastrointestinal stromal tumours has not been shown.

Doses are expressed in terms of the base; 1 mg pazopanib is equivalent to about 1.08 mg pazopanib hydrochloride. The recommended oral dose of pazopanib is 800 mg once daily at least 1 hour before or 2 hours after food. Dose modifications should be in steps of 200 mg, although US licensed product information allows for an initial dose reduction to 400 mg once daily if needed in patients with renal cell carcinoma. The daily dose should not exceed 800 mg. Tablets should be swallowed whole and not crushed. If a daily dose is missed and it is less than 12 hours until the next dose, the missed dose should be omitted and the next daily dose taken as usual. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

If a potent cytochrome P450 isoenzyme CYP3A4 inhibitor must also be used, US licensed product information recommends that the pazopanib dose should be reduced to 400 mg once daily; the dose may be reduced further if adverse effects occur.

For dose adjustments in hepatic impairment or if hepatotoxicity occurs, see p. 844.1.

Pazopanib eye drops are under investigation for the treatment of age-related macular degeneration.

Administration in hepatic impairment. Patients with mild hepatic impairment, defined as either normal bilirubin and any degree of alanine aminotransferase (ALT) elevation or an elevation of bilirubin up to 1.5 times the upper limit of normal (ULN) regardless of the ALT value, have been shown to have similar pazopanib pharmacokinetics to patients with normal hepatic function, and therefore can be given the usual initial recommended dose of pazopanib (see Uses and Administration, p. 843.3). Clearance of pazopanib is reduced by about 50% in patients with moderate hepatic impairment, and patients with pre-existing moderate impairment (defined as an elevation of bilirubin > 1.5 to 3 times the ULN, regardless of ALT values) should be given a lower initial oral dose of pazopanib 200 mg once daily. Due to poor tolerability, pazopanib is not recommended in those with pre-existing severe impairment, defined as total bilirubin > 3 times the ULN.

Hepatotoxicity may occur during pazopanib treatment at the usual recommended dose, and liver function should be monitored before and during treatment, see Adverse Effects and Precautions, below. The following adjustments are recommended, according to increases in ALT and bilirubin concentrations:

- For isolated ALT increases of between 3 and 8 times the ULN, the current pazopanib dose may be continued, with weekly monitoring of liver function until ALT returns to grade 1 or baseline.
- For isolated ALT increases of > 8 times the ULN, treatment should be withheld until ALT returns to grade 1 or baseline. If the benefit of continued treatment is thought to outweigh the risk of hepatotoxicity, pazopanib can be restarted at a dose of no more than 400 mg once daily, and liver function monitored weekly for 8 weeks. If ALT increases of > 3 times the ULN recur, pazopanib should be stopped permanently.
- For ALT increases of > 3 times the ULN with bilirubin increases of > 2 times the ULN, pazopanib should be stopped permanently. Liver function should be monitored until toxicity has resolved.

Patients with Gilbert's syndrome (mild unconjugated hyperbilirubinaemia), and an increase in ALT > 3 times the ULN, should be managed according to the above recommendations.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The most common adverse effects with pazopanib include diarrhoea and other gastrointestinal disturbances, headache, hair colour changes, fatigue, asthenia, anorexia, dysgeusia, and abdominal pain. Hypertension has also occurred commonly and hypertensive crisis may develop; patients should be monitored and treated with antihypertensives as required. If hypertension persists despite treatment, the dose of pazopanib may be reduced; pazopanib should be stopped for severe hypertension despite treatment and dose reduction. QT prolongation and torsade de pointes have occurred, and caution is required in those with cardiac disease or a history of QT prolongation, those taking antiarrhythmics, or those taking other medicines that prolong the QT interval. ECGs and electrolytes should be monitored before starting pazopanib and periodically during treatment. Pazopanib has been associated with cardiac dysfunction such as a reduction in left ventricular ejection fraction and congestive heart failure in some patients. Arterial thrombotic adverse effects have been reported, including myocardial infarction, angina, ischaemic stroke, and transient ischaemic attacks; fatalities have occurred. Caution is required in patients with risk factors for thrombosis, and use is not recommended in those who have suffered an event in the previous 6 months. Cases of venous thrombosis and pulmonary embolism have also occurred. Haemorrhagic adverse effects including fatal haemorrhages have also been reported with pazopanib, and use is not recommended in those who have suffered haemoptysis, cerebral haemorrhage, or significant gastrointestinal haemorrhage in the previous 6 months.

Use of pazopanib is not recommended in those with pre-existing severe hepatic impairment. Hepatotoxicity, manifested as raised serum transaminases and bilirubin, has been reported during treatment and can be severe; fatalities have occurred. Liver function should be monitored before starting treatment, at least once every 4 weeks for the first 4 months, and periodically thereafter. Treatment may need to be stopped or the dose reduced for severe hepatotoxicity, see Administration in Hepatic Impairment, above.

Hypothyroidism has been reported with pazopanib and monitoring of thyroid function is recommended. Monitoring for proteinuria is also recommended, before and during treatment, and pazopanib should be stopped permanently if severe proteinuria develops.

Other common adverse effects include alopecia, chest pain, oedema, palmar-plantar erythrodysesthesia, rash, skin depigmentation, and changes in electrolyte and glucose concentrations. Pazopanib has been associated with gastrointestinal perforation and fistula, including some fatalities. Thrombocytopenia, neutropenia, leucopenia, dizziness, paraesthesia, hot flushes, epistaxis, dysphonia, erythema, pruritus, dry skin, hyperhidrosis, myalgia, muscle spasms, mucosal inflammation, and increased blood creatinine have also commonly occurred. Less commonly reported effects include bradycardia, pancreatitis, peritonitis, photosensitivity reactions, and skin exfoliation. Reversible posterior leukoencephalopathy syndrome, which presents with visual and neurological disturbances, has been reported.

Vascular endothelial growth factor receptor inhibitors such as pazopanib may impair healing, and it is recommended that treatment is stopped at least 7 days before surgery; pazopanib should be stopped permanently if wound dehiscence develops.

Interactions

Pazopanib is metabolised by cytochrome P450 isoenzymes, mainly CYP3A4, and inhibitors or inducers of CYP3A4 may affect exposure to pazopanib. Pazopanib is also a substrate for P-glycoprotein (PgP) and breast cancer resistance protein (BCRP) and use with potent PgP or BCRP inhibitors or inducers may alter exposure and distribution of pazopanib.

Use of pazopanib eye drops with ketoconazole (a potent CYP3A4 inhibitor and a PgP inhibitor) increased exposure to pazopanib. Use of lapatinib (a substrate for and weak inhibitor of CYP3A4 and PgP, and a potent inhibitor of BCRP) also substantially increased exposure to pazopanib. Combination of pazopanib with strong CYP3A4, PgP, or BCRP inhibitors should therefore be avoided. If use together cannot be avoided, US licensed product information states that a dose reduction of pazopanib can be considered, see Uses and Administration, p. 843.3. Grapefruit juice inhibits CYP3A4 activity and it should be avoided during treatment with pazopanib.

Combination of pazopanib with strong CYP3A4, PgP, or BCRP inducers is also not recommended.

In vitro, pazopanib is a weak inhibitor of CYP3A4, CYP2C8, and CYP2D6 and may affect exposure to substrates of these enzymes. It is also an inhibitor of glucuronidation by the enzyme UGT1A1, and inhibits the organic anion transporting polypeptide (OATP) 1B1.

Concomitant use of pazopanib with simvastatin increases the incidence of elevations of alanine aminotransferase. In such cases the dose of pazopanib should be adjusted (see Administration in Hepatic Impairment, above), and consideration given to stopping simvastatin. The effect of pazopanib use with other statins is unknown.

Pharmacokinetics

Peak plasma concentrations occur about 2 to 4 hours after an oral dose of pazopanib. Absorption and bioavailability are increased when tablets are crushed and systemic exposure is increased when given with food. Pazopanib is highly protein bound (> 99%) and is a substrate for P-glycoprotein and breast cancer resistant protein (BCRP). Metabolism occurs via cytochrome P450 isoenzymes, mainly CYP3A4, with a minor contribution from CYP1A2 and CYP2C8. Elimination is mostly via the faeces with less than 4% in the urine. Pazopanib has a mean half-life of about 31 hours after an oral dose.

Pemetrexed Disodium

(BANM, USAN, rINNM)

LY-231514 (pemetrexed or pemetrexed disodium); MTA; Multi-targeted Antifolate; Pemetreksed Disodyum; Pemetrexed disódico; Pémétrexed Disodique; Pemetrexedum Dinatricum; Динатрий Пеметрексед.

Disodium *N*-[*p*-[2-(2-amino-4,7-dihydro-4-oxo-1*H*-pyrrolo[2,3-*d*]pyrimidin-5-yl)ethyl]benzoyl]-L-glutamate.

$C_{20}H_{19}N_5Na_2O_6$=471.4

CAS — 137281-23-3 (pemetrexed); 150399-23-8 (pemetrexed disodium); 357166-29-1 (pemetrexed disodium heptahydrate).

ATC — L01BA04.

ATC Vet — QL01BA04.

UNII — 2PKU919BA9 (pemetrexed disodium); 9T47E4OM16 (pemetrexed disodium heptahydrate).

NOTE. In practice, pemetrexed is given as the disodium heptahydrate ($C_{20}H_{19}N_5Na_2O_6.7H_2O$ = 597.5).

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Pemetrexed Disodium Heptahydrate). A white or almost white powder. Freely soluble in water; very slightly soluble in dehydrated alcohol; practically insoluble in dichloromethane. pH of a 5.6% solution in water is 7.5 to 8.4.

Incompatibility. Licensed product information states that pemetrexed is physically incompatible with diluents containing calcium, including Ringer's solution and lactated Ringer's solution. A study[1] found pemetrexed disodium 20 mg/mL to be physically incompatible with 24 drugs resulting in precipitation or colour change during simulated Y-site administration. These drugs include amphotericin B, some cephalosporin and cephamycin antibacterials, chlorpromazine hydrochloride, ciprofloxacin, dobutamine hydrochloride, doxorubicin hydrochloride, doxycycline hyclate, droperidol, gemcitabine hydrochloride, gentamicin sulfate, irinotecan hydrochloride, metronidazole, minocycline hydrochloride, mitoxantrone hydrochloride, nalbuphine hydrochloride, ondansetron hydrochloride, prochlorperazine edisilate, tobramycin sulfate, and topotecan hydrochloride.

1. Trissel LA, *et al.* Physical compatibility of pemetrexed disodium with other drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 2004; 61: 2289–93.

Stability. Licensed product information states that pemetrexed is chemically and physically stable, once reconstituted and diluted, for 24 hours either refrigerated at 2 degrees to 8 degrees or at 25 degrees; from a microbiological point of view, solutions should be used immediately, unless prepared under controlled and validated aseptic conditions.

Pemetrexed, reconstituted in polypropylene syringes with sodium chloride 0.9% to a concentration of 25 mg/mL, was found to be both chemically and physically stable for 2 days when stored at room temperature, and for 31 days when refrigerated.[1] Although pemetrexed solutions of 2, 10, and 20 mg/mL in glucose 5% and sodium chloride 0.9% in PVC bags were chemically stable for 90 days when frozen at -20 degrees, microparticulates formed, possibly related to the PVC containers. Pemetrexed solutions should therefore not be frozen.[2]

2. Zhang Y, Trissel LA. Physical instability of frozen pemetrexed solutions in PVC bags. *Ann Pharmacother* 2006; 40: 1289–92.

Uses and Administration

Pemetrexed is mainly a thymidylate synthase inhibitor like raltitrexed (p. 850.3), but it also inhibits other folate-dependent enzymes involved in purine synthesis such as dihydrofolate reductase and glycinamide ribonucleotide formyltransferase. It is used as second-line monotherapy or first-line with cisplatin in the treatment of locally advanced or metastatic non-squamous non-small cell lung cancer (p. 710.2); it is also used as maintenance monotherapy in patients whose disease has not progressed after platinum-based first-line chemotherapy. Pemetrexed is also used with cisplatin in the first-line treatment of unresectable malignant pleural mesothelioma (p. 711.2).

Pemetrexed is given as the disodium heptahydrate but doses are expressed in terms of the base: pemetrexed disodium heptahydrate 1.4 g is equivalent to about 1 g of pemetrexed. A dose of pemetrexed 500 mg/m² is given by intravenous infusion over 10 minutes. The dose may be repeated in 21-day cycles, and should be adjusted according to toxicity. In combination therapy, cisplatin (at a dose of

75 mg/m² infused over 2 hours) is given about 30 minutes after the end of pemetrexed infusion. Doses may need to be modified according to toxicity, see Administration in Subsequent Cycles, below. For further information on use in renal impairment, see below.

Pretreatment with oral dexamethasone 4 mg twice daily for 3 days is recommended, starting the day before pemetrexed. At least 5 doses of oral folic acid (350 micrograms to 1 mg) should be taken during the 7 days before the first dose of pemetrexed; dosing should continue throughout pemetrexed therapy, and for 21 days after the last pemetrexed dose. Patients should also receive an intramuscular injection of vitamin B_{12} 1 mg in the week before the first pemetrexed dose, and once every 3 cycles thereafter; subsequent injections may be given on the same day as pemetrexed.

Pemetrexed is under investigation as an antifolate antimetabolite in the treatment of colon, pancreatic, breast, and head and neck cancer.

Administration in the elderly. A retrospective analysis found pemetrexed to be effective as a second-line therapy in non-small cell lung cancer patients aged 70 years or older, with a more favourable toxicity profile than docetaxel.[1]

UK licensed product information states that there are no data to suggest that patients aged 65 years or older are at increased risk of adverse effects compared with younger patients; no dose reductions are recommended on the basis of age alone.

1. Weiss GJ, *et al.* Elderly patients benefit from second-line cytotoxic chemotherapy: a subset analysis of a randomized phase III trial of pemetrexed compared with docetaxel in patients with previously treated advanced non-small-cell lung cancer. *J Clin Oncol* 2006; 24: 4405–11.

Administration in renal impairment. A pharmacokinetic study[1] found that pemetrexed clearance decreased with declining renal function. Although systemic exposure increased in these patients, this was not associated with an increase in drug-related dose-limiting toxicities for patients with a GFR of 40 mL/minute or more and receiving vitamin supplementation (folic acid and vitamin B_{12} supplementation appears to reduce toxicity without altering pemetrexed pharmacokinetics). Patients with a GFR of 80 mL/minute or more tolerated a dose of pemetrexed 600 mg/m², given intravenously every 3 weeks, whereas patients with a GFR of 40 to 79 mL/minute tolerated 500 mg/m² every 3 weeks. One patient with a GFR of 19 mL/minute died as a result of treatment-related toxicity and accrual into this group was stopped. As a result, no data were available for patients with a GFR below 40 mL/minute.

Licensed product information states that no dose adjustment is necessary in patients with a creatinine clearance (CC) of 45 mL/minute or more. Use in patients with a CC of less than 45 mL/minute is not recommended due to lack of data. Caution is advised when giving pemetrexed with NSAIDs in patients whose CC is less than 80 mL/minute (see Interactions, below).

1. Mita AC, *et al.* Phase I and pharmacokinetic study of pemetrexed administered every 3 weeks to advanced cancer patients with normal and impaired renal function. *J Clin Oncol* 2006; 24: 552–62.

Administration in subsequent cycles. Complete blood counts should be performed in all patients given pemetrexed. Patients should not begin a new cycle unless:
- the absolute neutrophil count (ANC) is ⩾ 1500 cells/mm³
- the platelet count is ⩾ 100 000 cells/mm³
- creatinine clearance is ⩾ 45 mL/min (see also Administration in Renal Impairment, above)

Dose adjustments at the start of a subsequent cycle should be based on nadir haematological counts or maximum non-haematological toxicity from the preceding cycle of therapy. Treatment should be delayed to allow sufficient time for recovery. Upon recovery, patients are treated according to the following recommendations, which are suitable for pemetrexed monotherapy or use with cisplatin.

For **haematological** toxicities:
- nadir ANC < 500 cells/mm³ and nadir platelets ⩾ 50 000 cells/mm³; 75% of previous dose (pemetrexed and cisplatin)
- nadir platelets < 50 000 cells/mm³ without bleeding, regardless of nadir ANC; 75% of previous dose (pemetrexed and cisplatin)
- nadir platelets < 50 000 cells/mm³ with bleeding, regardless of nadir ANC; 50% of previous dose (pemetrexed and cisplatin)

If **non-haematological** toxicities (excluding neurotoxicity) are severe, treatment should be withheld until resolution, and treatment resumed according to the following recommendations:
- any grade 3 or 4 toxicities except mucositis; 75% of previous dose (pemetrexed and cisplatin)
- any diarrhoea requiring hospitalisation, or grade 3 or 4 diarrhoea; 75% of previous dose (pemetrexed and cisplatin)
- grade 3 or 4 mucositis; 50% of previous pemetrexed dose and 100% of previous cisplatin dose

Patients should stop therapy if **neurotoxicity** is severe (grade 3 or 4); otherwise doses are adjusted as follows:
- grade 0 to 1; 100% of previous dose (pemetrexed and cisplatin)
- grade 2; 100% of previous pemetrexed dose and 50% of previous cisplatin dose

Pemetrexed should be stopped if patients have any severe haematological or non-haematological toxicities after 2 dose reductions.

Adverse Effects, Treatment, and Precautions

As for Raltitrexed, p. 851.1. Neutropenia and febrile neutropenia are common and myelosuppression may be dose-limiting.

Pemetrexed may also cause fatigue, stomatitis, pharyngitis, oesophagitis, chest pain, and neuropathy. Rare cases of hepatitis, colitis, and interstitial pneumonitis have occurred; fatalities have been reported. Bullous skin conditions have been reported, including Stevens-Johnson syndrome and toxic epidermal necrolysis, which in some cases were fatal. Serious renal events, including acute renal failure, have been reported with pemetrexed when it was used either alone or with other cytotoxic drugs; most patients had underlying risk factors such as dehydration, hypertension, or diabetes. Cardiovascular events, including myocardial infarction and cerebrovascular events, have occurred rarely, usually when pemetrexed was used with other cytotoxic drugs and in patients with cardiovascular risk factors. Arrhythmias have been reported. Cases of radiation pneumonitis or oesophagitis, and radiation recall have been reported in patients treated with radiotherapy. Hypersensitivity reactions may occur. Cases of peripheral ischaemia leading to extremity necrosis have been reported. The effect of pleural effusions or ascites on pemetrexed is unknown; in those patients with significant third-space fluid, draining of any effusions before treatment with pemetrexed should be considered.

Complete blood cell counts should be monitored, and folate and vitamin B_{12} are given as prophylaxis against haematological and gastrointestinal toxicity during pemetrexed therapy. Pretreatment with a corticosteroid, such as oral dexamethasone, reduces the incidence and severity of skin reactions. (For dosing details, see Uses and Administration, p. 844.3.) Gastrointestinal toxicity may be severe, leading to dehydration, and antiemetics and appropriate hydration should be given before and after treatment.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies pemetrexed as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

High doses of NSAIDs and aspirin may decrease pemetrexed elimination. In patients with mild to moderate renal impairment (creatinine clearance 45 to 79 mL/minute) high doses of NSAIDs and aspirin should be avoided from 2 days before until 2 days after pemetrexed use, and NSAIDs that have longer half-lives, such as piroxicam, should be avoided from 5 days before until 2 days after pemetrexed.

Analgesics. Enteric-coated *aspirin* 325 mg given orally every 6 hours for a total of 9 doses before pemetrexed, did not affect the pharmacokinetic profile of pemetrexed in an interaction study; the authors considered no dose adjustment necessary when moderate doses of aspirin were given with pemetrexed. However, this result could not be extrapolated to high-dose aspirin regimens, as the interaction might be dependent on salicylate concentrations. In contrast, oral *ibuprofen* 400 mg every 6 hours for a total of 9 doses before pemetrexed significantly reduced systemic pemetrexed clearance. Despite an increase in pemetrexed exposure, no increase in toxicity was seen. Dose adjustments were not considered necessary in patients with normal renal function (defined as creatinine clearance of 80 mL/minute or greater). However, in patients with pre-existing reduced pemetrexed clearance due to renal impairment, giving ibuprofen may result in further increases in pemetrexed exposure; the authors advised caution when using these 2 drugs together in patients with a creatinine clearance of less than 80 mL/minute.[1] For licensed product information regarding the use of aspirin and NSAIDs with pemetrexed, see above.

1. Sweeney CJ, *et al.* Two drug interaction studies evaluating the pharmacokinetics and toxicity of pemetrexed when coadministered with aspirin or ibuprofen in patients with advanced cancer. *Clin Cancer Res* 2006; 12: 536–42.

Pharmacokinetics

Pemetrexed has a plasma elimination half-life of 3.5 hours in patients with normal renal function. *In-vitro* data indicate that pemetrexed is about 81% bound to plasma proteins. It undergoes limited hepatic metabolism, and about 70 to 90% of a dose is eliminated unchanged in the urine within 24 hours.

Pentostatin *(BAN, USAN, rINN)*

CI-825; Co-vidarabine; Covidarabine; Deoxycoformycin; NSC-218321; PD-81565; Pentostatina; Pentostatine; Pentostatinum; 2'-Deoxycoformycin; YK-176; Пентостатин.

(*R*)-3-(2-Deoxy-β-D-*erythro*-pentofuranosyl)-3,6,7,8-tetrahydroimidazo[4,5-*d*][1,3]diazepin-8-ol; 1,2-Dideoxy-1-[(*R*)-3,6,7,8-tetrahydro-8-hydroxyimidazo[4,5-*d*][1,3]diazepin-3-yl]-D-*erythro*-pentofuranose.

$C_{11}H_{16}N_4O_4$=268.3

CAS — 53910-25-1.

ATC — L01XX08.

ATC Vet — QL01XX08.

UNII — 395575MZO7.

Uses and Administration

Pentostatin is a potent inhibitor of the enzyme adenosine deaminase and probably exerts its cytotoxic actions through the interruption of normal purine metabolism and DNA synthesis. Lymphocytes are particularly sensitive to its actions.

Pentostatin is used as a single agent in the treatment of hairy-cell leukaemia (p. 694.3), in usual doses of 4 mg/m² every other week. The dose is given as an intravenous bolus injection, or as an infusion over 20 to 30 minutes. Hydration with 500 mL to 1 litre of glucose 5% in sodium chloride 0.18 or 0.9%, or equivalent, is recommended beforehand; a further 500 mL of the hydration solution should be infused once the drug has been given.

Pentostatin has been tried in cutaneous T-cell lymphomas (see Mycosis Fungoides, p. 698.3). It is also under investigation in some other lymphoid malignancies, including chronic lymphocytic leukaemia (p. 693.3), and for the management of chronic graft-versus-host disease following haematopoietic stem cell transplantation (p. 1937.1).

Adverse Effects and Precautions

The most common adverse effects in patients given pentostatin include myelosuppression (and in particular suppression of the CD4+ lymphocyte subset), headache, abdominal pain, fever and chills, gastrointestinal disturbances (notably diarrhoea and nausea and vomiting), hypersensitivity reactions, and hepatotoxicity. Central neurotoxicity may manifest as tiredness, anxiety, depression, sleep disturbances, and paraesthesias: treatment should be withheld or stopped in such patients. Impaired renal function and pulmonary toxicity (cough, dyspnoea, and pneumonia) may occur. Severe toxicity in early studies, affecting mainly the CNS, kidneys, liver, and lungs, was associated with the use of doses higher than those currently recommended and produced some fatalities.

Other adverse effects reported with pentostatin include dry skin and rashes (sometimes severe and worsening with continued treatment), pruritus, conjunctivitis, alopecia, arthralgia and myalgia, peripheral oedema, thrombophlebitis, and cardiovascular disorders including arrhythmias, angina pectoris, and heart failure.

Pentostatin should not be given to patients with impaired renal function, or in active infection. It is teratogenic in *animals* and potentially genotoxic: it is therefore contra-indicated in pregnancy and men given pentostatin should not father children for 6 months after therapy.

Interactions

Pentostatin should not be given with fludarabine, as the combination may increase pulmonary toxicity. A similar increase in toxicity is expected when pentostatin is used with vidarabine.

Use of pentostatin with carmustine, etoposide and high-dose cyclophosphamide, has produced acute pulmonary oedema and hypotension, leading to death. Pentostatin should therefore not be given with high-dose cyclophosphamide.

Allopurinol. Fatal acute necrotising arteritis developed in a patient given pentostatin and allopurinol.[1] Although the hypersensitivity vasculitis may have been due to allopurinol alone there is circumstantial evidence to suggest that pentostatin may predispose patients to drug hypersensitivity and it may be wise to avoid this combination, and to observe pentostatin-treated patients closely for allergic manifestations.

1. Steinmetz JC, *et al.* Hypersensitivity vasculitis associated with 2-deoxycoformycin and allopurinol therapy. *Am J Med* 1989; 86: 498–9.

Pharmacokinetics

After intravenous injection, pentostatin has an elimination half-life of about 6 hours. About 90% of a dose is excreted in the urine as unchanged drug and metabolites. Pentostatin crosses the blood-brain barrier and can be measured in the CSF.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Denm.*: Nipent; *Fr.*: Nipent; *Ger.*: Nipent; *Gr.*: Nipent; *Irl.*: Nipent; *Ital.*: Nipent; *Neth.*: Nipent; *Port.*: Nipent; *Spain*: Nipent; *UK*: Nipent; *USA*: Nipent.

Peplomycin Sulfate *(USAN, rINNM)*

N^1-[3-[(*S*)-(α-Methylbenzyl)amino]propyl]bleomycinamide sulphate.

$C_{61}H_{88}N_{18}O_{21}S_2.H_2SO_4$=1571.7

CAS — 68247-85-8 *(peplomycin)*; 70384-29-1 *(peplomycin sulfate)*.

UNII — 6A668951HW.

Pharmacopoeias. In *Jpn*.

Profile

Peplomycin is an antineoplastic derived from bleomycin (p. 749.3) and with similar properties. It has been given as the sulfate in the treatment of a variety of malignant neoplasms, including lymphomas and tumours of the head and neck, breast, cervix, lung, oesophagus, prostate, and skin.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Pepleo.

Peretinoin *(rINN)*

Ácido poliprénico; Acyclic Retinoid; E-5166; NIK-333; Peretinoína; Péritinoïne; Peretinoinum; Polyprenic Acid; Polyprenoic Acid; Полипреноевая Кислота; Перетиноин.

(*all-E*)-3,7,11,15-Tetramethyl-2,4,6,10,14-hexadecapentaenoic acid.

$C_{20}H_{30}O_2$=302.5

CAS — 81485-25-8.

UNII — 11ALM7A4RV.

Profile

Peretinoin is a retinoid that has been tried in psoriasis and keratoderma and is being studied in the treatment of liver cancers.

References.

Perifosine *(rINN)*

D-21266; KRX-0401; Perifosina; Périfosine; Perifosinum; Перифозин.

4-Hydroxy-1,1-dimethylpiperidinium hydroxide octadecyl hydrogen phosphate inner salt.

$C_{25}H_{52}NO_4P$=461.7

CAS — 157716-52-4.

UNII — 2GWV496552.

Profile

Perifosine is an oral alkylphospholipid compound that is structurally related to miltefosine (p. 829.3); it has similarities to the phospholipid components of the cell membrane and exerts its antineoplastic action by disruption of cell-membrane functions. It is under investigation for the treatment of multiple myeloma and advanced metastatic colorectal cancer.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

Pertuzumab *(BAN, USAN, rINN)*

2C4; Pertuzumabum; R-1273; rhuMAb-2C4; Пертузумаб.

Immunoglobulin G1, anti-(human v (receptor)) (human-mouse monoclonal 2C4 heavy chain), disulfide with human-mouse monoclonal 2C4 κ-chain, dimer.

CAS — 380610-27-5.

ATC — L01XC13.

ATC Vet — QL01XC13.

UNII — K16AIQ8CTM.

NOTE. The name Omnitarg has been used as a trade mark for pertuzumab.

Uses and Administration

Pertuzumab is a humanised monoclonal antibody and a human epidermal growth factor receptor (HER) dimerisation inhibitor. It inhibits HER2 heterodimerisation with other HER family receptors, thereby preventing the activation of HER signalling pathways. Pertuzumab is used with trastuzumab and docetaxel in the treatment of HER2-positive metastatic breast cancer (p. 702.1), in patients who have not been given anti-HER2 therapy or chemotherapy.

The initial dose of pertuzumab is 840 mg given by intravenous infusion over 60 minutes. This is followed by a dose of 420 mg given by infusion over 30 to 60 minutes once every 3 weeks. If a dose is delayed or missed then treatment should be resumed as soon as possible, but if the time between doses is 6 weeks or more then pertuzumab should be restarted at 840 mg followed by 420 mg once every 3 weeks.

Pertuzumab should be withheld or stopped if trastuzumab is withheld or stopped. Pertuzumab and trastuzumab should be withheld for at least 3 weeks if there is a drop in left ventricular ejection fraction (LVEF) to less than 40%, or if LVEF is 40 to 45% with a 10% or greater absolute decrease below pretreatment values. Pertuzumab may be restarted if the LVEF has recovered to more than 45%, or to 40 to 45% associated with less than a 10% absolute decrease below pretreatment values. If the LVEF has not improved, or has declined further, after about 3 weeks then stopping pertuzumab and trastuzumab permanently should be strongly considered.

Pertuzumab is under investigation in the treatment of HER2-positive gastric cancer.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Hypersensitivity and infusion reactions have been reported in patients given pertuzumab. Patients should be monitored for 60 minutes after the first dose, and for 30 minutes after subsequent doses. Other adverse effects reported in patients given pertuzumab (with trastuzumab and docetaxel) include diarrhoea, nausea, neutropenia, fatigue, rash, and peripheral neuropathy. Decreases in left ventricular ejection fraction (LVEF) have occurred in patients who have been given drugs that block HER2 activity, including pertuzumab; LVEF should be assessed before starting pertuzumab and regularly during treatment (see also Uses and Administration, above).

Licensed product information warns against the use of pertuzumab during pregnancy, based on reports of oligohydramnios, delayed fetal kidney development, and embryo-fetal death in *animal* studies.

References.

Effects on the heart. Pertuzumab is anticipated to have adverse cardiac effects because of its inhibition of human epidermal growth factor receptor 2 dimerisation, which has a role in cardiac myocyte homoeostasis. Cardiac safety data from 598 patients in phase 2 studies of pertuzumab have been pooled and analysed.[1] Pertuzumab had been given as monotherapy and in combination regimens with non-anthracycline cytotoxics, trastuzumab, or erlotinib, for various malignancies including metastatic breast cancer. In 331 patients given monotherapy there were 13 cases (6.9%) of asymptomatic left ventricular systolic dysfunction and 1 case (1.4%) of symptomatic heart failure. The incidence of cardiac dysfunction was not significantly different when pertuzumab was given in combination therapy. The median time to these effects was about cycle 4.

However, these studies included patients with a lifetime exposure to anthracyclines up to doxorubicin 360 mg/m^2 or equivalent and excluded those with cardiac comorbidities, which probably contributed to the low rates of cardiac events. In addition, where patients had a history of anthracycline treatment, it had generally been given several months or years before pertuzumab therapy. The effects of regimens containing pertuzumab and anthracyclines is under investigation.

See Effects on the Heart under Trastuzumab (p. 876.3) and Doxorubicin (p. 784.1, for anthracyclines) for further information about the cardiotoxicity of these other drugs.

Picoplatin *(BAN, USAN, rINN)*

AMD-473; NX-473; Picoplatine; Picoplatino; Picoplatinum; ZD-0473; Пикоплатин.

cis-Amminedichloro(2-methylpyridine)platinum(II).

$C_6H_{10}Cl_2N_2Pt$=376.1

CAS — 181630-15-9.

UNII — B5TAN0L720.

Profile

Picoplatin is a platinum derivative that is under investigation as an intravenous antineoplastic for the treatment of small-cell lung cancer, and other solid tumours such as colorectal, ovarian, and prostate cancer. An oral dosage form is also being developed.

References.

Pipobroman *(USAN, pINN)*

A-8103; NSC-25154; Pipobromán; Pipobromanum; Пипоброман.

1,4-Bis[3-bromopropionyl)piperazine.

$C_{10}H_{16}Br_2N_2O_2$=356.1

CAS — 54-91-1.

ATC — L01AX02.

ATC Vet — QL01AX02.

UNII — 6Q99RDT97R.

Profile

Pipobroman is an antineoplastic which appears to act by alkylation. It may be used in the treatment of polycythaemia vera (p. 695.2), in patients requiring myelosuppressive therapy, and in refractory chronic myeloid leukaemia (p. 694.2).

The usual initial dose for polycythaemia vera is 1 mg/kg daily, given orally, and increased to 3 mg/kg, if necessary, according to response. Maintenance dosage is 100 to 200 micrograms/kg daily. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

The main adverse effect is moderate bone-marrow depression, which may develop 4 weeks or more from starting treatment. Anaemia may be marked at higher doses and is usually accompanied by leucopenia. Thrombocytopenia and haemolysis have occurred. In the initial stages of treatment, white cell and platelet counts should be determined on alternate days and complete blood counts once or twice weekly. Dosage should be stopped if the white cell or platelet counts fall below acceptable levels (see also Bone-marrow Depression, p. 730.3).

UNII — D58G680W0G.

Pharmacopoeias. In *Jpn*.

Profile

Pirarubicin is an antineoplastic anthracycline antibiotic that is a structural analogue of doxorubicin (p. 782.3), and has similar properties. It is used in the management of breast cancer and has also been tried in other solid neoplasms, acute leukaemias and lymphomas.

Pirarubicin is formulated as the hydrochloride but doses are in terms of the base. A usual dose of 25 to 50 mg/m² every 3 to 4 weeks has been recommended in breast cancer, but other dosage regimens have been used. Doses may be given by intravenous injection over 5 to 10 minutes into a rapidly-flowing intravenous infusion of glucose 5%. Patients should undergo regular blood counts and monitoring of cardiac function: at cumulative doses above 600 mg/m² ventricular ejection fraction should be checked before each course. Pirarubicin has also been given by the intra-arterial and intravesical routes.

$C_{17}H_{19}N_5O_2.2C_4H_4O_4$=557.5

CAS — 144675-97-8.

ATC — L01DB11.

ATC Vet — QL01DB11.

UNII — P0R64C4CR9.

Profile

Pixantrone is an aza-anthracenedione anthracycline derivative that is structurally similar to mitoxantrone (p. 833.1). However, it lacks the 5,8-dihydroxy substitution groups thought to be responsible for mitoxantrone-induced cardiotoxicity. It is a weak inhibitor of topoisomerase II that directly alkylates DNA to form stable DNA adducts and cross-strand breaks.

Pixantrone is given as monotherapy for the treatment of patients with relapsed or refractory aggressive non-Hodgkin's B-cell lymphomas (p. 696.3).

Pixantrone is given as the dimaleate, but doses are expressed in terms of the base; 1.7 mg of the dimaleate is equivalent to about 1 mg of pixantrone. It is given in a dose equivalent to pixantrone 50 mg/m² on days 1, 8, and 15 of each 28-day cycle, for up to 6 cycles. It is diluted to 250 mL in sodium chloride 0.9% and given by slow intravenous infusion over at least 60 minutes.

Doses may need to be delayed or adjusted according to the degree of toxicity produced.

Pomalidomide *(USAN, rINN)*

CC-4047; IMiD-3; Pomalidomid; Pomalidomida; Pomalidomidum; Помалидомид.

4-Amino-2-[(3*RS*)-2,6-dioxopiperidin-3-yl]-1*H*-isoindole-1,3(2*H*)-dione.

$C_{13}H_{11}N_3O_4$=273.2

CAS — 19171-19-8.

UNII — D2UX06XLB5.

NOTE. IMiD-3 has also been used as a synonym for lenalidomide (p. 816.1).

Uses and Administration

Pomalidomide is a derivative of thalidomide (p. 867.3) that has immunomodulatory and antiangiogenic properties. It is used with dexamethasone or as monotherapy for the treatment of multiple myeloma (p. 699.2) in patients who have been treated with at least 2 other therapies including lenalidomide and bortezomib, and whose disease has progressed within 60 days of completing the last therapy. A usual oral dose of pomalidomide is 4 mg once daily taken on an empty stomach, for 21 days of a 28-day cycle. The dose may need to be modified if toxicities occur, see Administration in Subsequent Cycles, p. 848.1. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Pomalidomide is also under investigation in myelofibrosis.

5. Schey S, Ramasamy K. Pomalidomide therapy for myeloma. *Expert Opin Invest Drugs* 2011; 20: 691–700.
6. Leleu X, *et al.* Pomalidomide plus low-dose dexamethasone is active and well tolerated in bortezomib and lenalidomide-refractory multiple myeloma: Intergroupe Francophone du Myélome 2009-02. *Blood* 2013; 121: 1968–75.
7. Elkinson S, McCormack PL. Pomalidomide: first global approval. *Drugs* 2013; 73: 595–604.

Administration in subsequent cycles. The usual oral dose of pomalidomide may need to be modified if toxicity occurs.

If haematological toxicity occurs, the absolute neutrophil count (ANC) must be at least 500 cells/mm³ and the platelet count must be at least 50 000 cells/mm³ before a dose of pomalidomide is given. The following dose modifications are required when values fall below these concentrations.

- For ANC < 500 cells/mm³, ANC < 1000 cells/mm³ with fever ≥ 38.5 degrees, or platelets < 25 000 cells/mm³: pomalidomide should be withheld until values recover and then resumed at a dose of 3 mg once daily.
- For each subsequent fall (ANC < 500 cells/mm³ or platelets < 25 000 cells/mm³): pomalidomide should be withheld until values recover and then resumed at a daily dose 1 mg less than the previous dose. If toxicities occur at a dose of 1 mg once daily, treatment should be stopped.

If other grade 3 or 4 toxicities occur, pomalidomide should be withheld until values recover to at least grade 2 and then resumed at a daily dose 1 mg less than the previous dose. If toxicities occur at a dose of 1 mg once daily, treatment should be stopped.

Adverse Effects and Precautions

For general discussions, see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Because of its potential teratogenicity, pomalidomide use is restricted in women of child-bearing potential and similar precautions to thalidomide are required, see p. 869.2.

Pomalidomide is associated with haematological toxicity, particularly neutropenia, anaemia, and thrombocytopenia. Full blood counts should be monitored weekly for the first 8 weeks of treatment and then monthly thereafter; dose adjustments may be required, see Administration in Subsequent Cycles, above. Venous thromboembolism has occurred during pomalidomide treatment, and prophylactic measures should be considered in those at increased risk.

Neuropathy, including peripheral neuropathy, has been reported with pomalidomide. Dizziness, confusion, anxiety, insomnia, and headache have occurred.

Other common adverse effects include fatigue, pyrexia, chills, gastrointestinal disorders, anorexia, changes in body weight, muscle spasm or weakness, arthralgia, pain including bone and muscle pain, dyspnoea, cough, epistaxis, hyperhidrosis, rash, dry skin, pruritus, electrolyte disturbances, hyperglycaemia, increases in blood creatinine, and renal failure. Vertigo, increases in bilirubin and hepatic enzymes, and interstitial lung disease have also occurred.

Licensed product information recommends that pomalidomide should be avoided in patients with serum creatinine greater than 3 mg/dL, or with serum bilirubin greater than 2 mg/dL and aspartate aminotransferase or alanine aminotransferase greater than 3 times the upper limit of normal, due to a lack of data in such patients.

There have been reports of acute myeloid leukaemia in patients treated with pomalidomide.

Effects on the lungs. For reports of respiratory toxicity associated with pomalidomide, see under Thalidomide, p. 870.1.

Interactions

Pomalidomide is mainly metabolised by the cytochrome P450 isoenzymes CYP1A2 and CYP3A4; potent inhibitors or inducers of these isoenzymes may affect exposure to pomalidomide. Tobacco smoking may reduce pomalidomide exposure due to induction of CYP1A2.

Pomalidomide is a substrate of P-glycoprotein and other drugs that inhibit or induce P-glycoprotein may affect its exposure.

Pharmacokinetics

Maximum serum concentrations of pomalidomide occur 2 to 3 hours after an oral dose. Plasma protein binding ranges from 12 to 44%. Pomalidomide is distributed into the semen. It is mainly metabolised in the liver by the cytochrome P450 isoenzymes CYP1A2 and CYP3A4, with CYP2C19 and CYP2D6 playing a minor role. Pomalidomide is excreted via the kidneys with a plasma half-life of about 9.5 hours in healthy adults and 7.5 hours in those with multiple myeloma. About 73% of a dose was eliminated in the urine and 15% in the faeces, mainly as metabolites with a small portion as unchanged drug.

$C_{29}H_{27}F_3N_6O$,HCl=569.0

CAS — 1114544-31-8.

UNII — 96R6PU3D8J.

Uses and Administration

Ponatinib is a BCR-ABL tyrosine kinase inhibitor that is used for the treatment of chronic, accelerated, or blast phase chronic myeloid leukaemia, or Philadelphia chromosome-positive acute lymphoblastic leukaemia, that is resistant to, or in patients who are intolerant of, prior tyrosine kinase inhibitor therapy. An oral dose of 45 mg once daily is used and continued until disease progression is noted. Treatment may need to be modified if toxicities occur (see Administration in Subsequent Cycles, below).

If ponatinib is used with a potent cytochrome P450 isoenzyme CYP3A inhibitor, a reduced oral dose of 30 mg once daily is recommended.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

References.
1. Cortes JE, *et al.* Ponatinib in refractory Philadelphia chromosome-positive leukemias. *N Engl J Med* 2012; 367: 2075–88.

Administration in subsequent cycles. The oral dose of ponatinib may need to be modified if toxicity occurs during treatment for chronic myeloid leukaemia, or Philadelphia chromosome-positive acute lymphoblastic leukaemia.

If myelosuppression occurs with the absolute neutrophil count (ANC) falling below 1000 cells/mm³ or platelets falling below 50 000 cells/mm³, interrupt ponatinib until the ANC recovers to at least 1500 cells/mm³ and platelets recover to at least 75 000 cells/mm³. When restarting, the dose should be adjusted as follows:

- for the first occurrence, resume ponatinib at the usual dose of 45 mg once daily
- for the second occurrence, resume ponatinib at a reduced dose of 30 mg once daily
- for the third occurrence, resume ponatinib at a further reduced dose of 15 mg once daily

Treatment modifications for other toxicities are as follows:

- if hepatotoxicity occurs with liver transaminases increased to > 3 times the upper limit of normal (ULN), interrupt ponatinib until transaminases have recovered to < 3 times the ULN
- for asymptomatic grade 1 or 2 increases in serum lipase, consider interruption or dose reduction of ponatinib
- for asymptomatic grade 3 or 4 increases in serum lipase (> 2 times the ULN) or asymptomatic grade 2 pancreatitis, interrupt ponatinib until lipase has recovered to < 1.5 times the ULN
- for symptomatic grade 3 pancreatitis, interrupt ponatinib until symptoms have completely resolved and lipase has recovered to < 1.5 times the ULN
- for grade 4 pancreatitis, stop ponatinib treatment

When restarting therapy, the dose should be adjusted as follows:

- when toxicity occurs on a dose of 45 mg once daily, resume ponatinib at a reduced dose of 30 mg once daily
- when toxicity occurs on a dose of 30 mg once daily, resume ponatinib at a further reduced dose of 15 mg once daily
- when toxicity occurs on a dose of 15 mg once daily, stop ponatinib treatment

Adverse Effects, Treatment, and Precautions

The most common adverse effects with ponatinib are gastrointestinal disorders such as constipation and nausea, hypertension, rash, dry skin, abdominal pain, fatigue, headache, arthralgia, and pyrexia. Other commonly reported effects include arterial ischaemia, heart failure, peripheral oedema, myelosuppression, infections, peripheral neuropathy, dizziness, cough, dyspnoea, myalgia, muscle spasm, pain including back pain and bone pain, mucositis, anorexia, and insomnia. Abnormalities associated with ponatinib treatment include increased liver and pancreatic enzyme values, increased bilirubin, decreased albumin, increased creatinine, increased triglycerides, and electrolyte and blood glucose abnormalities.

Severe myelosuppression has occurred in nearly half of patients treated with ponatinib. Thrombocytopenia, neutropenia, leucopenia, anaemia, and lymphopenia have been seen. Blood counts should be measured every 2 weeks for the first 3 months and then monthly or as clinically indicated, and the dose adjusted as necessary, see Administration in Subsequent Cycles, above.

Arterial thrombotic events have included cardiovascular, cerebrovascular, and peripheral thrombosis, including myocardial infarction and stroke. Most of the patients who developed arterial thrombosis had one or more cardiovascular risk factors. Ponatinib should be interrupted or stopped if such events occur. Venous thromboembolism including deep-vein thrombosis and pulmonary embolism has also occurred, and may require dose modification or treatment to be stopped. Serious bleeding events have been reported, particularly cerebral or gastrointestinal haemorrhage, and were most often seen in patients with severe thrombocytopenia; treatment should be interrupted if bleeding occurs.

Cardiovascular adverse effects include cardiac arrhythmias such as bradyarrhythmias and supraventricular tachyarrhythmias, congestive heart failure or left ventricular dysfunction, and hypertension sometimes leading to hypertensive crisis. Blood pressure should be monitored, and treatment may need to be stopped for severe heart failure. Fluid retention has been seen, particularly peripheral oedema, and pleural or pericardial effusion.

Hepatotoxicity and acute liver failure have occurred and liver function tests should be checked at baseline and at least monthly thereafter; treatment should be adjusted as necessary. Ponatinib is metabolised in the liver and use should be avoided in those with moderate to severe hepatic impairment due to the risk of increased exposure. Pancreatitis has been reported; lipase concentrations may be increased and should be monitored every 2 weeks for the first 2 months and then monthly thereafter or as needed, and treatment modified as necessary.

Hyperuricaemia has occurred, and tumour lysis syndrome has developed occasionally. Ponatinib could compromise wound healing, and gastrointestinal perforation has occurred over a month after abdominal surgery was carried out. Treatment should be stopped at least 1 week before major surgery, and reintroduced once wound healing is deemed adequate.

Interactions

In vitro studies have suggested that ponatinib is a substrate for the cytochrome P450 isoenzyme family CYP3A. Exposure to ponatinib was increased when given with the potent CYP3A4 inhibitor ketoconazole, and ponatinib dose adjustments are required when used with a potent CYP3A inhibitor; for further details, see Uses and Administration, above. Potent inducers of the CYP3A family should be avoided where possible during ponatinib treatment due to the risk of reduced efficacy.

An increase in gastric pH may reduce the bioavailability of, and exposure to, ponatinib and caution is advised with drugs that increase gastric pH such as proton pump inhibitors, histamine H_2-antagonists, or antacids.

Pharmacokinetics

Peak plasma concentrations of ponatinib are seen within 6 hours of an oral dose. Solubility is pH dependent, with higher pH resulting in lower solubility. It is more than 99% bound to plasma proteins *in vitro*, and is a weak substrate for, and an inhibitor of, P-glycoprotein and breast cancer resistance protein (BCRP or ABCG2). Ponatinib is metabolised by the cytochrome P450 isoenzymes CYP3A4 and to a lesser extent CYP3A5, CYP2C8, and CYP2D6, as well as by esterases and amidases. The elimination half-life ranged from 12 to 66 hours (mean 24 hours) once steady state was achieved. Ponatinib is excreted mainly in the faeces (nearly 90%), with a small amount in the urine (about 5%).

Porfimer Sodium *(BAN, USAN, rINN)*

CL-184116; Dihaematoporphyrin Ether; Éter de dihematoporfirina; Porfimeerinatrium; Porfimère Sodique; Porfimera-

trium; Porfímero sódico; Porfimerum Natricum; Порфимер Натрий.
CAS — 87806-31-3.
ATC — L01XD01.
ATC Vet — QL01XD01.
UNII — Y3834SIK5F.

Uses and Administration

Porfimer sodium is a haematoporphyrin derivative that reportedly accumulates in malignant tissue on injection. It is then activated by laser light to release oxygen radicals within malignant cells, producing cytotoxicity. Porfimer sodium is used as a photosensitiser in the photodynamic therapy of endobronchial non-small cell lung cancer (p. 710.2), oesophageal cancer (p. 705.3), and superficial bladder cancer (p. 700.2). It is also used for the treatment of dysplasia associated with Barrett's oesophagus (see Gastro-oesophageal Reflux Disease, p. 1810.2).

Porfimer sodium should be reconstituted with glucose 5% or sodium chloride 0.9% to a final concentration of 2.5 mg/mL. It is given by slow intravenous injection at a dose of 2 mg/kg. This is followed, 40 to 50 hours later, by activation using a laser tuned to a wavelength of 630 nanometres and delivered to the area of the tumour using a fibre optic guide. Residual tumour may subsequently be debrided surgically. A second laser treatment may be given 96 to 120 hours after the original injection. A maximum of 3 courses of photodynamic therapy may be used, with each injection separated by a minimum of 30 days for oesophageal and endobronchial tumours, and a minimum of 90 days for dysplasia in Barrett's oesophagus. However, in the treatment of superficial bladder cancer, only one dose of drug and light is given due to an increased risk of bladder contracture, and no surgical debridement is performed.

For further information about use in hepatic or renal impairment, see below.

Administration in hepatic impairment. US licensed product information states that hepatic impairment could prolong the elimination of porfimer, and that patients with mild to severe hepatic impairment should be warned that the precautions for photosensitivity (see below) may need to be followed for longer than 90 days. EU licensed product information recommends similar warnings for those with mild to moderate impairment; use is contra-indicated in severe hepatic impairment.

Administration in renal impairment. EU licensed product information for some porfimer products (*Photofrin, Axcan*) states that, because excretion of porfimer is mainly via the faecal route, no special precautions are necessary in patients with renal impairment. However, EU licensed product information for other porfimer products (*Photo-Barr*, Axcan) contra-indicates use in severe renal impairment, as it has not been evaluated. US licensed product information (*Photofrin, Axcan*) states that renal impairment could prolong the elimination of porfimer, and that patients with severe renal impairment should be warned that the precautions for photosensitivity (see below) may need to be followed for longer than 90 days.

Photodynamic therapy. Photodynamic therapy (PDT) probably has the greatest potential of the various forms of light-activated treatment.[1] Photosensitising drugs are given intravenously, orally, or topically, and are selectively retained by tumour cells. When exposed to the correct wavelength of light the drug produces toxic oxygen radicals that destroy cell membranes and thereby kill the tumour cells. Vascular damage and immune-mediated injury may also occur.[2-4] Tumour cells must have an adequate supply of oxygen to be sensitive to PDT,[2] and as light penetration is usually limited, early or superficial malignant lesions respond best to therapy.[1,2] Photodynamic therapy has been tried in skin, gastrointestinal, head and neck, bladder, gynaecological, pancreatic, pulmonary, and various intraperitoneal malignancies[2,3,5-12] It is also used for the treatment of Barrett's oesophagus[12-14] and for the treatment of age-related macular degeneration (p. 880.2); it has been tried for other ocular disorders.[15] There is also an interesting report of cytotoxicity against leukaemic cells *in vitro* when exposure to porfimer sodium was combined with ultrasound.[6]

The main adverse effect of photosensitisers such as porfimer is photosensitivity lasting 4 to 8 weeks; patients should be advised to avoid sunlight during this period and therapy is best delayed until the darker winter months if possible.[1] Newer photosensitisers are being developed to show increased tissue penetration and less prolonged photosensitivity.[3] The natural haem precursor 5-aminolevulinic acid (p. 740.1) has the advantage that photosensitivity lasts only a few hours.

Adverse Effects and Precautions

Photosensitivity occurs in all patients treated with porfimer sodium. This effect is likely to be prolonged, and patients should avoid sunlight or bright indoor light for at least 30 days. Some patients may remain photosensitive for longer, and may need to follow these precautions for at least 90 days. However, exposure to ambient indoor light is encouraged, as it allows gradual inactivation of any remaining drug. Other reported adverse effects include local inflammation and pain, including chest, back, or abdominal pain, respiratory insufficiency or distress (including dyspnoea), dehydration, dysphagia, constipation, nausea and vomiting, fever, tachycardia, atrial fibrillation, pleural effusion, and anaemia due to tumour bleeding. Pneumonia, bronchitis, anxiety, insomnia, cardiac failure, and peripheral or generalised oedema have also been reported. Photodynamic therapy with porfimer sodium is contra-indicated in patients with porphyria, oesophageal or gastric varices, large oesophageal ulcers, oesophageal fistulas, erosion of major blood vessels, or severe acute respiratory distress. Sufficient time should be allowed between photodynamic therapy and radiotherapy to allow inflammatory reactions from either treatment to subside.

Porphyria. Licensed product information states that the use of porfimer sodium is contra-indicated in patients with porphyria.

Interactions

Use of porfimer sodium with other drugs causing photosensitivity should be avoided as the reaction may be increased.

Pharmacokinetics

Porfimer sodium is distributed and eliminated slowly after intravenous injection, with plasma elimination half-life reported to be between 11 and 28 days. *In vitro* studies indicate that plasma protein binding is about 90%. Excretion occurs mainly via the faeces.

Porfiromycin *(BAN, USAN, rINN)*

Methyl Mitomycin; NSC-56410; Porfiromicina; Porfiromycine; Porfiromycinum; U-14743; Порфиромицин.
6-Amino-1,1a,2,8,8a,8b-hexahydro-8-(hydroxymethyl)-8a-methoxy-1,5-dimethylazirino[2',3':3,4]pyrrolo[1,2-*a*]indole-4,7-dione carbamate ester.
$C_{16}H_{20}N_4O_5$=348.4
CAS — 801-52-5.
UNII — H1WK901OA6.

Profile

Porfiromycin is an antibiotic antineoplastic structurally related to mitomycin (p. 830.3). It is under investigation for the treatment of malignant neoplasms of the cervix, and the head and neck.

References.

Pralatrexate *(USAN, rINN)*

PDX; Pralatrexato; Pralatrexatum; Пралатрексат.
(2*S*)-2-[(4-{(1*RS*)-1-[(2,4-Diaminopteridin-6-yl)methyl]but-3-ynyl}benzoyl)amino]pentanedioic acid.
$C_{23}H_{23}N_7O_5$=477.5
CAS — 146464-95-1.
ATC — L01BA05.
ATC Vet — QL01BA05.
UNII — A8Q8I19Q20.

Uses and Administration

Pralatrexate is an antineoplastic that acts as an antimetabolite of folic acid; it competitively inhibits the enzyme dihydrofolate reductase. Pralatrexate is used for the treatment of patients with relapsed or refractory peripheral T-cell lymphoma. It is given as an intravenous bolus over 3 to 5 minutes into a free-flowing infusion of sodium chloride 0.9%. The recommended dose is 30 mg/m² once weekly for 6 weeks, in 7-week cycles.

Patients are also given oral folic acid 1 to 1.25 mg daily, which should be started up to 10 days before starting pralatrexate, and continued until 30 days after the last dose. In addition, an intramuscular dose of vitamin B_{12} 1 mg, is given no more than 10 weeks before starting pralatrexate, and every 8 to 10 weeks thereafter; doses may be given on the same day as pralatrexate.

Doses of pralatrexate are modified according to toxicity (see Administration in Subsequent Cycles, below); once the dose is reduced, it should not be increased again.

Pralatrexate is also under investigation for diffuse large B-cell lymphoma, follicular lymphoma, and non-papillary transitional cell carcinoma of the urinary bladder.

5. Zain J, O'Connor O. Pralatrexate: basic understanding and clinical development. *Expert Opin Pharmacother* 2010; 11: 1705–14.

Administration in subsequent cycles. Before any dose of pralatrexate is given, the following conditions are required:
- mucositis must be grade 1 or less
- platelet count should be at least 100 000 cells/mm³ for the first dose, and 50 000 cells/mm³ for all subsequent doses
- absolute neutrophil count (ANC) should be at least 1000 cells/mm³

Doses are omitted or reduced according to toxicity, as outlined below. Once the dose is reduced, it is not increased again.

For **mucositis**, according to grade on the day of treatment, and upon recovery to grade 1 or better, respectively:
- grade 2: omit dose, restart at previous dose
- grade 2 recurrence, or grade 3: omit dose, reduce next dose to 20 mg/m²
- grade 4: stop therapy

For **haematological toxicity**, according to blood count on the day of treatment, duration, and dose upon restarting:
- platelets < 50 000 cells/mm³:
  for 1 week: omit dose, restart at previous dose
  for 2 weeks: omit dose, reduce next dose to 20 mg/m²
  for 3 weeks: stop therapy
- ANC 500 to 1000 cells/mm³ and no fever for 1 week: omit dose, restart at previous dose
- ANC 500 to 1000 cells/mm³ with fever, or ANC < 500 cells/mm³:
  for 1 week: omit dose, give colony-stimulating factor (CSF) support, and restart with previous dose (with CSF support)
  for 2 weeks, or recurrence: omit dose, give CSF support, and reduce next dose to 20 mg/m² (with CSF support)
  for 3 weeks or at second recurrence: stop therapy

For all **other** toxicities, based on grade on day of treatment, and upon recovery to grade 2 or less:

- grade 3: omit dose, restart with 20 mg/m²
- grade 4: stop therapy

Adverse Effects, Treatment, and Precautions

As for Methotrexate, p. 825.1, p. 826.3, and p. 827.1. Patients treated with pralatrexate are also given folic acid and vitamin B_{12} (see Uses and Administration, p. 849.3) to reduce treatment-related haematological toxicity and mucositis.

Interactions

As for Methotrexate, p. 827.3.

Pharmacokinetics

Pralatrexate exposure and peak plasma concentrations have been reported to increase proportionally with dose. Pralatrexate is about 67% bound to plasma proteins. The terminal elimination half-life is about 12 to 18 hours after a single intravenous dose. It is excreted in the urine and clearance decreases with decreasing creatinine clearance.

UNII — XH0NPH5ZX8.

Pharmacopoeias. In *Chin.*, *Int.*, *Jpn*, and *US*.

USP 36: (Procarbazine Hydrochloride). Store in airtight containers. Protect from light.

Uses and Administration

Procarbazine hydrochloride is a methylhydrazine derivative whose antineoplastic effect, although not fully understood, may resemble that of the alkylating agents; it appears to inhibit protein and nucleic acid synthesis and suppress mitosis. It does not show cross-resistance with other cytotoxic drugs.

Its main use is the treatment of Hodgkin's disease (p. 696.1) when it is usually given with other drugs. Procarbazine has also been used in the treatment of non-Hodgkin's lymphomas (p. 696.3) and refractory solid tumours.

Doses of procarbazine hydrochloride are calculated in terms of procarbazine; procarbazine hydrochloride 116 mg is equivalent to about 100 mg of procarbazine. Procarbazine is given orally. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* In combination regimens such as MOPP (with chlormethine, vincristine, and prednisone), procarbazine hydrochloride is given in doses equivalent to procarbazine 100 mg/m² daily for 10 to 14 days of each 4- to 6-week cycle. If used as a single agent, a dose equivalent to 50 mg of procarbazine daily, increased by 50 mg daily to 250 to 300 mg daily in divided doses has been suggested in the UK, while in the USA the recommended regimen is 2 to 4 mg/kg daily for the first week, subsequently increased to 4 to 6 mg/kg daily, doses being given to the nearest 50 mg. These doses are continued until maximum response is achieved or leucopenia, thrombocytopenia, or other signs of toxicity occur. Maintenance doses are usually 50 to 150 mg daily in the UK, given until a total dose of at least 6 g has been reached; in the USA maintenance doses of 1 to 2 mg/kg daily are given. Procarbazine treatment should be withheld if toxicity occurs, and restarted upon recovery. For doses in children, see below.

Administration in children. Procarbazine hydrochloride is used in children mainly for Hodgkin's disease when it is usually given with other drugs. It has also been used for other advanced lymphomas or solid tumours. In combination regimens such as MOPP (with chlormethine, vincristine, and prednisone), procarbazine hydrochloride is given to children in equivalent doses to adults, see above. If used as a single agent, an initial oral dose equivalent to procarbazine 50 mg/m² daily for the first week is suggested in the USA (UK licensed product information suggests a dose of 50 mg), increased to 100 mg/m² thereafter until maximum response or toxicity occurs. US licensed product information suggests the dose may be reduced to 50 mg/m² for maintenance when maximum response has been obtained. Procarbazine treatment should be withheld if toxicity occurs, and restarted upon recovery.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The most common adverse effects associated with procarbazine are gastrointestinal disturbances such as anorexia, nausea and vomiting (although patients may soon become tolerant), and bone-marrow depression. Leucopenia and thrombocytopenia may be delayed with a nadir at about 4 weeks after a dose, and recovery usually within 6 weeks. Anaemia, haemolysis, and bleeding tendencies have been reported.

Neurotoxicity is also common, with central effects such as somnolence, depression, nervousness or confusion, headache, hallucinations, and dizziness, and peripheral neuropathies including paraesthesias and decreased reflexes. Lethargy, ataxia, and sleep disorders have also occurred, and tremors, convulsions, and coma have been reported.

Other adverse effects reported include fever and myalgia, pulmonary fibrosis or pneumonitis, haematuria, urinary frequency, skin reactions including dermatitis, pruritus, and hyperpigmentation, tachycardia, orthostatic hypotension, ocular defects, infertility, and hepatic impairment.

Procarbazine is a carcinogen, mutagen, and teratogen.

Procarbazine should be used with caution in patients with hepatic or renal impairment, and is contra-indicated if impairment is severe. The haematological status of the patient should be determined at least every 3 or 4 days and hepatic and renal function determined weekly. Care is also advisable in patients with phaeochromocytoma, epilepsy, or cardiovascular or cerebrovascular disease. Treatment should be interrupted if allergic skin reactions occur.

Handling and disposal. *Urine* produced for up to 48 hours after a dose of procarbazine should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Procarbazine is a weak MAOI and the possibility of reactions with other drugs and food, although very rare, must be borne in mind—for details of MAOI reactions see p. 444.3 and p. 445.1. Procarbazine may enhance the sedative effects of other CNS depressants. A disulfiram-like reaction has been reported with alcohol and the effects of antihypertensive agents may be enhanced.

Antiepileptics. Use with enzyme-inducing antiepileptics is associated with an increased risk of hypersensitivity reactions to procarbazine, possibly through a reactive intermediate generated by induction of the cytochrome P450 isoenzyme CYP3A subfamily.[1] Non-enzyme-inducing antiepileptics might be more appropriate in patients with brain tumours in whom procarbazine therapy is anticipated.

1. Lehmann DF, *et al.* Anticonvulsant usage is associated with an increased risk of procarbazine hypersensitivity reactions in patients with brain tumors. *Clin Pharmacol Ther* 1997; 62: 225–9.

Pharmacokinetics

Procarbazine is readily absorbed from the gastrointestinal tract. It crosses the blood-brain barrier and diffuses into the CSF. A plasma half-life of about 10 minutes has been reported. Procarbazine is rapidly metabolised (mainly in liver and kidneys) and only about 5% is excreted unchanged in the urine. The remainder is oxidised to *N*-isopropylterephthalamic acid and excreted in the urine, up to about 70% of a dose being excreted in 24 hours. Some of the drug is excreted as carbon dioxide and methane via the lungs. During oxidative breakdown in the body hydrogen peroxide is formed which may account for some of the drug's actions.

Raltitrexed *(BAN, USAN, rINN)*

D-1694; ICI-D1694; Raltitreksed; Raltitreksedi; Raltitrexedum; ZD-1694; Ралтитрексед.

N-{5-[3,4-Dihydro-2-methyl-4-oxoquinazolin-6-ylmethyl(methyl)amino]-2-thenoyl}-L-glutamic acid.

$C_{21}H_{22}N_4O_6S$=458.5

CAS — 112887-68-0.

ATC — L01BA03.

ATC Vet — QL01BA03.

UNII — FCB9EGG971.

Uses and Administration

Raltitrexed is a folate analogue that is a potent and specific inhibitor of the enzyme thymidylate synthase, which is involved in the synthesis of DNA. It has been used in the treatment of advanced colorectal cancer (p. 706.3) and has also been tried in breast cancer (p. 702.1) and other solid neoplasms.

The recommended initial dose of raltitrexed in patients with normal renal function is 3 mg/m² given by intravenous infusion over 15 minutes. Subsequent doses, which should be reduced by up to 50% depending on the severity of initial toxicity, may be given at intervals of 3 weeks provided toxicity has resolved.

A full blood count should be performed before each dose and treatment withheld if the white cell or platelet counts are below acceptable levels (see also Bone-marrow Depression, p. 730.3). Hepatic and renal function should also be tested. It is essential that doses be adjusted in renal impairment (see below).

12. Wilson KS, Malfair Taylor SC. Raltitrexed: optimism and reality. *Expert Opin Drug Metab Toxicol* 2009; 5: 1447–54.

Administration in renal impairment. It is essential that doses of raltitrexed be adjusted in renal impairment (creatinine clearance less than 65 mL/minute) as fatalities have been associated with the failure to make such adjustments (see Toxicity, under Adverse Effects, p. 851.1). The dosage

interval should be increased from 3 to 4 weeks and the dose adjusted on the basis of creatinine clearance (CC) as follows:

- CC of 55 to 65 mL/minute, 2.25 mg/m²
- CC of 25 to 54 mL/minute, 1.5 mg/m²(in some countries, adjustment of the dose to a percentage of the full dose equivalent to the value of the CC in mL/minute is suggested in this group, e.g. reduction to 30% in those with a CC of 30 mL/minute, or 40% if CC is 40 mL/minute)
- CC less than 25 mL/minute, treatment contra-indicated

Adverse Effects, Treatment, and Precautions

Raltitrexed produces bone marrow depression, usually mild to moderate, with leucopenia, anaemia, and, less frequently, thrombocytopenia. The nadir of the white cell count usually occurs 7 to 14 days after a dose, with recovery by the third week. Full blood counts should be monitored before each dose, and treatment may be withheld and restarted at reduced doses if needed (see Uses and Administration, p. 850.3). Gastrointestinal toxicity is also common, with nausea and vomiting, diarrhoea, and anorexia; mucositis may occur. Gastrointestinal bleeding has been reported rarely. Reversible increases in liver enzyme values have occurred. Other adverse effects include weakness and malaise, fever, pain, headache, rashes, desquamation, arthralgia, muscle cramps, weight loss, dehydration, peripheral oedema, alopecia, increased sweating, taste disturbance, and conjunctivitis. Cellulitis and sepsis have been reported. The use of folinic acid 25 mg/m² every 6 hours intravenously has been suggested in licensed product information for patients who develop very severe toxicity.

Raltitrexed should be given with care to patients with hepatic impairment and should be avoided if impairment is severe. It should also be avoided in severe renal impairment and be given in reduced doses in moderate impairment, based on creatinine clearance (see Administration in Renal Impairment, p. 850.3). Care is also advisable in debilitated or elderly patients or in patients who have had radiotherapy.

Raltitrexed is teratogenic; pregnancy should be avoided while either partner is receiving the drug and for at least 6 months after treatment. It may impair male fertility.

Toxicity. A large multicentre study comparing raltitrexed with fluorouracil plus folinic acid was suspended in 1999 due to an excess of deaths in the raltitrexed arm.[1] This decision has led to some controversy,[1-3] as in 11 of the 17 deaths in patients taking raltitrexed there was evidence that the dose had not been correctly adjusted to take account of renal function. In addition, and further confusing the issue, the incidence of reported serious adverse effects was lower in raltitrexed-treated patients than in controls. A further study[4] reported an increased rate of raltitrexed-related deaths compared with fluorouracil-based regimens. Almost all of the 18 deaths were caused by gastrointestinal and haematological toxicity, and in 3 of these the dose of raltitrexed had not been adjusted for toxicity.

4. Maughan TS, *et al.* Comparison of survival, palliation, and quality of life with three chemotherapy regimens in metastatic colorectal cancer: a multicentre randomised trial. *Lancet* 2002; **359:** 1555–63.

Interactions

Raltitrexed should not be given with folic or folinic acid, which may impair its cytotoxic action. (For the deliberate use of folinic acid to counteract the effects of raltitrexed in patients with severe toxicity, see above.)

Pharmacokinetics

After intravenous doses raltitrexed has triphasic pharmacokinetics, with an initial rapid decline from peak plasma concentrations followed by a slow terminal elimination phase. Raltitrexed is actively transported into cells and metabolised to active polyglutamate forms. The remainder of a dose is excreted unchanged, about 50% of a dose appearing in the urine, and about 15% in the faeces. The terminal elimination half-life is about 8 days. Clearance is markedly reduced in renal impairment.

Ramucirumab *(USAN, rINN)*

IMC-1121B; Ramucirumabum; Рамуцирумаб.
CAS — 947687-13-0.
UNII — D99YVK4L0X.

Profile

Ramucirumab is a human monoclonal antibody that targets the vascular endothelial growth factor receptor-2 (VEGFR-2). It is under investigation for the treatment of various solid tumours, including those of the breast, gastrointestinal tract, and lung.

CAS — 58994-96-0.
ATC — L01AD07.
ATC Vet — QL01AD07.
UNII — RYH2T97J77.

Profile

Ranimustine is a nitrosourea derivative with general properties similar to those of carmustine (p. 761.2). It is used intravenously in the treatment of malignant neoplasms in usual doses of 50 to 90 mg/m² every 6 to 8 weeks according to haematological response.

Ranpirnase *(USAN, rINN)*

P-30 Protein; Ranpirnasa; Ranpirnasum; Раппирназа.
CAS — 196488-72-9.

NOTE. Ranpirnase has been incorrectly stated to contain ergotamine. The name Onconase has been used as a trade mark for ranpirnase.

Profile

Ranpirnase is a ribonuclease reported to have antineoplastic properties. It is under investigation in the treatment of malignant mesothelioma. Ranpirnase has also been investigated in the management of solid tumours. It is also reported to have activity *in vitro* against HIV.

Regorafenib *(USAN, rINN)*

Bay-73-4506; Regorafenib; Regorafenibum; Регорафениб.
4-[4-[[[4-Chloro-3-(trifluoromethyl)phenyl]carbamoyl]amino]-3-fluorophenoxy]-*N*-methylpyridine-2-carboxamide.
$C_{21}H_{15}ClF_4N_4O_3$=482.8
CAS — 755037-03-7 (anhydrous regorafenib); 1019206-88-2 (regorafenib hydrate).
ATC — L01XE21.
ATC Vet — QL01XE21.
UNII — 24T2A1DOYB.

Profile

Regorafenib is an oral inhibitor of several receptor tyrosine kinases. It is used for the treatment of patients with metastatic colorectal cancer (p. 706.3) who have been previously treated with fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy, a vascular endothelial growth factor inhibitor, and an epidermal growth factor receptor inhibitor (if *KRAS* wild-type). Regorafenib is also used in those with locally-advanced unresectable or metastatic gastrointestinal stromal tumours (see Soft Tissue Sarcoma, p. 718.2) that have been previously treated with imatinib and sunitinib. The recommended dose is 160 mg orally once daily for the first 21 days of each 28-day cycle. Treatment is continued until patients no longer benefit, or unacceptable toxicity occurs. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* Regorafenib should be taken at the same time each day with a low-fat meal. If a daily dose is missed, the next day's dose should not be doubled. Doses may need to be adjusted or treatment withheld or permanently stopped for severe toxicity.

It is also under investigation for the treatment of various other malignant neoplasms.

Hepatotoxicity has occurred and may be severe; deaths have been reported. Liver function should be monitored before, and every 2 weeks during the first 2 months of treatment; thereafter, monitoring should be monthly. Regorafenib is metabolised by the cytochrome P450 isoenzyme CYP3A4 and by the uridine diphosphate glucuronosyltransferase enzyme UGT1A9 and concomitant use of strong CYP3A4 inhibitors and inducers should be avoided.

$C_{53}H_{84}NO_{14}P$=990.2
CAS — 572924-54-0.
ATC — L01XE19.
ATC Vet — QL01XE19.
UNII — 48Z35KB15K.

NOTE. The name Jenzyl has been used as a trade mark for ridaforolimus.

Profile

Ridaforolimus is an analogue of sirolimus (p. 1970.2). It inhibits the 'mammalian target of rapamycin' (mTOR), interfering with the cell cycle, and is under investigation for the treatment of malignancies such as breast, endometrial, prostate, and lung cancer.

Rituximab *(BAN, USAN, rINN)*

IDEC-102; IDEC-C2B8; R-105; Rituksimab; Rituksimabi; Rituximabum; Ритуксимаб.

Immunoglobulin G1 (human-mouse monoclonal IDEC-C2B8 γ1-chain anti-human antigen CD 20), disulfide with human-mouse monoclonal IDEC-C2B8 κ-chain, dimer.

CAS — 174722-31-7.
ATC — L01XC02.
ATC Vet — QL01XC02.
UNII — 4F4X42SYQ6.

Uses and Administration

Rituximab is a chimeric monoclonal antibody that binds specifically to the CD20 antigen. Rituximab is used in the treatment of non-Hodgkin's lymphomas (p. 696.3), as monotherapy in relapsed or refractory low-grade or follicular lymphoma, or in first-line regimens for follicular lymphoma with combination chemotherapy, such as CVP (cyclophosphamide, vincristine, and prednisolone). Rituximab monotherapy may also be used in patients with low-grade stable disease after first-line treatment with CVP chemotherapy. It is also indicated for maintenance therapy in patients with follicular lymphoma who respond to induction chemotherapy that may or may not have contained rituximab. Rituximab is also used with CHOP chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisone or prednisolone) or other anthracycline-based regimens for CD20-positive diffuse large B-cell non-Hodgkin's lymphoma. Rituximab also forms part of the combination regimen employing ibritumomab tiuxetan (p. 804.3). Rituximab is also used with combination chemotherapy for chronic lymphocytic leukaemia (p. 693.3). Rituximab with methotrexate is used in adults with severe active rheumatoid arthritis (p. 853.3) who have had an inadequate response to, or are intolerant of, other disease-modifying antirheumatic drugs (DMARDs), including at least one TNF inhibitor; in the USA, it may also be used in moderate disease. Rituximab plus corticosteroids is used in adults with Wegener's granulomatosis (p. 1615.2) and microscopic polyangiitis (p. 1610.2).

Rituximab is licensed for use by intravenous infusion over several hours, diluted in sodium chloride 0.9% or glucose 5% to a final concentration of between 1 and 4 mg/mL. The first infusion is normally begun at a rate of 50 mg/hour; this may be increased in increments of 50 mg/hour every 30 minutes to a maximum of 400 mg/hour, if well tolerated. Subsequent doses may be begun at a rate of 100 mg/hour, and increased in increments of 100 mg/hour every 30 minutes to a maximum of 400 mg/hour.

In the UK for the *treatment* of refractory or relapsed follicular **lymphoma**, rituximab is given as a single agent in a usual dose of 375 mg/m² once weekly for 4 doses; in the USA 4 or 8 doses may be given. Patients in either country may be re-treated after relapse for a further 4 doses. When given with combination chemotherapy for previously untreated follicular lymphoma, or for diffuse large B-cell lymphoma (with CHOP), rituximab 375 mg/m² is given on day 1 of the chemotherapy cycle, after the corticosteroid component of the regimen, for up to a total of 8 cycles. In patients previously treated with 6 to 8 cycles of CVP chemotherapy for low-grade lymphoma and who have not progressed, rituximab 375 mg/m² may be given once weekly for 4 doses, repeated every 6 months, for up to 16 doses.

In the regimen with ibritumomab tiuxetan, rituximab is usually given at a dose of 250 mg/m², within 4 hours before the ibritumomab infusions.

For *maintenance* treatment in those with follicular lymphoma who have responded to induction chemotherapy, rituximab is given as monotherapy. In previously untreated patients rituximab 375 mg/m² is started 2 months after the last dose of induction chemotherapy and given once every 2 months. In the UK this is continued until disease progression or for a maximum of 2 years, whereas in the USA, 12 doses of rituximab are given for maintenance. In the UK rituximab maintenance is also used in those with refractory or relapsed disease that responds to subsequent induction treatment with a combination regimen; 375 mg/m² is started 3 months after the last dose of induction chemotherapy and given once every 3 months. Maintenance treatment is continued until disease progression or for a maximum of 2 years.

In the treatment of **chronic lymphocytic leukaemia**, the recommended dose of rituximab is 375 mg/m², given on the day before chemotherapy in cycle 1, followed by 500 mg/m² given on day 1 of each subsequent cycle, for up to 6 cycles in total; chemotherapy is given after the rituximab infusion. Prophylactic hydration and allopurinol or rasburicase is recommended, starting 48 hours before rituximab, to reduce the risk of tumour lysis syndrome; in the UK, those with high lymphocyte counts are given intravenous corticosteroids before rituximab to reduce the incidence and severity of infusion reactions.

In the treatment of **rheumatoid arthritis**, rituximab is given in a dose of 1 g, for 2 doses; the infusions are separated by 2 weeks. It is given with methotrexate, and intravenous corticosteroids are recommended before each infusion to reduce the incidence and severity of infusion reactions. Licensed product information states that subsequent courses should be given every 24 weeks or based on clinical evaluation, but no sooner than every 16 weeks; however, guidance issued by NICE in the UK recommends that rituximab should be given no more often than every 6 months.

For the treatment of **Wegener's granulomatosis** and **microscopic polyangiitis**, rituximab is given in a dose of 375 mg/m² once weekly for 4 doses; corticosteroids are also given to treat severe vasculitic symptoms, preferably beginning within 14 days before rituximab is started, and continuing during and after rituximab therapy.

General reviews.

2. McDonald V, Leandro M. Rituximab in non-haematological disorders of adults and its mode of action. *Br J Haematol* 2009; **146**: 233–46.

Administration. *RATE.* Licensed product information states that rituximab infusions should be given at a specific rate (see Uses and Administration, above). In an effort to reduce infusion times, faster rates have been investigated. One study gave the first infusion of rituximab in cycle 1 as in the licensed product information, but subsequent infusions were given over 90 minutes, with 20% of the dose given in the first 30 minutes, and the remaining 80% over 60 minutes; the total dose was delivered in 250 mL. Rapid infusion was well tolerated with no serious infusion reactions; 10 out of 150 patients who had an adverse reaction with the first cycle (given at the standard licensed rate) tolerated subsequent rapid infusion without event, and 8 patients were not premedicated with corticosteroids.[1] Another study also reported that rituximab infusions given over 90 minutes, with or without corticosteroids, were well tolerated and safe.[2] In another study, 40 patients were given rituximab; the first infusion was given as licensed and averaged 5 hours. All subsequent infusions were given over 1 hour. It was reported that even those patients who had shown some hypersensitivity during the first infusion were able to tolerate the rapid infusion without problems.[3] A survey found that the majority of chemotherapy units in the UK were infusing second and subsequent rituximab infusions over 90 minutes if patients had no significant reactions to the initial rituximab infusion. In this study 54 patients were given an initial infusion over 90 minutes and, if no serious reactions were noted, were given subsequent infusions over 60 minutes; the 1-hour infusion was well tolerated in all patients.[4]

ROUTE. Rituximab has been used *intralesionally* in the treatment of cutaneous B-cell lymphoma. There are reports of benefit, with long-term remission in some patients,[1] but rapid recurrence in others.[2] In a study of 8 patients, intralesional rituximab was given to 6 patients, in doses of 10 to 30 mg per lesion, 3 times weekly; if clinical remission was incomplete, another cycle of 3 injections was given 1 month later. Two patients were treated intravenously with weekly infusions for 4 weeks. Complete remission was seen in all 8 patients. No relapse was seen in those given intravenous therapy, but recurrences were seen in 4 of the 6 patients treated intralesionally. Moderate pain was reported during intralesional injection.[3]

Rituximab has also been used *intrapleurally* for the treatment of malignant pleural effusions in a patient with non-Hodgkin's lymphoma, in whom effusions continued to increase despite systemic chemotherapy and chest drainage. An initial test dose of rituximab 50 mg in 50 mL of sterile saline was given as a bolus into the right pleural cavity on day 1. This was followed by 200 mg in 100 mL on day 2 into the left cavity, and 400 mg in 100 mL on day 3 into the right cavity; both doses were given over 5 minutes. The therapy was well tolerated, and the effusions resolved within 2 weeks. The patient received 4 courses of intravenous rituximab consolidation therapy during a follow-up of 6 months; the effusions did not recur.[4]

Massive ascites developed in a patient with stage IV mantle cell lymphoma that was refractory to conventional chemotherapy (including intravenous rituximab added to the CHOP regimen). A palliative experimental treatment with *intraperitoneal* rituximab was given in a dose of 600 mg in 500 mL of sodium chloride 0.9%, and instilled over 4 hours. This was applied weekly for 11 courses, each time after drainage of ascites. No systemic adverse effects were noted, and the general status of the patient improved significantly; ascites resolved completely and partial remission of intra-abdominal lymph nodes and splenomegaly was noted. The patient remained asymptomatic for more than 6 months.[5]

Patients with CNS lymphoma have been treated with *intraventricular* or *intrathecal* doses of rituximab. Dose ranged from 10 to 40 mg in volumes of 1 to 4 mL, and an equivalent volume of CSF was removed before intraventricular use. Rituximab therapy was reported to be effective in those with leptomeningeal involvement, but solid parenchymal tumours progressed or showed only minor response.[6] A further study of intrathecal rituximab in patients with acute lymphoblastic leukaemia and CNS disease reported complete remission in 5 patients, with no clinical evidence of neurotoxicity after 2 years of follow-up. Rituximab 10 mg was diluted in 6 mL of saline and given intrathecally every week for 4 consecutive weeks.[7]

Administration in children. Although not licensed in the UK or the USA for use in children, there are reports of benefit in children with various diseases, such as autoimmune haemolytic anaemia, immune thrombocytopenia (see also below and p. 853.1, respectively), and post-transplantation lymphoproliferative disease,[1] as well as rheumatoid arthritis, and SLE.[2] Standard doses of 375 mg/m² weekly have usually been given, in most cases for a median course of 4 doses.

HAEMORRHAGIC DISORDERS. Although data are limited, reports suggest that rituximab may be an effective alternative for the treatment of acquired haemophilia (p. 1126.3) after established therapies have failed.[1,2] Durable responses have been reported after rituximab was used first-line or as salvage therapy;[3] the usual intravenous dose used was 375 mg/m² once weekly for 4 weeks. Patients with high autoantibody titres may only achieve a partial response, or be slow to respond, but increasing the number of doses of rituximab or using it with cyclophosphamide and/or corticosteroids may improve response. Rituximab may be an effective alternative for those patients unable to have cytotoxic therapy.

An analysis[4] of the use of rituximab in 49 patients with congenital haemophilia (haemophilia A or B) concluded

that about half of haemophiliacs with inhibitors resistant to previous immune tolerance regimens could be durably rescued with rituximab, and that the highest responses were seen in adult haemophiliacs with mild or moderate disease who were given rituximab as part of a protocol that included factor VIII concentrates or other immunosuppressive drugs.

IMMUNE THROMBOCYTOPENIA. Rituximab has been reported[1-3] to be effective in patients, including children and infants, with immune thrombocytopenia (p. 1606.1) refractory to standard treatments. Some consider it to be a possible alternative treatment, with good response rates and durable responses obtained in both adults and children.[4] Two patterns of response have been seen: within 4 weeks, or until several weeks or even months after the start of rituximab, suggesting additional mechanisms of action besides depletion of autoantibodies. While most studies used rituximab in a usual intravenous dose of 375 mg/m^2 once weekly for 4 weeks, lower doses (including a single dose regimen for children) have been used. Re-treatment of patients who relapse after an initial response to rituximab is also an option, and rituximab has been used alone or with other drugs.[4] However, a review[5] cautioned against the indiscriminate use of rituximab in this patient population, given the lack of controlled data.

THROMBOTIC MICROANGIOPATHIES. Rituximab has been reported[1-3] to be of benefit in relapsed or refractory thrombotic thrombocytopenic purpura (see under Plasma, p. 1159.1). Time to response has ranged from less than 1 week to about 13 weeks;[4] durable remissions have been reported.[5] Most patients are reported to have received the standard intravenous dose of rituximab 375 mg/m^2 once weekly for 4 weeks; however, some patients required prolonged therapy, whereas others responded with only 1 or 2 doses.[4]

Castleman's disease. Castleman's disease is a rare lymphoproliferative disorder, often associated with HIV infection (p. 957.2) and thought to be caused by the same virus (human herpesvirus 8) as Kaposi's sarcoma. No standard treatment has been established. Responses to rituximab therapy have been reported in two small open-label studies in patients with HIV-associated Castleman's disease;[1,2] rituximab 375 mg/m^2 was given intravenously once weekly for 4 weeks. However, exacerbation of Kaposi's sarcoma lesions may be a problem.

2. Bower M, *et al.* Brief communication: rituximab in HIV-associated multicentric Castleman disease. *Ann Intern Med* 2007; **147:** 836–9.

Eye disorders. Orbital pseudolymphomas are uncommon benign tumours which usually affect the lachrymal gland, orbital soft tissue, or extra-ocular muscles. Clinical presentation includes painless onset of ptosis, proptosis, diplopia, or eyelid swelling. There are reports of durable response to rituximab.[1]

1. Witzig TE, *et al.* Treatment of benign orbital pseudolymphomas with the monoclonal anti-CD20 antibody rituximab. *Mayo Clin Proc* 2007; **82:** 692–9.

Glomerular kidney disease. In a report of 5 patients with corticosteroid-resistant nephrotic syndrome, 4 patients had a complete remission and 1 patient had a partial remission after treatment with rituximab in standard doses for 4 weeks. Complete remission was maintained in 3 patients, despite tapering of corticosteroids and calcineurin inhibitors.[1] The limited evidence for such use has subsequently been reviewed.[2]

Organ and tissue transplantation. Rituximab is a treatment option for patients with chronic graft-versus-host disease (GVHD; see Haematopoietic Stem Cell Transplantation, p. 1937.1). Available data suggest that rituximab may be particularly effective for patients with extensive corticosteroid-refractory chronic GVHD manifesting as thrombocytopenia, or for those with sclerodermatous, cutaneous, or rheumatological involvement.[1] Post-transplant lymphoproliferative disorder (PTLD) after solid organ transplantation (see p. 1936.2 *et seq*) is rare but life-threatening; many cases, especially more aggressive lymphomas, do not respond to the usual first-line therapy of reduction in immunosuppression. Rituximab and/or chemotherapy have been used for PTLD. Some recommend that patients with Epstein-Barr virus (EBV) positive and early-onset PTLD be given rituximab monotherapy if reduction in immunosuppression fails; treatment with chemotherapy is reserved for those who fail to respond to rituximab. More aggressive treatment, including the use of rituximab with combination chemotherapy (given sequentially or concurrently), should be considered initially, along with reduction of immunosuppressive treatment, in those patients with CD20-positive or high-grade PTLDs. The use of granulocyte colony-stimulating factors and antibacterials as prophylaxis against infectious complications should be considered in this high-risk population.[2] Rituximab has been investigated as induction therapy for patients undergoing renal transplantation, but a small study reported an excess risk of acute cellular rejection in those given rituximab.[3]

Pemphigus. Rituximab has been reported to be of benefit in pemphigus vulgaris (p. 1687.1) and its use has been reviewed.[1,2] In a review of 17 cases, it was used in patients with severe and widespread disease that had not responded to usual therapy with corticosteroids and immunosuppressants. A dose of 375 mg/m^2 once weekly was used and most patients were given a course of 4 doses. Most patients showed some improvement from rituximab, including 9 who were free of clinical disease for more than 6 months and 5 who had a partial response. However, although concomitant therapy could be reduced in 8 patients, only 2 were able to stop systemic corticosteroids and immunosuppressants; in 6 cases this information was not reported. Rituximab might therefore be useful for remission induction when corticosteroids have not been effective, but long-term follow-up is needed. Rituximab with normal immunoglobulins has also been reported to be effective in patients with refractory pemphigus vulgaris.[3]

Rituximab has also been reported to be of benefit in pemphigus foliaceus,[4-6] a less common variant of pemphigus. A single cycle of 4 weekly infusions of rituximab was reported to achieve complete remission in 12 of 14 patients with pemphigus vulgaris and 6 of 7 patients with pemphigus foliaceus; 2 patients in the former group achieved delayed complete remission. Of these 20 patients, 6 with pemphigus vulgaris and 3 with pemphigus foliaceus had a relapse; 2 of these 9 patients were given a second course of rituximab and again achieved complete remission. After 34 months of follow-up, 18 patients were free of disease, and 8 of these were not receiving any systemic therapy.[7]

Rheumatoid arthritis. Rituximab is of benefit in patients with rheumatoid arthritis (p. 13.2) refractory to standard therapy.[1-4] The ability of rituximab to prevent articular damage, its efficacy for extra-articular manifestations, the efficacy and safety of repeated courses, and long-term effects on the immune system remain to be determined.[5] Radiographic data from a placebo-controlled study showed a trend towards less progression of structural joint damage with a course of rituximab (2 doses); assessment was made at 24 weeks.[6] In a consensus statement, European and Canadian rheumatologists stated that re-treatment with rituximab may be considered after week 24 in those who respond to initial therapy.[7]

Vasculitic syndromes. Rituximab has been reported to be of benefit in treating vasculitic syndromes (p. 1615.2), including those associated with antineutrophil cytoplasmic antibodies (ANCA-associated vasculitis).[1-4] Similar efficacy to cyclophosphamide has been reported,[3,4] with some suggestion that rituximab may be more effective in relapsing disease.[4] Successful treatment of scleritis associated with Wegener's granulomatosis has also been described.[5] Safety and efficacy have also been reported[6] with the use of rituximab in patients with refractory Henoch-Schönlein purpura (see Hypersensitivity Vasculitis, p. 1606.1).

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Infusion of rituximab has been associated with a cytokine release syndrome of fever, chills, and rigors, usually within 2 hours of beginning therapy (see also Infusion-related Reactions, below). Other reported symptoms include pruritus, urticaria, rashes, dyspnoea, bronchospasm, angioedema, transient hypotension, and flushing; myocardial infarction, ventricular fibrillation, and cardiogenic shock can occur. Asthenia, headache, rhinitis, and hypertension may also be associated with infusion reactions. Severe cases may be associated with tumour lysis syndrome (and its associated electrolyte abnormalities such as hyperuricaemia, hyperkalaemia, hypocalcaemia, and hyperphosphataemia), acute renal failure, acute respiratory failure, and death. Hypersensitivity reactions manifest similarly to the cytokine release syndrome, but usually occur within minutes of starting infusion. Mucocutaneous reactions, some fatal, and including Stevens-Johnson syndrome or toxic epidermal necrolysis have also occurred. A reaction resembling serum sickness has been reported.

Patients with an extensive tumour burden, pulmonary tumour infiltration or pulmonary insufficiency may be at increased risk of severe infusion reactions and should be treated with caution and possibly a decreased initial infusion rate. Therapy should be interrupted in patients who develop severe symptoms and only resumed, at up to half the previous rate, once all signs and symptoms have resolved. Premedication with analgesics, antihistamines, and possibly corticosteroids is recommended in all patients before receiving rituximab.

Use of rituximab is associated with an increased risk of progressive multifocal leukoencephalopathy (PML), and fatalities have been reported. In most cases, patients had multiple risk factors, including long-term treatment with combination chemotherapy or immunosuppression, or were undergoing haematopoietic stem cell transplantation. Patients should be monitored regularly for new or worsening neurological clinical manifestations suggestive of PML; rituximab should be permanently stopped if PML develops.

Reactivation of hepatitis B virus (HBV) has occurred in some patients; fulminant hepatitis, hepatic failure, and fatalities have been reported. Patients at high risk of HBV infection should be screened before starting rituximab therapy and carriers should be monitored for signs of active infection or hepatitis during and for several months after therapy. Rituximab should be stopped if viral hepatitis develops. Other serious infections, which may be fatal, can occur with rituximab.

Haematological adverse effects including lymphopenia, leucopenia, neutropenia, thrombocytopenia, and anaemia have occurred in some patients; effects are usually considered mild and reversible. Complete blood and platelet counts should be monitored regularly. Exacerbation of heart failure and angina pectoris has also been reported, and other cardiac events include arrhythmias and tachycardia. Gastrointestinal disturbances may also occur. Abdominal pain, bowel obstruction, and perforation, in some cases fatal, have been reported with rituximab, usually with combination chemotherapy.

Effects on the blood. Late-onset neutropenia (defined as neutropenia occurring 30 days after the last dose) has been reported in patients receiving rituximab.[1] Acute and potentially severe thrombocytopenia associated with rituximab therapy has also been reported occasionally.[2,3] Haemolytic anaemia occurred in a patient given 4 doses of rituximab, plus corticosteroid therapy, for refractory pemphigus vulgaris.[4] Although there was a drop in haemoglobin after the first and second doses of rituximab, concentrations then stabilised; the reticulocyte count remained high throughout treatment.

Effects on the eyes. About 20 minutes after the start of a rituximab infusion, a patient developed bilateral conjunctivitis without pain, lachrymation, or discharge. No other clinical manifestations of a hypersensitivity reaction were apparent, and the conjunctivitis resolved spontaneously, about 30 minutes after the end of the infusion. No recurrence was evident with subsequent rituximab therapy.[1]

1. Marinella MA. Bilateral conjunctivitis due to rituximab. *Ann Pharmacother* 2007; 41: 1318.

Effects on the gastrointestinal tract. In November 2006 the manufacturer noted that 47 cases of bowel obstruction (9 fatal) and 37 cases of gastrointestinal perforation (4 fatal) had been reported in patients given rituximab.[1] Interpretation of data was difficult due to confounding factors; however, a contributory role of rituximab could not be excluded. The mean time to onset of symptoms was 6 days (range 1 to 77 days) for documented perforation. Complaints of abdominal pain, especially early in a course of rituximab treatment, should prompt thorough diagnostic evaluation and treatment.

There have been reports of ulcerative colitis when rituximab was used to deplete B-lymphocytes in Graves' disease[2] and nephrotic syndrome.[3] A severe exacerbation of pre-existing ulcerative colitis occurred in a patient with refractory disease given rituximab as salvage therapy.[4]

Effects on the lungs. Pulmonary reactions have been reported with rituximab use,[1] including reversible interstitial pneumonia[2-4] and interstitial fibrosis.[5] A fatal intra-alveolar haemorrhage in 1 patient was attributed to a hypersensitivity reaction to rituximab;[6] a further case of alveolar haemorrhage associated with interstitial lung disease has been reported.[7]

Effects on the nervous system. As of December 2006, the FDA had received a total of 24 reports of progressive multifocal leukoencephalopathy (PML) in patients given rituximab.[1] PML is a fatal demyelinating disease that follows reactivation of latent JC or PK polyomavirus (also known as papovavirus) in the CNS; the virus is present in about 80% of adults. In the first 12 cases reported to the FDA, 10 patients tested positive for the JC virus and 1 had confirmed BK virus. PML presents with rapidly progressive focal neurological deficits including hemiparesis, paraesthesias, visual-field deficits, ataxia, and behavioural and cognitive changes.[2] In a report of 57 cases,[3] 52 patients had haematological malignancies and 5 had auto-immune disorders; all patients had received previous immunosuppressive therapies, including alkylating agents, purine analogues, corticosteroids, or drugs to prevent allogeneic stem cell or solid organ rejection. The case-fatality rate was 90%.

There have also been reports[4,5] of *reversible* posterior leukoencephalopathy syndrome with rituximab. Symptoms have varied between patients, with drowsiness, confusion, hallucinations, nausea, and vomiting occurring in one,[4] and hypertension, headache, blurred vision, and seizures in another.[5]

Infection. In addition to progressive multifocal leukoencephalopathy associated with JC or BK virus reactivation (see Effects on the Nervous System, above), rituximab therapy for lymphomas is associated with an increased risk of viral infection or reactivation, notably from hepatitis B and CMV;[1,2] there is less evidence of any increased risk of serious infection in patients treated with rituximab for rheumatoid arthritis.[3]

Hepatitis C reactivation has also been reported in a patient after rituximab was added to the chemotherapy regimen.[4] In another patient, chronic hepatitis was caused by a persistent hepatitis E infection with active viral replication, in a patient receiving maintenance therapy for lymphoma with rituximab.[5]

Infusion-related reactions. By November 1998 there had been 74 cases of serious infusion-related reactions to rituximab reported worldwide, with 8 fatal cases.[1] An estimated 12 000 to 14 000 patients had been treated.

The reaction usually occurs within the first 2 hours of infusion and the underlying mechanism is believed to be a severe cytokine release syndrome, with some elements of tumour lysis syndrome.[1-3] In one series of cases tumour necrosis factor-α and interleukin-6 levels were found to peak 90 minutes after the onset of the infusion, and these elevated cytokine levels coincided with infusion-related symptoms.[2] The reaction is usually most marked after the first infusion and subsequent infusions are usually tolerated, emphasising that this is not a true hypersensitivity reaction.[4]

Patients with a high tumour burden (lesions over 10 cm in diameter or more than 500 000 circulating malignant cells/mm^3), a history of pulmonary infiltration or insufficiency, or underlying cardiac disease are believed to be at greater risk of severe reactions.[1,2,4] The UK CSM recommends that premedication with an analgesic and an antihistamine should always be given before rituximab, and corticosteroids should be considered.[1] However, serious or fatal reactions have occurred despite such premedication.[3,4] Alternative infusion schedules and/or combination therapy with chemotherapeutic drugs may be required to decrease the tumour burden before rituximab therapy.[2,4]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies rituximab as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pregnancy. Giving 4 cycles of rituximab (with doxorubicin, vincristine, and prednisolone) to a pregnant woman with lymphoma, from 21 weeks of gestation until delivery at 35 weeks, resulted in no adverse effects to either the mother or the infant.[1] In another report, a 31-year-old woman was diagnosed with non-Hodgkin's lymphoma during pregnancy. She received 6 cycles of rituximab with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone). Two months after treatment, she spontaneously delivered a premature but healthy infant. Patient and child were clinically assessed every 3 months; the infant's B cells were severely diminished at birth but recovered over 6 to 12 weeks. Rituximab concentrations in both mother and child also decreased as expected. No adverse effects were seen during 16 months of follow-up.[2] In 2 case reports of rituximab use during the first trimester of pregnancy, no significant adverse effects on the neonates were seen; transient granulocytopenia and lymphopenia were reported.[3,4] A 35-year-old woman diagnosed with Burkitt's lymphoma in week 15 of pregnancy received 4 weekly infusions of rituximab starting in week 16, followed by four courses of rituximab with CHOP, and then 2 courses of CHOP alone. In week 41, a healthy infant was delivered by caesarean section. Both the mother and child had very high serum concentrations of rituximab at birth with a complete absence of B cells; rituximab levels in the cord blood serum were three times that in the mother's serum. However, B-cell recovery was reported to be rapid, and no overt infectious complications were seen in the child up to the age of 26 months; growth and developmental status were also normal.[5] Nonetheless, licensed product information advises against rituximab use during pregnancy, given the potential for B-cell depletion in the fetus; women of child-bearing potential should use effective contraceptive methods during treatment and for up to 12 months after therapy.

Interactions

Statins. It has been reported that, in a laboratory study, statins significantly decreased rituximab cytotoxicity, suggesting that statins may induce conformational changes in CD20 through cholesterol depletion, resulting in impaired binding of rituximab. While noting that there are no clinical data to support withholding statins during rituximab therapy, the authors advised that it might be prudent to consider doing so.[1] However, a subsequent prospective study[2] found no evidence that concomitant statin therapy in patients with diffuse large B-cell lymphoma or follicular lymphoma had any adverse effect on response to rituximab-based therapy; event-free survival was actually improved in patients with follicular lymphoma who took statins, regardless of other therapy.

2. Nowakowski GS, *et al.* Statin use and prognosis in patients with diffuse large B-cell lymphoma and follicular lymphoma in the rituximab era. *J Clin Oncol* 2010; 28: 412–17.

Pharmacokinetics

The mean peak plasma concentration of rituximab has been reported to increase with successive infusions; however, considerable interindividual variation is seen. Serum concentrations are negatively correlated with tumour burden and the number of circulating B-cells. The mean terminal half-life is about 20 days. Rituximab is bound to B lymphocytes, and is detectable in the body for 3 to 6 months after treatment.

Romidepsin *(USAN, rINN)*

Depsipeptide; FK-228; FR-901228; NSC-630176; Romidepsina; Romidepsine; Romidepsinum; Ромидепсин.

(1*S*,4*S*,10*S*,16*E*,21*R*)-7-[(2*Z*)Ethylidene]-4,21-diisopropyl-2-oxa-12,13-dithia-5,8,20,23-tetraazabicyclo[8.7.6]tricos-16-ene-3,6,9,19,22-pentone.

$C_{24}H_{36}N_4O_6S_2$=540.7

CAS — 128517-07-7.

ATC — L01XX39.

ATC Vet — QL01XX39.

UNII — CX3T89XQBK.

NOTE. The name Chromadax has been used as a trade mark for romidepsin.

Uses and Administration

Romidepsin is a histone deacetylase inhibitor used for the treatment of cutaneous T-cell lymphoma (see Mycosis Fungoides, p. 698.3) and peripheral T-cell lymphoma. It is given intravenously; the reconstituted solution is diluted in 500 mL of sodium chloride 0.9% and infused over 4 hours. The initial dose is romidepsin 14 mg/m² on days 1, 8, and 15 of a 28-day cycle. Treatment should be withheld for severe haematological toxicity or for moderate or severe non-haematological toxicity, except alopecia, see below. Romidepsin may be continued for as long as there is benefit from treatment and toxicity allows.

Romidepsin is under investigation in the treatment of solid tumours.

Administration in subsequent cycles. Romidepsin treatment should be withheld for severe haematological toxicity or for moderate or severe non-haematological toxicity, except alopecia.

- For grade 3 or 4 neutropenia or thrombocytopenia, romidepsin may be restarted at 14 mg/m² when the cytopenia returns to an absolute neutrophil count of 1500 cells/mm³ and/or a platelet count of 75 000 cells/mm³
- For grade 4 febrile neutropenia or thrombocytopenia that requires a platelet transfusion, treatment should be delayed until the cytopenia has returned to baseline measurements or grade 1 or less, and the romidepsin dose permanently reduced to 10 mg/m²
- For grade 2 or 3 non-haematological toxicity, romidepsin may be restarted at 14 mg/m² when toxicity has returned to baseline measurements or grade 1 or less
- For grade 4 non-haematological toxicity, or if grade 3 toxicity recurs, treatment should be delayed until toxicity has returned to baseline measurements or grade 1 or less, and the romidepsin dose permanently reduced to 10 mg/m²

Romidepsin treatment should be stopped if grade 3 or 4 non-haematological toxicities recur after dose reduction.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Romidepsin can cause haematological adverse effects such as thrombocytopenia, leucopenia, and anaemia; blood counts should be monitored during treatment and the dose adjusted if necessary, see above. Arrhythmias, QT prolongation, and other ECG changes have also been noted during romidepsin treatment. Potassium and magnesium concentrations should be within the normal range before starting treatment, and ECG and electrolyte monitoring should be considered at baseline and periodically during treatment in patients with congenital long QT syndrome, a history of cardiovascular disease, or those taking antiarrhythmics or medicines that prolong the QT interval. Electrolyte disturbances such as hypokalaemia and hypophosphataemia have also been reported during treatment. Hyperuricaemia can occur, and patients with advanced-stage disease or high tumour burden should be monitored for the development of tumour lysis syndrome.

Gastrointestinal disturbances, fatigue, fever, and infections are common adverse effects of romidepsin. Other reported effects include oedema, dyspnoea, taste disturbances, hypotension, dermatitis, pruritus, increases in liver enzyme concentrations, hypoalbuminaemia, and hyperglycaemia. There have been isolated cases of cardiopulmonary adverse events and acute renal failure, including fatalities.

Due to a lack of data romidepsin should be used with caution in patients with end-stage renal disease or with moderate or severe hepatic impairment.

Interactions

Romidepsin is metabolised by the cytochrome P450 isoenzyme CYP3A4 and its concentration may be affected by CYP3A4 inhibitors or inducers given at the same time. Strong CYP3A4 inhibitors and inducers should be avoided during romidepsin treatment, and caution is advised if moderate CYP3A4 inhibitors are given. Romidepsin is also a substrate of P-glycoprotein, and caution is advised if it is given with P-glycoprotein inhibitors as increased concentrations of romidepsin are likely.

A prolonged prothrombin time (PT) and an elevated international normalised ratio (INR) has been reported in a patient given romidepsin while taking warfarin; monitoring of these parameters is advised if romidepsin is to be given with a coumarin anticoagulant.

Pharmacokinetics

Romidepsin is highly bound to plasma proteins (about 93%). It is mainly metabolised by the cytochrome P450 isoenzyme CYP3A4; the isoenzymes CYP3A5, CYP1A1, CYP2B6, and CYP2C19 play a minor role. During usual intravenous dosing, the terminal half-life is about 3 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *USA*: Istodax.

Rostaporfin *(USAN, rINN)*

Rostaporfina; Rostaporfine; Rostaporfinum; SnET2; Tin Ethyl Etiopurpurin; Tin etiopurpurin dichloride; Ростапорфин.

(*OC*-6-13)-Dichloro[ethyl (18*R*,19*R*)-3,4,20,21-tetradehydro-4,9,14,19-tetraethyl-18,19-dihydro-3,8,13,18-tetramethyl-20-phorbinecarboxylato (2-)-N^{23},N^{24},N^{25},N^{26}]tin.

$C_{37}H_{42}Cl_2N_4O_2Sn$=764.4

CAS — 284041-10-7; 114494-17-6.

UNII — 466G63QE7G.

NOTE. The names Photrex and Purlytin have been used as trade marks for rostaporfin.

Profile

Rostaporfin is a photosensitiser that is under investigation in the photodynamic therapy of neovascular (wet) age-related macular degeneration (p. 880.2). It has also been investigated for photodynamic therapy of malignant neoplasms.

Ruxolitinib Phosphate *(USAN, rINNM)*

Fosfato de ruxolitinib; INC-424 (ruxolitinib); INCB-018424 salt; Ruxolitinib Phosphate de; Ruxolitinibi Phosphas; Руксолитиниба Фосфат.

(3*R*)-3-Cyclopentyl-3-[4-(7*H*-pyrrolo[2,3-*d*]pyrimidin-4-yl)-1*H*-pyrazol-1-yl]propanenitrile phosphate (1:1).

$C_{17}H_{18}N_6.H_3O_4P$=404.4

CAS — 941678-49-5 (ruxolitinib); 1092939-17-7 (ruxolitinib phosphate).

UNII — 436LRU32HS.

Uses and Administration

Ruxolitinib is an inhibitor of the Janus-associated tyrosine kinases JAK1 and JAK2, and is used in the treatment of intermediate- or high-risk myelofibrosis (p. 856.1). It is

given orally as the phosphate, but doses are expressed in terms of the base; 13.2 mg of ruxolitinib phosphate is equivalent to about 10 mg of ruxolitinib. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

The recommended starting dose for myelofibrosis is based on platelet count:

- > 200 000 cells/mm³: 20 mg orally twice daily
- 100 000 to 200 000 cells/mm³: 15 mg orally twice daily

The dose is adjusted according to efficacy and tolerability. If efficacy is insufficient, and providing platelet and neutrophil counts are adequate, the daily dose may be increased in 10-mg increments to a maximum of 25 mg twice daily. Doses should not be increased in the first 4 weeks of treatment and, after that, not more often than every 2 weeks. Treatment should be stopped after 6 months if there has been no reduction in spleen size or improvement in symptoms.

Doses should be reduced if platelet counts fall, to avoid thrombocytopenia (see Administration in Toxicity, below). If ruxolitinib is stopped for reasons other than thrombocytopenia, the dose may be reduced gradually; a reduction of 10 mg each week has been suggested. Doses should also be reduced in patients with hepatic or renal impairment (see below).

If a potent cytochrome P450 isoenzyme inhibitor must also be used, ruxolitinib should be started at a dose of 10 mg twice daily in patients with a platelet count of ≥ 100 000 cells/mm³; those with a count below this should avoid ruxolitinib altogether.

Ruxolitinib is under investigation in the treatment of polycythaemia vera.

Administration in hepatic impairment. A starting dose of ruxolitinib 10 mg orally twice daily is suggested for patients with hepatic impairment and a platelet count of 100 000 to 150 000 cells/mm³. Ruxolitinib should be avoided in patients with hepatic impairment and lower platelet counts.

Administration in renal impairment. The dose of ruxolitinib should be reduced in patients with renal impairment. Starting doses (given below) have been recommended based on platelet count and renal function. Further dose adjustment should be made according to response.

Patients with renal impairment that is moderate (creatinine clearance 30 to 59 mL/min) or severe (15 to 29 mL/min):

- platelet count 100 000 to 150 000 cells/mm³: 10 mg orally twice daily
- platelet count < 100 000 cells/mm³: avoid ruxolitinib

Ruxolitinib should not be given to patients with end-stage renal disease not requiring dialysis (creatinine clearance < 15 mL/min).

Patients with end-stage renal disease on dialysis:

- platelet count > 200 000 cells/mm³: 20 mg orally
- platelet count 100 000 to 200 000 cells/mm³: 15 mg orally
- subsequent doses should be given on dialysis days, after the dialysis session

Administration in toxicity. The dose of ruxolitinib may need to be reduced to avoid thrombocytopenia during therapy. Adjustments are made in relation to the platelet count and the dose of ruxolitinib at the time of platelet decline.

- platelets 100 000 to < 125 000 cells/mm³: the dose should be no more than 15 mg orally twice daily (or 20 mg twice daily if the dose at the time of platelet decline was 25 mg twice daily)
- platelets 75 000 to < 100 000 cells/mm³: the dose should be no more than 10 mg orally twice daily
- platelets 50 000 to < 75 000 cells/mm³: the dose should be no more than 5 mg orally twice daily
- platelets < 50 000 cells/mm³: withhold ruxolitinib

If ruxolitinib treatment has been interrupted because of thrombocytopenia, it may be restarted after the platelet count rises to an acceptable level above 50 000 cells/mm³. The dose used should be at least 5 mg twice daily below the dose at interruption, and no more than the following maximum recommended doses:

- platelets ≥ 125 000 cells/mm³: maximum 20 mg orally twice daily
- platelets 100 000 to < 125 000 cells/mm³: maximum 15 mg orally twice daily
- platelets 75 000 to < 100 000 cells/mm³: maximum 10 mg orally twice daily for at least 2 weeks, which may be increased to 15 mg twice daily if stable
- platelets 50 000 to < 75 000 cells/mm³: 5 mg orally twice daily for at least 2 weeks, which may be increased to 10 mg twice daily if stable
- platelets < 50 000 cells/mm³: continue to withhold ruxolitinib

Myelofibrosis. An early phase study of ruxolitinib in 153 patients reported improvements in signs and symptoms of advanced myelofibrosis[1] (p. 695.1). However, follow-up over 3 years in 51 of these patients found that treatment had been stopped in 40% because of disease progression or loss or lack of response, and in 34% because of toxicity with or without disease progression or lack of response.[2]

1. Verstovsek S, *et al.* Safety and efficacy of INCB018424, a JAK1 and JAK2 inhibitor, in myelofibrosis. *N Engl J Med* 2010; 363: 1117–27.
2. Tefferi A, *et al.* Long-term outcome of treatment with ruxolitinib in myelofibrosis. *N Engl J Med* 2011; 365: 1455–7.

Adverse Effects, Treatment, and Precautions

The most common adverse effect of ruxolitinib phosphate is myelosuppression, which is manifest as thrombocytopenia and anaemia to some degree in most patients while neutropenia occurs less frequently. These effects are dose-related and generally managed by dose reduction or withholding treatment. Complete blood counts and platelet counts should be measured before starting ruxolitinib, every 2 to 4 weeks until doses are stabilised, then as clinically indicated.

Bruising is common in patients given ruxolitinib; petechiae, ecchymosis, contusion, haematoma, and injection-site haematoma have all been reported. Other adverse effects include dizziness, headache, weight gain, and flatulence. Low-grade elevations of alanine and aspartate transaminases and cholesterol have also been reported. Patients given ruxolitinib are at risk of developing serious infection, and any active infection should be treated before starting ruxolitinib.

Dose reductions are recommended in patients with hepatic or renal impairment.

Withdrawal. Withdrawal effects after stopping ruxolitinib have been described in 5 patients being treated for myelofibrosis.[1] Acute relapse of symptoms and splenomegaly were accompanied by other signs and symptoms that included worsening of cytopenias, respiratory distress, pleural and pericardial effusion, and syndromes similar to septic shock and disseminated intravascular coagulation. The effects generally started within days after ruxolitinib was stopped because of loss of treatment benefit or adverse effects, even after the dose had been tapered in some cases.

1. Tefferi A, Pardanani A. Serious adverse events during ruxolitinib treatment discontinuation in patients with myelofibrosis. *Mayo Clin Proc* 2011; 86: 1188–91.

Interactions

Ruxolitinib phosphate is metabolised mainly by the cytochrome P450 isoenzyme CYP3A4. Inhibitors of CYP3A4 can increase the concentrations and prolong the half-life of ruxolitinib. The dose of ruxolitinib should be adjusted when it is used with potent inhibitors such as ketoconazole (see Uses and Administration, p. 855.3). No dose adjustment is considered necessary in general when ruxolitinib is given with mild or moderate inhibitors such as erythromycin.

Inducers of CYP3A4 such as rifampicin can reduce concentrations of ruxolitinib but with an associated increase in exposure to its active metabolites. Patients should be closely monitored and the dose of ruxolitinib adjusted as necessary.

Pharmacokinetics

Ruxolitinib phosphate is well absorbed from the gastrointestinal tract, with a peak plasma concentration occurring 1 to 2 hours after an oral dose. It is about 97% bound to plasma proteins, mainly albumin. Ruxolitinib is eliminated by metabolism, mainly through the cytochrome P450 isoenzyme CYP3A4. There are several active metabolites that together contribute 18% of the overall pharmacodynamics of ruxolitinib. About 74% of a dose is excreted in the urine and about 22% via the faeces. The mean elimination half-life of ruxolitinib is about 3 hours, but that of ruxolitinib plus its metabolites is about 5.8 hours.

Sabarubicin *(rINN)*

MEN-10755; Sabarubicina; Sabarubicine; Sabarubicinum; Сабарубицин.

(7*S*,9*S*)-7-[[4-*O*-(3-Amino-2,3,6-trideoxy-α-L-*lyxo*-hexopyranosyl)-2,6-dideoxy-α-L-*lyxo*-hexopyranosyl]oxy]-6,9,11-trihydroxy-9-(hydroxyacetyl)-7,8,9,10-tetrahydrotetracene-5,12-dione.

$C_{32}H_{37}NO_{13}$=643.6

CAS — 211100-13-9.

UNII — XS499WOZ93.

Profile

Sabarubicin, an anthracycline, is an analogue of doxorubicin (p. 782.3). It acts as a potent topoisomerase II inhibitor and is under investigation for the treatment of various solid tumours, such as cancers of the lung, ovary, breast, and prostate. Myelosuppression is the main adverse effect.

Satraplatin *(USAN, rINN)*

BMS-182751; BMY-45594; JM-216; Satraplatine; Satraplatino; Satraplatinum; Сатраплатин.

(*OC*-6-43)-Bis(acetato)amminedichloro(cyclohexylamine)platinum.

$C_{10}H_{22}Cl_2N_2O_4Pt$=500.3

CAS — 129580-63-8.

ATC — L01XA04.

ATC Vet — QL01XA04.

UNII — 8D7B37T28G.

NOTE. The name Orplatna has been used as a trade mark for satraplatin.

Profile

Satraplatin is an analogue of cisplatin (p. 766.1) with generally similar properties, but which is well absorbed after oral dosage. It has been investigated for its antineoplastic properties in the treatment of prostate cancer and other solid tumours. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Sipuleucel-T (USAN)

APC-8015.
CAS — 917381-47-6.
UNII — 8Q622VDR18.

Pharmacopoeias. In *US*.

USP 36: (Sipuleucel-T). The active components of sipuleucel-T are autologous antigen presenting cells (APCs) and a recombinant protein, PAP-GM-CSF that consists of human prostatic acid phosphatase (PAP) fused through the *C*-terminus to the *N*-terminus of human granulocyte-macrophage colony-stimulating factor (GM-CSF) by a Gly-Ser linker. It is prepared using a patient's own peripheral blood mononuclear cells. Store at a temperature of 2 degrees to 8 degrees.

Uses and Administration

Sipuleucel-T is a personalised cancer vaccine (p. 757.3) prepared by combining a recombinant human fusion protein with antigen-presenting cells isolated from the patient's blood. It is used in the treatment of metastatic, hormone-refractory prostate cancer (p. 712.3). The patient's peripheral blood cells are sampled by leucapheresis about 3 days before the scheduled dose and sent for combination with the protein. The resulting suspension is given as 3 infusions, at intervals of about 2 weeks. Doses are given intravenously over 60 minutes; an in-line filter should not be used. Premedication is recommended (see below), and the infusion rate may be decreased or the infusion stopped if an infusion reaction occurs.

References.

1. Patel PH, Kockler DR. Sipuleucel-T: a vaccine for metastatic, asymptomatic, androgen-independent prostate cancer. *Ann Pharmacother* 2008; **42**: 91–8.
2. Higano CS, *et al.* Integrated data from 2 randomized, double-blind, placebo-controlled, phase 3 trials of active cellular immunotherapy with sipuleucel-T in advanced prostate cancer. *Cancer* 2009; **115**: 3670–9.

Adverse Effects, Treatment, and Precautions

Acute infusion reactions have occurred frequently with sipuleucel-T, including fever, chills, dyspnoea, bronchospasm, nausea, vomiting, fatigue, asthenia, dizziness, headache, muscle ache, hypertension, and tachycardia. Patients with cardiac or pulmonary conditions should be closely monitored. Oral premedication with paracetamol and an antihistamine is recommended, about 30 minutes before infusion. If an infusion reaction occurs, the infusion rate may be decreased, or the infusion stopped depending on the severity of the reaction. Supportive care should also be given.

Cerebrovascular adverse effects have also been reported, such as haemorrhagic and ischaemic strokes. There have been isolated cases of eosinophilia, rhabdomyolysis, myasthenia gravis, myositis, and tumour flare. Other possible adverse effects (some of which may be associated with the accompanying leucapheresis procedure) include pain, haematuria, anaemia, muscle spasms, rash, tremor, paraesthesia, citrate toxicity, gastrointestinal disturbances, peripheral oedema, cough, and respiratory-tract and urinary-tract infections. Some patients who required a central venous catheter for treatment with sipuleucel-T developed infections, including sepsis.

Sipuleucel-T is a personalised treatment, and is only suitable for autologous use. It is not routinely tested for transmissible infectious diseases, and healthcare workers should observe handling precautions. Use with immunosuppressants or chemotherapy has not been studied, and caution is advised, as sipuleucel-T is designed to stimulate the immune system. Consideration should be given to stopping or reducing immunosuppressant therapy, if appropriate.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *USA*: Provenge.

Sizofiran (rINN)

Schizophyllan; Sizofirán; Sizofiranum; Сизофиран.
Poly[3→1-(*O*-β-D-glucopyranosyl-(1→3)-*O*-[β-D-glucopyranosyl-(1→6)]-*O*-β-D-glucopyranosyl-(1→3)-*O*-β-D-glucopyranosyl)→1].
$(C_{24}H_{40}O_{20})_n$
CAS — 9050-67-3.

Profile

Sizofiran is a polysaccharide obtained from cultures of the basidiomycete fungus *Schizophyllum commune*. It is reported to have antineoplastic and immunomodulating activity and is given with radiotherapy in malignant neoplasms of the cervix (p. 704.2). It is given by intramuscular injection in usual doses of 40 mg weekly. It has also been tried with chemotherapy or radiotherapy in other malignant neoplasms. Hypersensitivity reactions, including anaphylactoid shock, may occur.

Sobuzoxane (rINN)

MST-16; Sobuzoxano; Sobuzoxanum; Собузоксан.
4,4'-Ethylenebis[1-(hydroxymethyl)-2,6-piperazinedione] bis(isobutyl carbonate).
$C_{22}H_{34}N_4O_{10}$=514.5
CAS — 98631-95-9.
UNII — R1308VH37P.

Profile

Sobuzoxane is an orally active inhibitor of topoisomerase II that is used for its antineoplastic properties in the treatment of non-Hodgkin's lymphomas and adult T-cell leukaemia/lymphoma. Adverse effects include myelosuppression, bleeding tendency, renal and hepatic dysfunction, gastrointestinal disturbances, alopecia, headache, and fever.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

4-(4-{3-[4-Chloro-3-(trifluoromethyl)phenyl]ureido}phenoxy)-*N*²-methylpyridine-2-carboxamide 4-methylbenzenesulfonate.
$C_{21}H_{16}ClF_3N_4O_3$, $C_7H_8O_3S$=637.0
CAS — 475207-59-1.
ATC — L01XE05.
ATC Vet — QL01XE05.
UNII — 5T62Q3B36J.

Uses and Administration

Sorafenib is an inhibitor of multiple intracellular and cell surface kinases thought to be involved in angiogenesis. It is given orally as the tosilate but doses are expressed in terms of the base; sorafenib tosilate 274 mg is equivalent to about 200 mg of sorafenib. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* Sorafenib is used in the treatment of advanced renal cell carcinoma and hepatocellular carcinoma. The recommended oral dose is 400 mg twice daily, given at least 1 hour before or 2 hours after food. Treatment is continued until no clinical benefit is seen or until unacceptable toxicity occurs. Doses are reduced to 400 mg once daily if toxicity occurs; further reduction to a single dose of 400 mg every other day may be necessary.

Sorafenib is under investigation for the treatment of locally unresectable and metastatic melanoma.

Administration in hepatic or renal impairment. Sorafenib is mainly metabolised in the liver. Hepatic impairment might reduce exposure to sorafenib. However, exposure is comparable in patients with mild or moderate (Child-Pugh A and B) impairment to that in patients with normal hepatic function. Licensed product information therefore states that no dose adjustment is needed in patients with mild to moderate impairment. No data are available on patients with severe (Child-Pugh C) hepatic impairment.

Licensed product information states that no dose adjustment is needed in patients with mild, moderate, or severe renal impairment, but that no data are available for patients on dialysis.

A study[1] involving patients with varying degrees of hepatic or renal impairment recommended the following empirical starting doses of oral sorafenib, based on tolerability and the development of dose-limiting toxicity in patient cohorts with hepatic impairment:

- mild hepatic dysfunction (bilirubin between upper limit of normal (ULN) and 1.5 X ULN and/or AST > ULN): a standard dose of 400 mg twice daily
- moderate hepatic dysfunction (bilirubin between 1.5 and 3 X ULN, any value of AST): 200 mg twice daily
- severe dysfunction (bilirubin over 3 X ULN, any value of AST): patients were unable to tolerate even 200 mg every third day; however, a separate cohort defined as having very severe dysfunction (albumin less than 25 micro-

grams/mL and any values of bilirubin and AST) were able to tolerate 200 mg daily

Based on the patient cohorts with renal impairment, the following empirical recommendations for initial dose were made:

- mild renal impairment (creatinine clearance (CC) between 59 and 40 mL/minute): the standard dose of 400 mg twice daily
- moderate renal impairment (CC between 39 and 20 mL/minute): 200 mg twice daily
- severe renal impairment (CC less than 20 mL/minute): a dose could not be defined due to low patient numbers enrolled in this cohort
- patients on haemodialysis: 200 mg daily

1. Miller AA, *et al.* Phase I and pharmacokinetic study of sorafenib in patients with hepatic or renal dysfunction: CALGB 60301. *J Clin Oncol* 2009; 27: 1800–5.

Age-related macular degeneration. Two patients with recurrent exudative age-related macular degeneration (AMD; p. 880.2) elected to have oral sorafenib added to their treatment in an attempt to decrease the number of intra-ocular injections; they were treated with 200 mg three times weekly. Vision stabilised or improved in both patients, and neither patient developed serious adverse effects. Although oral sorafenib is not licensed for AMD, the authors suggested that further study of this regimen for refractory or recurrent exudative AMD was warranted.[1]

1. Diago T, *et al.* Ranibizumab combined with low-dose sorafenib for exudative age-related macular degeneration. *Mayo Clin Proc* 2008; 83: 231–4.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2. Diarrhoea and dermatological toxicities such as palmar-plantar syndrome and rash are the most common adverse effects with sorafenib. Treatment may include topical therapies, or dose adjustment, or temporary interruption of sorafenib. Congestive heart failure, cardiac ischaemia, and myocardial infarction have been reported with sorafenib, and treatment should be interrupted or stopped in patients who develop ischaemia and/or infarction. Mild to moderate hypertension can occur, which may be manageable with antihypertensive therapy, but severe or persistent hypertension or hypertensive crisis despite treatment, may force sorafenib to be stopped. Blood pressure should be regularly monitored. There is an increased risk of bleeding with sorafenib and fatalities have been reported; if severe enough to need intervention, the drug should be permanently stopped. Leucopenia, lymphopenia, anaemia, neutropenia, and thrombocytopenia are common. Hypophosphataemia and transient disturbances in liver function tests can occur. Elevations in lipase and amylase concentrations are very common. Fatal hepatitis has been reported. Pancreatitis can occur. Renal failure is common. Other adverse effects include alopecia, pruritus, dry skin, erythema, acne, flushing, exfoliative dermatitis, hoarseness, gastrointestinal disturbances, arthralgia, myalgia, asthenia, pain, and peripheral neuropathy. Tinnitus, depression, and erectile dysfunction are often reported, as are pyrexia, flu-like illness, and weight decrease. Gastrointestinal perforation has been reported rarely; therapy should be stopped if it occurs. Reversible posterior leukoencephalopathy has also occurred rarely, as have symptoms suggestive of interstitial lung disease, including pneumonitis and acute respiratory distress syndrome. Other uncommon adverse events include hypersensitivity reactions, changes in thyroid function, hyponatraemia, gynaecomastia, rhinorrhoea, Stevens-Johnson syndrome, and squamous cell carcinoma of the skin. Angioedema and radiation-recall dermatitis can also occur.

6. Lee WJ, *et al.* Cutaneous adverse effects in patients treated with the multitargeted kinase inhibitors sorafenib and sunitinib. *Br J Dermatol* 2009; 161: 1045–51.

Effects on the blood. Reversible erythrocytosis occurred in 5 patients treated with sorafenib or sunitinib; onset was relatively rapid over 1 to 2 weeks, reaching a peak at 4 to 9 weeks after the start of tyrosine kinase inhibitor treatment.[1]

1. Alexandrescu DT, *et al.* Secondary erythrocytosis produced by the tyrosine kinase inhibitors sunitinib and sorafenib. *J Clin Oncol* 2008; 26: 4047–8.

Effects on the cardiovascular system. A meta-analysis[1] of data involving 4599 patients indicated that 23.4% of those given *sorafenib* developed hypertension; about 5% of sorafenib-treated patients developed severe (grade 3 or 4) hypertension. This represented a relative risk of developing high blood pressure 6.1 times that of patients not given sorafenib. Hypertension may also develop with other angiogenesis inhibitors; relative risk has been shown to be similar with high-dose *bevacizumab*, and there is evidence of a slightly smaller risk (incidence of hypertension 22.5%, relative risk 3.89) with *sunitinib*.

An observational study[2] in patients taking either sorafenib or sunitinib found that about a third of patients had a cardiovascular event; median duration of tyrosine kinase inhibitor therapy at event occurrence was 8 weeks. Some patients were asymptomatic, with biochemical signs and ECG changes only, whereas others had mild to life-threatening clinical symptoms. All symptomatic and some asymptomatic patients received cardiovascular treatment, recovered, and were considered eligible to resume treatment with the tyrosine kinase inhibitor. The authors considered cardiovascular monitoring as well as prophylactic treatment to be essential; this might allow for continued treatment of the underlying cancer. It was also noted that cardiotoxicity might mimic disease progression.

For reference to the incidence of cardiotoxicity with *lapatinib* see Effects on the Heart, p. 815.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sorafenib as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/09/11)

Interactions

For a general discussion of antineoplastic drug interactions, see p. 733.3. Sorafenib is metabolised by the cytochrome P450 isoenzyme CYP3A4. Rifampicin can reduce exposure to sorafenib. Other inducers of this enzyme (such as carbamazepine, dexamethasone, St John's wort, phenobarbital, and phenytoin) may also reduce blood concentrations of sorafenib. However, ketoconazole did not alter exposure to sorafenib and other drugs that inhibit CYP3A4 are considered unlikely to alter the metabolism of sorafenib.

In vitro studies have indicated that sorafenib itself inhibits the cytochrome P450 isoenzymes CYP3A4, CYP2C19, and CYP2D6, but use of sorafenib with midazolam, or omeprazole, or dextromethorphan did not alter the exposure to any of these drugs; interactions with drugs that are substrates of these enzymes are considered unlikely.

Sorafenib inhibits the cytochrome P450 isoenzyme CYP2C9 *in vitro*, and may increase concentrations of its substrates. Use with warfarin may affect the INR, see Antineoplastics, under Warfarin, p. 1532.2.

Sorafenib also inhibits the isoenzymes CYP2B6 and CYP2C8 *in vitro*, and drug interactions with substrates of these may occur.

Sorafenib may increase exposure to docetaxel, doxorubicin, and irinotecan; variable effects on fluorouracil have been reported. Variable effects have also been seen with paclitaxel; use of continuous sorafenib with paclitaxel and carboplatin caused an increase in sorafenib exposure, an increase in paclitaxel exposure, and an increase in the exposure to 6α-hydroxypaclitaxel, while carboplatin pharmacokinetics were unaffected. Licensed product information states that the clinical significance of these increases is unknown. However, when sorafenib was given 2 days before, and then on the same day as carboplatin plus paclitaxel, it had no significant effect on the pharmacokinetics of paclitaxel; licensed product information advocates no dose adjustments when these 3 drugs are given in this way. Higher mortality was seen in a subset of patients with squamous cell lung carcinoma treated with sorafenib, carboplatin, and paclitaxel compared with those treated with carboplatin plus paclitaxel alone; no definitive cause was identified.

Neomycin interferes with enterohepatic recycling of sorafenib, resulting in decreased exposure to sorafenib.

Pharmacokinetics

Peak plasma concentrations of sorafenib occur about 3 hours after an oral dose. Absorption is reduced by about 30% after a high-fat meal. Plasma protein binding is about 99.5%. Sorafenib is metabolised mainly in the liver via the cytochrome P450 isoenzyme CYP3A4. It also undergoes glucuronidation. The elimination half-life of sorafenib is about 25 to 48 hours. About 96% of a dose is excreted within 14 days, with 77%, mostly as unchanged drug, recovered in the faeces, and 19% in the urine as glucuronidated metabolites.

Estreptozocina; NSC-85998; Streptotsosiini; Streptozocine; Streptozocinum; Streptozosin; Streptozotocin; U-9889; Стрептозоцин.

2-Deoxy-2-(3-methyl-3-nitrosoureido)-D-glucopyranose.

$C_8H_{15}N_3O_7$=265.2

CAS — 18883-66-4.

ATC — L01AD04.

ATC Vet — QL01AD04.

UNII — 5W494URQ81.

Storage. Licensed product information recommends that the freeze-dried streptozocin preparation be stored at 2 degrees to 8 degrees and protected from light.

Uses and Administration

Streptozocin is an antibiotic antineoplastic belonging to the nitrosoureas (see Carmustine, p. 761.2) and is used, alone or with other antineoplastics, mainly in the treatment of pancreatic endocrine (islet-cell) tumours (p. 716.3). It is given by intravenous injection or infusion in doses of 1 g/m² weekly, increased if necessary after 2 weeks to up to 1.5 g/m². Alternatively doses of 500 mg/m² may be given daily for 5 days and repeated every 6 weeks.

It has also been tried in other tumours including exocrine pancreatic cancer and prostate cancer.

Streptozocin has also been given by intra-arterial infusion (but see Adverse Effects below).

Full blood counts, and renal and hepatic function tests should be performed routinely during treatment; doses should be reduced or treatment withdrawn if renal toxicity occurs.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Cumulative nephrotoxicity is common with streptozocin and may be severe and irreversible. Mild proteinuria may be the first sign of toxicity. Intra-arterial use may be associated with more rapid development of nephrotoxicity.

Other adverse effects include severe nausea and vomiting and alterations in liver function or occasionally severe hepatotoxicity. Myelosuppression may occur but is rarely severe. Confusion, lethargy, and depression have been reported in some patients given streptozocin by 5-day continuous infusion. Streptozocin may affect glucose metabolism. A diabetogenic effect has been reported; hypoglycaemia attributed to the release of insulin from damaged cells has also occurred.

Streptozocin is irritant to tissues and extravasation may lead to local ulceration and necrosis.

Streptozocin should be used with extreme care in patients with pre-existing renal impairment.

Handling and disposal. Methods for the destruction of streptozocin *waste* by reaction with hydrobromic acid in glacial acetic acid or by oxidation with a solution of pota-

sium permanganate in sulfuric acid.[1] Residues produced by either method were free of mutagenic activity.

1. Castegnaro M. *et al.*, eds. Laboratory decontamination and destruction of carcinogens in laboratory wastes: some antineoplastic agents. *IARC Scientific Publications* 73. Lyon: WHO/International Agency for Research on Cancer, 1985.

Interactions

Streptozocin should not be given with other potentially nephrotoxic drugs. For increased doxorubicin toxicity when given with streptozocin see p. 785.2.

Phenytoin. It has been suggested that because phenytoin appeared to protect the beta cells of the pancreas from the cytotoxic effects of streptozocin, its use with streptozocin should be avoided in patients being treated for pancreatic tumours.[1]

1. Koranyi L, Gero L. Influence of diphenylhydantoin on the effect of streptozotocin. *BMJ* 1979; **1**: 127.

Pharmacokinetics

After intravenous doses streptozocin is rapidly cleared from the blood and distributed to body tissues, particularly the liver, kidneys, intestines, and pancreas. It is extensively metabolised, mainly in the liver and perhaps the kidney, and excreted principally in the urine as metabolites and a small amount of unchanged drug. About 60 to 70% of an intravenous dose is excreted in urine within 24 hours. Some is also excreted via the lungs. Streptozocin itself does not cross the blood-brain barrier but its metabolites are found in the CSF.

Preparations

Sunitinib Malate *(BANM, USAN, rINNM)*

Malato de sunitinib; PHA-290940AD; SU-010398; SU-011248 (sunitinib); Sunitinib, Malate de; Sunitinibi Malas; Сунитиниба малат.

N-[2-(Diethylamino)ethyl]-5-[(*Z*)-(5-fluoro-2-oxo-1,2-dihydro-3*H*-indol-3-ylidene)methyl]-2,4-dimethyl-1*H*-pyrrole-3-carboxamide hydrogen (2*S*)-2-hydroxybutanedioate.

$C_{22}H_{27}FN_4O_2.C_4H_6O_5$=532.6

CAS — 557795-19-4 (sunitinib); 341031-54-7 (sunitinib malate).

ATC — L01XE04.

ATC Vet — QL01XE04.

UNII — LVX8N1UT73.

Uses and Administration

Sunitinib malate is an inhibitor of several receptor tyrosine kinases. It is used for the treatment of gastrointestinal stromal tumours (GIST; see Soft-tissue Sarcoma, p. 718.2) after disease progression during imatinib treatment, or in patients intolerant to imatinib. It is also used for the treatment of advanced and/or metastatic renal cell carcinoma (RCC; p. 708.3). It is also licensed in some countries for the treatment of unresectable or metastatic, well-differentiated pancreatic neuroendocrine tumours (pNET; p. 716.3).

Sunitinib is given orally as the malate, but doses are expressed in terms of the base; sunitinib malate 66.8 mg is equal to about 50 mg of sunitinib. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

For the treatment of GISTs or RCC, the recommended dose is 50 mg once daily, for 4 weeks of a 6-week treatment cycle. Doses may be increased or decreased in steps of 12.5 mg, based on individual tolerability. UK licensed product information recommends that the daily dose should not normally exceed 75 mg nor be decreased below 25 mg.

For the treatment of pNETs, the recommended dose of sunitinib is 37.5 mg once daily; doses are given continuously. Dose modification is made in steps of 12.5 mg, based on individual tolerability; doses above 50 mg daily in pNETs have not been evaluated.

Use of inhibitors or inducers of CYP3A4 may increase or decrease sunitinib plasma concentrations. If no alternative is available, a dose reduction of sunitinib to a minimum of 37.5 mg daily for GIST or RCC, or 25 mg daily for pNET, should be considered if it is given with a strong CYP3A4 inhibitor. Doses can be increased to a maximum of 87.5 mg daily for GIST or RCC, or 62.5 mg daily for pNET, if sunitinib is given with a CYP3A4 inducer; the patient should be closely monitored for toxicity.

Adverse Effects, Treatment, and Precautions

Common adverse effects of sunitinib include gastrointestinal disturbances, anorexia, headache, fatigue, fever, hypertension, hypothyroidism, mouth pain or irritation, dry mouth, mucosal inflammation, oedema, taste disturbances, arthralgia, and myalgia. Myelosuppression is common, and complete blood counts should be performed at the beginning of each treatment cycle. Other effects include dizziness, paraesthesia, dyspnoea, alopecia, Yellow skin discoloration and chromaturia can occur. Other dermatological effects include depigmentation of the hair or skin, dryness, rash, exfoliative dermatitis, or palmar-planter syndrome. Gastrointestinal perforation has been reported rarely; fatalities have been reported in patients with intra-abdominal malignancies.

Decreases in left ventricular ejection fraction (LVEF) have occurred with sunitinib; baseline and periodic evaluations of LVEF should be taken. Patients should be monitored for signs of congestive cardiac failure and therapy interrupted or stopped if they occur. Dose reductions may be necessary in patients who show no signs of heart failure but who show decreases in LVEF. Sunitinib may prolong the QT interval and should be used with caution in patients with a history of this, who are taking antiarrhythmics, or who have pre-existing cardiac disease, bradycardia, or electrolyte disturbances.

There is an increased risk of bleeding at all sites; epistaxis is the most common treatment-related bleeding event but fatal pulmonary haemorrhage has occurred in patients with lung cancer. Pulmonary embolism or venous thromboembolic events may occur. Patients under stresses such as surgery, trauma, or severe infection should be monitored for adrenal insufficiency. Increases in serum amylase and lipase concentrations have been seen and there are rare reports of pancreatitis and hepatic failure. There are also rare reports of seizures and reversible posterior leukoencephalopathy syndrome.

Effects on the blood. For a report of reversible erythrocytosis in patients given sunitinib or sorafenib, see Effects on the Blood, under Sorafenib, p. 858.1.

Effects on the cardiovascular system. A retrospective review in 75 patients given repeating cycles of sunitinib in phase I/II studies of its efficacy for gastrointestinal stromal tumours found that cardiovascular events occurred in 8, of whom 6 developed congestive heart failure.[1] Of 36 patients given the subsequently approved dose, 10 had reductions in left ventricular ejection fraction of at least 10%. Hypertension developed in 35 of the 75 patients, and it was suggested that left ventricular dysfunction might be due to a combination of hypertension and a direct toxic effect on heart muscle.

For the relative risk of developing hypertension with sunitinib, and results of a study analysing cardiotoxicity of sunitinib and sorafenib, see under Sorafenib, p. 858.2.

1. Chu TF, *et al.* Cardiotoxicity associated with tyrosine kinase inhibitor sunitinib. *Lancet* 2007; **370**: 2011–19.

Effects on the kidneys. For a report of haemolytic-uraemic syndrome after the use of bevacizumab and sunitinib, see Effects on the Kidneys, under Bevacizumab, p. 748.2.

Effects on the musculoskeletal system. As of 31st January 2010, the German manufacturer (*Pfizer*) reported 27 cases of osteonecrosis of the jaw (similar to that seen with the bisphosphonates, see under Bisphosphonates, p. 1176.3) related to sunitinib therapy.[1] There are other reports in cancer patients treated with sunitinib,[2-6] the majority of whom had also received treatment with intravenous bisphosphonates.However, in one case,[4] the patient had never received bisphosphonates, but had previously had dental extraction.

There have been similar reports of bisphosphonate-related osteonecrosis of the jaw in patients given bevacizumab (see under Bevacizumab, p. 748.2) and it has been postulated that the strong anti-angiogenic action of these drugs contributed to oral mucosal breakdown and the subsequent development of osteonecrosis of the jaw.[3] Caution is advised when sunitinib and bisphosphonates are used together or sequentially,[1] and dental care precautions similar to those in patients prescribed bisphosphonates (see under Bisphosphonates, p. 1175.2) are recommended.

Effects on the nervous system. Coma has been reported with sunitinib; therapy was immediately stopped and the patient regained consciousness within 24 hours.[1]

1. Arnaud L, *et al.* Transient sunitinib-induced coma in a patient with fibromyxoid sarcoma. *J Clin Oncol* 2008; **26**: 1569–71.

Effects on the skin. Palmar-plantar syndrome is a well-recognised adverse effect of several tyrosine kinase inhibitors, including sunitinib.[1] A patient developed palmar-plantar syndrome and rashes resembling seborrhoeic dermatitis while taking sunitinib. Therapy was stopped and the rash was treated with a topical corticosteroid; blisters on the palms and soles resolved with desquamation.[2] In another report,[3] 5 out of 40 patients treated with sunitinib developed erythema and desquamation in the scrotal and inguinal areas; these effects decreased or disappeared after the drug was stopped, and reappeared upon restarting sunitinib. Histological analysis of 3 specimens mimicked the pathological features of psoriasis. Pyoderma gangrenosum has also been reported.[4]

4. ten Prcyhaus K, *et al.* Pyoderma gangrenosum: another cutaneous side-effect of sunitinib? *Br J Dermatol* 2008; **159**: 242–3.

Effects on thyroid function. Hypothyroidism is common after sunitinib therapy. A cohort study found that 36% of patients developed hypothyroidism after an average of 50 weeks of therapy. The incidence of hypothyroidism increased with the duration of therapy, and the effect was not transient; patients needed replacement therapy with levothyroxine. Mild thyrotoxicosis may precede the onset of hypothyroidism. Although the mechanism is not clear, the drug may cause destructive thyroiditis. Patients should be screened for hypothyroidism and serum concentrations of thyroid-stimulating hormone (TSH) measured at suggested intervals of 2 to 3 months.[1]

1. Desai J, *et al.* Hypothyroidism after sunitinib treatment for patients with gastrointestinal stromal tumors. *Ann Intern Med* 2006; **145**: 660–4.

Mucositis. Sunitinib has been reported to cause stomatitis, characterised by bullous and erosive lesions with widespread lichenoid and necrotising areas.[1]

1. Mignogna MD, *et al.* Sunitinib adverse event: oral bullous and lichenoid mucositis. *Ann Pharmacother* 2009; **43**: 546–7.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sunitinib as probably not porphyrinogenic it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/09/11)

Tumour lysis syndrome. Tumour lysis syndrome has been reported after treatment with sunitinib; electrolytes and renal function should be closely monitored.[1,2]

1. Nicholaou T, *et al.* Tumour lysis syndrome in a patient with renal-cell carcinoma treated with sunitinib malate. *Lancet* 2007; **369**: 1923–4.
2. Saylor PJ, Reid TR. Tumor lysis syndrome after treatment of a gastrointestinal stromal tumor with the oral tyrosine kinase inhibitor sunitinib. *J Clin Oncol* 2007; **25**: 3544–6.

Interactions

Sunitinib is metabolised mainly by the cytochrome P450 isoenzyme CYP3A4 to produce an active metabolite, which is further metabolised by CYP3A4. Ketoconazole increased exposure to sunitinib, and use with other potent inhibitors of CYP3A4 (such as other azole antifungals, macrolide antibacterials, HIV-protease inhibitors, or grapefruit juice) may also increase sunitinib concentrations. Conversely, use with rifampicin decreased exposure to sunitinib, and inducers of CYP3A4 (such as dexamethasone, phenytoin, carbamazepine, phenobarbital, or St John's wort) may decrease plasma sunitinib concentrations. If the use of alternative drugs is not feasible, dose adjustments of sunitinib may be necessary (see Uses and Administration, p. 859.1).

Antineoplastics. The US manufacturer of *bevacizumab* has recommended that it should not be used with sunitinib after several patients receiving the combination had developed microangiopathic haemolytic anaemia.[1]

1. Genentech, USA. Important drug warning subject: microangiopathic hemolytic anemia (MAHA) in patients treated with Avastin (bevacizumab) and sunitinib malate (issued July 2008). Available at: http://www.fda.gov/downloads/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/ucm126434.pdf (accessed 21/07/10)

Pharmacokinetics

Peak plasma concentrations occur 6 to 12 hours after an oral dose of sunitinib. Bioavailability is unaffected by food. Sunitinib is metabolised mainly via the cytochrome P450 isoenzyme CYP3A4 to its primary active metabolite, which itself is then further metabolised via CYP3A4. Plasma protein binding of sunitinib and its metabolite is about 95% and 90%, respectively; plasma elimination half-lives are 40 to 60 hours, and 80 to 110 hours, respectively. Sunitinib is excreted mainly in faeces; about 16% is found in urine, as unchanged drug and metabolites.

Talactoferrin Alfa *(USAN, rINN)*

LF-00; rhLF; Talactoferrin; Talactoferrina alfa; Talactoferrine Alfa; Talactoferrinum Alfa; Талактоферрин Альфа.

Lactoferrin (recombinant human LF00).

CAS — 308240-58-6.

UNII — 7A055A9QRR.

Profile

Talactoferrin alfa is a recombinant form of human lactoferrin (p. 2539.3) that acts on the immune system as a dendritic cell recruiter and activator. An oral formulation is under investigation for the treatment of malignancies such as non-small cell lung cancer and renal cell carcinoma. It is also being investigated as an oral treatment for sepsis, and topically as a wound healing agent for diabetic foot ulcers.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

$C_{38}H_{41}N_5Na_4O_9$=803.7

CAS — 110230-98-3 (talaporfin); 220201-34-3 (talaporfin sodium).

UNII — L63605PZ70.

NOTE. The names Aptocine and Laserphyrin have been used as trade marks for talaporfin sodium.

Profile

Talaporfin sodium is a photosensitiser that is used for the photodynamic therapy (see under Porfimer Sodium, p. 849.1) of lung cancer. It is also under investigation for the treatment of other tumours, such as hepatocellular carcinoma and metastatic colorectal cancer.

Tamibarotene *(rINN)*

AM-80; NSC-608000; Tamibarotène; Tamibaroteno; Tamibarotenum; Тамибаротен.

N-(5,6,7,8-Tetrahydro-5,5,8,8-tetramethyl-2-naphthyl)terephthalamic acid.

$C_{22}H_{25}NO_3$=351.4

CAS — 94497-51-5.

UNII — 08V52GZ3H9.

Profile

Tamibarotene is a synthetic retinoid that is given orally for the treatment of relapsed or refractory acute promyelocytic leukaemia. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Malignant neoplasms. Tamibarotene has been used to induce remission in patients with acute promyelocytic leukaemia (see Acute Myeloid Leukaemias, p. 693.1) who relapsed after successful remission induction with tretinoin.[1,2] Twenty-four patients received tamibarotene at a daily oral dose of 6 mg/m^2; 14 patients obtained complete remission after a median of 41 days.[1] Reported adverse effects include hypercholesterolaemia, hypertriglyceridaemia,[1,3] cheilitis, xerosis, gastrointestinal disturbances, bone pain, headache, dermatitis, liver damage, and leucocytosis; in one case, retinoic acid syndrome occurred.[1]

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Jpn***: Amnolake.

Tamoxifen Citrate *(BANM, USAN, rINNM)* ⊗

Citrato de tamoxifeno; ICI-46474; Tamoksifeenisitraatti; Tamoksifen Sitrat; Tamoksifeno citratas; Tamoxifen citrát; Tamoxifencitrat; Tamoxifén-citrát; Tamoxifène, citrate de; Tamoxifeni Citras; Tamoxifeno, citrato de; Тамоксифена Цитрат.

(*Z*)-2-[4-(1,2-Diphenylbut-1-enyl)phenoxy]ethyldimethylamine citrate.

$C_{26}H_{29}NO.C_6H_8O_7$=563.6

CAS — 10540-29-1 (tamoxifen); 54965-24-1 (tamoxifen citrate).

ATC — L02BA01.

ATC Vet — QL02BA01.

UNII — 7FRV7310N6.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, and *US*.

Ph. Eur. 8: (Tamoxifen Citrate). A white or almost white, polymorphic, crystalline powder. Slightly soluble in water and in acetone; soluble in methyl alcohol.

USP 36: (Tamoxifen Citrate). A white, fine, crystalline powder. Very slightly soluble in water, in alcohol, in acetone, and in chloroform; soluble in methyl alcohol. Protect from light.

Uses and Administration

Tamoxifen is an oestrogen antagonist with actions similar to those of clomifene citrate (see p. 2259.1). It may also inhibit the production or release of cellular growth factors and induce apoptosis. It is used in the adjuvant endocrine therapy of node-positive breast cancer, in the treatment of metastatic disease, and for prophylaxis in women a increased risk including those with ductal carcinoma in situ It has been tried in some other malignancies including tumours of the ovary and in malignant melanoma Tamoxifen is also used to stimulate ovulation in women with anovulatory infertility. See also the cross-references below.

Tamoxifen is given orally as the citrate but doses are calculated in terms of the base; tamoxifen citrate 15.2 mg is equivalent to about 10 mg of tamoxifen. In the treatment of **breast cancer**, usual doses are tamoxifen 20 mg daily, in 2 divided doses or as a single daily dose. Doses of up to 40 mg daily may be given but no additional benefit has been found. Adjuvant therapy is normally continued for up to 5 years, although the optimum duration is still uncertain (p. 702.1). To reduce breast cancer incidence in women at high risk of the disease, the licensed dose of tamoxifen is 20 mg daily for 5 years.

In the treatment of anovulatory **infertility** the usual dose is tamoxifen 20 mg daily on days 2 to 5 of the menstrual cycle, increased if necessary in subsequent cycles up to 80 mg daily. In women with irregular menstruation the initial course may be begun on any day, and a second course begun at a higher dose after 45 days if there has been no response. If the patient responds with menstruation, subsequent courses may begin on day 2 of the cycle.

A topical formulation of 4-hydroxytamoxifen, a metabolite of tamoxifen, is under investigation for the treatment of cyclic mastalgia.

An oral formulation of the tamoxifen metabolite, endoxifen, is under investigation, see Metabolism, p. 864.1.

Breast disorders, non-malignant. *GYNAECOMASTIA.* Tamoxifen, usually in doses of 10 mg twice daily, has been reported to be effective[1-7] in reducing pain, swelling, and breast size in men or pubertal boys with gynaecomastia (p. 2264.3). Tamoxifen has been recommended as a drug of choice in patients requiring drug therapy, given for 3 months to see if a response occurs.[7] It has also been reported to be effective for the prevention and treatment of gynaecomastia and breast pain caused by the nonsteroidal anti-androgen bicalutamide,[8-11] which is used in the treatment of prostate cancer (see Gynaecomastia under Adverse Effects and Precautions of Flutamide, p. 799.1). A randomised study[12] in patients with prostate cancer treated with bicalutamide found that a daily schedule of tamoxifen was more effective than a weekly schedule in preventing gynaecomastia. In addition, switching to a weekly schedule after a daily schedule was followed by a dramatic increase in the development of gynaecomastia and mastalgia; this became apparent after 6 months of treatment, probably as a result of the study design, in which 2 months of daily treatment was given before switching to the weekly schedule, causing a loading effect.

MASTALGIA. Tamoxifen 20 mg daily has been shown to be effective in patients with both cyclic and non-cyclic mastalgia,[1] and improvement has also been reported at a lower dose of 10 mg daily.[2] However, there is concern about the use of tamoxifen in otherwise healthy premenopausal women,[3-5] particularly since many patients relapse on withdrawal,[2] and it has been recommended[6,7] that tamoxifen be reserved for patients who fail to respond to other drugs (see p. 2265.1).

A topical formulation of 4-hydroxytamoxifen, a metabolite of tamoxifen, is under investigation in the treatment of cyclic mastalgia.

Cardiovascular disorders. Tamoxifen has been reported to have a generally favourable effect on lipid profiles (see Effects on Blood Lipids, under Adverse Effects, p. 862.1) suggesting it may have cardiovascular benefits.[1] A cohort study of adjuvant tamoxifen found that the drug reduced the incidence of myocardial infarction,[2] and a randomised study of the same therapy also showed a trend towards a decrease in mortality from coronary heart disease.[3] However, in a much larger breast cancer prevention study, tamoxifen did not reduce the risk of, and mortality from, ischaemic heart disease, neither of which differed between placebo and tamoxifen recipients.[4,5] This lack of difference was independent of pre-existing cardiovascular disease.[5] A review[6] noted that while the available data suggested an overall benefit, most of them came from studies in women at low absolute risk of myocardial infarction; studies in men at high absolute risk would be needed to determine whether tamoxifen and related drugs were suitable as cardioprotectants.

Disorders related to the menstrual cycle. Apart from cyclic mastalgia (see above) tamoxifen has been used in cases in which disorders were linked to the hormonal changes of the menstrual cycle, including menorrhagia due to myometrial hypertrophy,[1] an auto-immune dermatitis due to post-ovulatory rises in serum progesterone[2,3] (see Effects on the Skin under Progesterone, p. 2301.3), and premenstrual migraine.[4] However, tamoxifen was thought to be a cause of recurrent migraines in another patient, because of its action at oestrogen receptors.[5] Tamoxifen has also been tried in primary dysmenorrhoea.[6]

Infertility. Tamoxifen is reported to be as effective as clomifene in the treatment of anovulatory infertility (p. 2253.1) in women,[1-3] and may be useful in women in whom abnormal cervical mucus acts as a barrier to spermatozoa.[4] In infertile men, however, results are reportedly contradictory, with some studies reporting increase in sperm density and improved pregnancy rates while others failed to find any effect.[5] The addition of testosterone may improve outcomes, however, and a later study of men with idiopathic oligozoospermia reported that tamoxifen with testosterone improved sperm variables and pregnancy rates compared with a placebo group (there was no comparison with tamoxifen alone).[6]

Malignant neoplasms. For reference to the use of tamoxifen in malignant neoplasms of breast, ovary, and in cutaneous melanoma, see p. 702.1, p. 711.2, and p. 714.3. The most common use of tamoxifen is for the endocrine therapy of oestrogen-receptor positive early or advanced breast cancer, where there seems to be a clear benefit. How long such therapy should be continued remains uncertain although continuing therapy beyond 5 years may not increase the overall benefit. However, extending therapy by following 5 years of tamoxifen therapy with several years of an aromatase inhibitor such as letrozole (see, p. 817.2) does seem to provide additional benefit.

Extension of tamoxifen use to the attempted prophylaxis of breast cancer has proved controversial (see p. 703.2). Nonetheless, evidence that tamoxifen can reduce short-term incidence of breast cancer in some women at increased risk has been seen, and tamoxifen has been approved for such use in the USA.

Osteoporosis. Tamoxifen has been reported to have favourable effects on bone mass,[1-3] and current use has been associated with a substantial reduction in osteoporotic fractures.[4] However, any general role in the prevention of osteoporosis (p. 1168.1) seems unlikely given concerns about the carcinogenicity of tamoxifen. The effects are reported to be comparable in magnitude to those of calcium supplementation, and less than those of oestrogens (see also p. 2246.1) or bisphosphonates. It has been suggested that such an effect on bone would provide an additional benefit in women receiving tamoxifen for the prophylaxis of breast cancer,[5] although others dispute the benefits.[6]

Precocious puberty. Tamoxifen has been reported to be beneficial in the treatment of precocious puberty (p. 2254.1).

Retroperitoneal fibrosis. Tamoxifen may be a viable therapeutic option in the treatment of adults with retroperitoneal fibrosis (p. 1612.1).[1-3] Tamoxifen was successful in treating a prepubertal child with disease that was unresponsive to high-dose corticosteroids.[4]

Adverse Effects

The most frequent adverse effects of tamoxifen are hot flushes. Other adverse effects include fluid retention, nausea, gastrointestinal intolerance, vaginal bleeding or discharge, pruritus vulvae, rashes, dry skin, and alopecia. There have also been reports of dizziness, headache, depression, confusion, fatigue, and muscle cramps. There may be an increased tendency to thromboembolism, and pulmonary embolism has occurred. Tumour pain and flare may be a sign of response, but hypercalcaemia, sometimes severe, has developed in patients with bony metastases. Transient thrombocytopenia and leucopenia have been reported. Blurred vision and loss of visual acuity, corneal opacities, retinopathies, and cataracts have occurred rarely. Tamoxifen has been associated with increased liver enzymes, and rarely with cholestasis and hepatitis. Hypertriglyceridaemia has occurred. Uterine fibroids and endometrial changes including hyperplasia and polyps may occur, and an increased incidence of endometrial carcinoma, and rarely uterine sarcoma, has been reported. Suppression of menstruation may occur in premenopausal women and cystic ovarian swellings have occasionally occurred. Very rare cases of interstitial pneumonitis have been reported.

Carcinogenicity. Tamoxifen has a stimulant effect on the endometrium (probably by acting as a partial oestrogen agonist) and its use has been associated with the development of endometrial polyps[1,2] and endometriosis,[3] and an increased risk of endometrial cancer.[4-6] The risk, which increases with duration of therapy, is generally agreed to be modest, and the clinical benefit in women with breast cancer outweighs any increased risk of endometrial neoplasm.[7-10] Women taking tamoxifen to prevent breast cancer have been estimated to have a 2.53-fold greater risk of developing endometrial carcinoma than untreated women.[11] The risk may increase with more prolonged use and a case-control study has reported that long-term (over 2 years) users may have a worse prognosis if endometrial cancer develops, due to less favourable history and stage.[12] Another case-control study showed that the relative risk of endometrial cancer increased with duration of tamoxifen treatment, up to at least 10 years. Risk was not associated with the daily dose of tamoxifen, and was comparable in pre- and postmenopausal women.[13]

It has been recommended that women with breast cancer taking tamoxifen should have annual gynaecological examinations, and any unusual symptoms, including abnormal bleeding or spotting should be investigated promptly.[14] Women taking tamoxifen for prophylaxis of breast cancer should be monitored carefully for endometrial hyperplasia. If atypical hyperplasia develops, tamoxifen should be stopped while the condition is treated and a hysterectomy should be considered before tamoxifen is restarted.[14] However, up to 39% of postmenopausal women taking tamoxifen show endometrial changes and as these seldom progress to cancer, the value of routine endometrial biopsies has been questioned.[8,9,14,15] Transvaginal ultrasonography has been used as a noninvasive method of endometrial screening, but has a high rate of false-positive results.[16] It has been suggested that colour doppler ultrasonography, which distinguishes vascularised lesions such as polyps and carcinomas from avascular atrophic lesions, may be a useful alternative.[17] There is some evidence that a levonorgestrel-releasing intra-uterine device can protect against benign endometrial polyps induced by tamoxifen.[18]

Although rare, there is an increase in the risk of uterine sarcoma in women receiving tamoxifen. Between 1978, when tamoxifen was first marketed in the USA, and April 2001, the FDA was aware of 43 cases in women who had been receiving tamoxifen; there had also been reports in 116 women in other countries.[19] Although less than the expected rate in this population, this was considered to be due to underreporting. An evaluation of data from 39 451 breast cancer patients initially treated with tamoxifen found that the overall risk of uterine corpus cancer was more than doubled with the use of tamoxifen; the risk of rare but aggressive forms of uterine tumours, notably malignant mixed mullerian tumours, was increased more than fourfold.[20]

Tamoxifen has been shown to form DNA adducts in *rat* livers, and there has been speculation that it may cause liver cancer in humans. However, there is considerable interspecies variation in the metabolism of tamoxifen and several large-scale clinical studies did not find an increase in liver carcinogenicity in humans.[10] No substantial increase in liver or colorectal cancer has been seen in tamoxifen-treated patients,[21] and there is little evidence of any increased risk for oesophageal cancer.[21,22] Stomach cancer was the most frequently seen secondary cancer in a Japanese cohort study,[21] and a Swedish cohort study concluded that women with breast cancer were at increased risk of gastric adenocarcinoma, and that tamoxifen therapy might play a role.[22] Results from a case-control study in the UK suggested that tamoxifen treatment did not increase the risk of ovarian cancer (although non-hormonal chemotherapy might).[23]

Although in treated women with breast cancer adjuvant tamoxifen reduces the risk of developing a second primary malignancy in the contralateral breast, a case-control study has suggested that 5 or more years of tamoxifen treatment increases the risk, should such a malignancy develop, that it will be oestrogen-receptor negative, and hence harder to treat.[24]

Effects on blood lipids. Tamoxifen has been reported to have a generally favourable effect on serum lipid profiles.[1] Patients with breast cancer and subsequent chemotherapy-induced ovarian failure developed marked increases in total cholesterol and low-density lipoprotein levels: adjuvant tamoxifen was found to decrease these serum lipid concentrations to below baseline concentrations. No significant changes in high-density lipoprotein or serum triglyceride concentrations were seen.[2] However, some cases of increased serum triglycerides, mainly in women with pre-existing hypertriglyceridaemia, have been reported.[3-5] Pancreatitis has also resulted.[5] It has been suggested that tamoxifen should be used with caution in patients with hypertriglyceridaemia.[3,4]

Effects on bones and joints. Arthralgia has been reported as an adverse effect of generic tamoxifen therapy; however, a crossover study[1] involving 121 postmenopausal women who developed new onset arthralgia during tamoxifen treatment for breast cancer found that arthralgia resolved in 114 when generic tamoxifen was swapped for another brand (*Nolvadex; AstraZeneca, UK*). Arthralgia recurred when the patients resumed taking a generic. It was suggested that possibly the generic tablets included an excipient responsible for symptoms, or Nolvadex contained an excipient with a protective effect.

1. Blencowe NS, *et al.* The use of Nolvadex in the treatment of generic Tamoxifen-associated small joint arthralgia. *Breast* 2010; 19: 243–5.

Effects on the cardiovascular system. *ISCHAEMIC HEART DISEASE.* For discussion of whether the effects of tamoxifen on lipid profiles can alter the incidence of ischaemic heart disease, see Cardiovascular Disorders under Uses and Administration, p. 861.1.

STROKE. An excess risk of stroke was seen in tamoxifen compared with placebo recipients (5 cases versus 1) in a study of adjuvant tamoxifen.[1] A statistically non-significant increase in stroke was also seen in a study on the use of tamoxifen for breast cancer prevention (0.5 excess cases per 1000 women per year).[2] A meta-analysis[3] of 9 studies for prevention or treatment of breast cancer, involved data from 39 601 women, of whom 19 954 received tamoxifen. It concluded that use of tamoxifen increased the risk of ischaemic stroke by 82%, and the risk of any stroke by 29%; however, the absolute increase in risk was small.

In contrast, a case-control study of 11 045 women with breast cancer, found that tamoxifen use was not associated with an increased risk of first stroke.[4]

A time-dependent effect of adjuvant tamoxifen has been seen, with significantly increased morbidity and mortality from cerebrovascular disease, including stroke, during the active treatment period; risk was significantly decreased after treatment was stopped.[5]

THROMBOEMBOLISM. A case control study,[1] involving 25 cases of deep-vein thrombosis or pulmonary embolism among more than 10 000 women with breast cancer, suggested that current use of tamoxifen was associated with an estimated relative risk of developing idiopathic venous thromboembolism of 7.1 (95% confidence interval 1.5 to 33). Past use of tamoxifen was not associated with a materially increased risk. In a randomised placebo-controlled study, there was an increase in pulmonary emboli in women receiving tamoxifen for cancer prevention (excess of 0.46 cases per 1000 women per year).[2] The fatality rate from pulmonary emboli in tamoxifen recipients was about 17%. In this study, there was also a trend towards more deep-vein thrombosis in tamoxifen recipients. In another controlled study[3] of breast cancer prevention, tamoxifen approximately doubled the risk of developing a major thromboembolic event such as pulmonary embolism, deep-vein thrombosis, or retinal thrombosis. Cerebral sinus thrombosis has also been reported.[4] An analysis[5] of 4 tamoxifen prevention studies also found that venous thromboembolic events were increased in all studies, with a relative risk of 1.9 for those taking tamoxifen compared with placebo. However, another randomised study[6] found only a borderline significantly higher risk of developing venous thromboembolic events in those women allocated to tamoxifen; most of these events were superficial thrombophlebitis. Furthermore, women already at risk for atherosclerosis had a higher risk of venous thromboembolism. While the authors could not exclude a selection bias for healthier subjects in the study, they commented that the prothrombotic effect of tamoxifen may depend on the patient's existing endocrine status, and may be attenuated in those women taking HRT, especially when it is used transdermally.

Effects on the eyes. Tamoxifen has been reported to be associated with decreased visual acuity, corneal opacities and cataract, and retinopathy. The latter is sometimes progressive although in most cases it has shown improvement once the drug was stopped.[1] A prospective study in 63 patients taking tamoxifen 20 mg daily found evidence of decreased visual acuity, macular oedema, and retinal opacities in 4, occurring after 10 to 35 months of therapy.[2] A small excess risk of developing cataracts (3.1 extra per year per 1000 women) and of requiring cataract surgery (1.7 per year per 1000 women) was found in women taking tamoxifen for up to 5 years to reduce the risk of breast cancer.[3] Studies *in vitro* have suggested that cataract formation may be due to inhibition of chloride channels in the lens by tamoxifen or its hydroxy metabolite.[4] Retinopathy after high-dose tamoxifen treatment may be associated with crystalline deposition of the drug in the retina.[5]

Effects on the genito-urinary system. Persistent nocturna priapism was reported in a man receiving tamoxifer 20 mg daily.[1] Symptoms abated within 24 hours of with drawing the drug. Impotence has been reported in met receiving tamoxifen, and has been attributed to a paradox ical oestrogenic effect.[2]

2. Collinson MP, *et al.* Two case reports of tamoxifen as a cause o impotence in male subjects with carcinoma of the breast. *Breast* 1993; 2: 48–9.

Effects on the liver. Cholestasis and increased liver enzyme values have been reported on use of tamoxifen in a 75 year-old patient.[1] Enzyme activity rose again on rechal lenge with tamoxifen. Fatal hepatocellular necrosis an agranulocytosis, possibly exacerbated by continuing t take the drug once jaundice developed, has also beer reported;[2] the authors noted that 4 cases of hepatic failure (3 fatal) and 5 cases of hepatitis (1 fatal) had beer reported to the UK CSM. Patients taking tamoxifen may also develop steatohepatitis,[3-7] which must be distin guished from alcohol-induced liver disease. Steatohepatiti is reversible on withdrawal of tamoxifen.[3,5,6] A study ir healthy women who had had hysterectomies found the risk of steatohepatitis to be particularly high among obese women, moderately high among overweight women, an similar to that with placebo in women of normal weight. Bezafibrate has been tried to prevent progression of steato hepatitis and permit continued use of tamoxifen.[9]

For a report of peliosis hepatis and liver haemorrhage in a patient receiving tamoxifen and warfarin, see Anticoa gulants, under Interactions, p. 863.2.

For reference to studies in *animals* suggesting tha tamoxifen has the potential to cause liver cancer, see Carcinogenicity, p. 861.3.

9. Saibara T, *et al.* Bezafibrate for tamoxifen-induced non-alcoholi steatohepatitis. *Lancet* 1999; 353: 1802.

Effects on the ovaries. Ovarian cysts are relatively com mon as an adverse effect in women receiving adjuvan tamoxifen: a study[1] in 95 such women reported the devel opment of ovarian cysts in 6 of 16 (37.5%) who were pre menopausal and in 5 of 79 postmenopausal womer (6.3%). In 2 of the premenopausal women the cysts were complex. Two women underwent laparotomy for persis tent cysts that were found to be benign, and 1 for leio myoma; the cysts in the other 8 women resolved afte withdrawal of tamoxifen. A study of 142 breast cance patients receiving tamoxifen found ovarian cysts in 2 patients after treatment. Cyst development was more com mon in pre-menopausal women, patients with high oes trogen levels, and patients who did not receive high-dos chemotherapy.[2] There is little evidence that tamoxifer increases the risk of ovarian cancer (see Carcinogenicity p. 861.3).

2. Mourits MJE, *et al.* Ovarian cysts in women receiving tamoxifen fo breast cancer. *Br J Cancer* 1999; 79: 1761–64.

Effects on the skin and hair. Vasculitis has been reported in patients given tamoxifen.[1,2] Withdrawal of the drug resulted in complete clearance of the lesions;[1,2] in one case, on re-introduction, purpura developed again within a few days.[1] The results suggest that tamoxifen can produce immune-mediated vascular damage.

In another report a patient with white hair developed darkening and repigmentation of the hair after about 2½ years of tamoxifen therapy.[3] Alopecia has also been reported in women given tamoxifen,[4,5] and in older patients the follicle may not recover.[4]

Precautions

All patients being considered for treatment with tamoxifen should be assessed for any increased risk of thromboembolism. Tamoxifen should not be used for treatment of infertility or the prophylaxis of breast cancer in women with a history of thromboembolic events. When used to treat breast cancer in such women, the risks and benefits should be considered; in some patients, especially those given cytotoxic drugs, prophylactic anticoagulation may be justified. Care is also needed during or immediately after major surgery or prolonged immobility; all patients should be given prophylaxis against thrombosis. In patients being treated for infertility, tamoxifen should be stopped at least 6 weeks before surgery or long-term immobility and only restarted when the patient is fully mobile. Patients should be made aware of the symptoms of thromboembolism and advised to report sudden breathlessness or any pain in the calf of one leg. Tamoxifen should be withdrawn immediately in any patient developing thromboembolism and appropriate treatment given. Treatment should not usually be restarted for infertility therapy but resumption of tamoxifen with prophylactic anticoagulation may be justified in selected patients with breast cancer.

Women treated with tamoxifen should have routine gynaecological monitoring, and any abnormal symptoms such as menstrual irregularities, abnormal vaginal bleeding or discharge, or pelvic pain should be investigated (see also under Carcinogenicity, p. 861.3). Periodic complete blood counts and liver function tests have been suggested.

Abuse. Although the supervised use of tamoxifen for the treatment of gynaecomastia resulting from the abuse of anabolic steroids has been reported[1] it also appears to be widely used without medical supervision. Tamoxifen can be used to treat idiopathic gynaecomastia and gynaecomastia resulting as an adverse effect of nonsteroidal anti-androgens used to treat prostate cancer (see under Breast Disorders, Non-malignant, p. 860.3).

1. de Luis DA, *et al.* Anabolizantes esteroldeos y ginecomastia: revisión de la literatura. *An Med Interna* 2001; **18:** 489–91.

Breast feeding. Tamoxifen was shown to inhibit lactation in 60 puerperal women.[1] Licensed product information recommends that it should not be given to lactating women as it is unknown if tamoxifen appears in breast milk.

1. Masala A, *et al.* Inhibition of lactation and inhibition of prolactin release after mechanical breast stimulation in puerperal women given tamoxifen or placebo. *Br J Obstet Gynaecol* 1978; **85:** 134–7.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies tamoxifen as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Pregnancy. Tamoxifen is contra-indicated in pregnancy. Ambiguous genitalia have been reported in an infant exposed to tamoxifen *in utero*, although no causal link was found.[1] Another infant was born with Goldenhar's syndrome (oculoauriculovertebral dysplasia) after exposure to tamoxifen throughout a 26-week pregnancy.[2] The mother had also taken cocaine and marijuana during the first 6 weeks of pregnancy, and a bone scan using technetium (^{99m}Tc) medronate had been performed. The US manufacturer of tamoxifen (*Zeneca, USA*) was aware of 50 pregnancies in patients taking tamoxifen, resulting in 19 normal births, 8 terminations, 13 unknown outcomes and 10 infants with fetal or neonatal abnormalities.[2]

Tamoxifen has also been used to stimulate ovulation in women with luteal phase dysfunction. In one study tamoxifen was given to 40 women, resulting in 14 pregnancies. Although 9 infants were born with no congenital abnormalities, there were 5 spontaneous abortions, which the authors felt was unacceptably high.[3] Another study, using lower doses of tamoxifen (in some cases sequentially with clomifene), reported 32 pregnancies and only 3 spontaneous abortions in 65 treated patients.[4]

4. Wu CH. Less miscarriage in pregnancy following tamoxifen treatment of infertile patients with luteal phase dysfunction as compared to clomiphene treatment. *Early Pregnancy* 1997; **3:** 301–5.

Radiotherapy. There are reports of radiation recall, with erythema at the site of previous radiotherapy, in patients receiving tamoxifen.[1-3]

1. Parry BR. Radiation recall induced by tamoxifen. *Lancet* 1992; **340:** 49.
2. Extermann M, *et al.* Radiation recall in a patient with breast cancer treated for tuberculosis. *Eur J Clin Pharmacol* 1995; **48:** 77–8.
3. Singer EA, *et al.* Tamoxifen-induced radiation recall dermatitis. *Breast J* 2004; **10:** 170–1.

Interactions

There is a risk of increased anticoagulant effect if tamoxifen is given with coumarin anticoagulants. Conversely, use with cytotoxic drugs may increase the risk of thromboembolic events; prophylactic anticoagulation should be considered. In order to avoid bleeding during a possible thrombocytopenic episode, platelet aggregation inhibitors should not be used with tamoxifen. Tamoxifen increases the dopaminergic effect of bromocriptine; bromocriptine increases serum concentrations of tamoxifen and its major metabolite *N*-desmethyltamoxifen (see Pharmacokinetics, below). Use with inhibitors of cytochrome P450 isoenzyme CYP2D6 has been shown to reduce plasma concentrations of endoxifen, a tamoxifen metabolite (see Pharmacokinetics, below); while the clinical relevance is unclear, a reduced effect of tamoxifen cannot be excluded, and use with potent CYP2D6 inhibitors should be avoided if possible.

Tamoxifen is metabolised by CYP3A4 and care is required when it is used with CYP3A4 inducers, as tamoxifen concentrations may be reduced; plasma concentrations of tamoxifen may be increased by use with CYP3A4 inhibitors.

Preparations of sex hormones, especially oestrogens, should not be used with tamoxifen as a mutual decrease in effect is possible. Medroxyprogesterone decreases concentrations of *N*-desmethyltamoxifen, but not of tamoxifen.

Tamoxifen is metabolised by cytochrome P450 isoenzymes, including CYP2D6 (see Pharmacokinetics, below), and drugs which inhibit CYP2D6 can reduce metabolism and potentially increase the risk of breast cancer recurrence. Recommendations regarding the use of these drugs with tamoxifen have been made:[1]

Potent inhibitors should be avoided; these include the SSRIs paroxetine, fluoxetine, bupropion, and duloxetine (see also Antidepressants, below), and other drugs such as perphenazine, pimozide, thioridazine, quinidine, ticlopidine, terbinafine, and cinacalcet.

Weak to moderate inhibitors should be used with caution, especially in patients considered to be CYP2D6 intermediate metabolisers (see Genetic Factors, below). These include the SSRIs sertraline, citalopram, and fluvoxamine, the tricyclic antidepressants clomipramine, doxepin, desipramine, imipramine, amitriptyline, and nortriptyline, as well as other drugs such as chlorpromazine, fluphenazine, haloperidol, amiodarone, amlodipine, felodipine, nicardipine, nifedipine, verapamil, chloroquine, halofantrine, ritonavir, cimetidine, clemastine, diphenylpyraline, hydroxyzine, promethazine, tripelennamine, and celecoxib.

1. Sideras K, *et al.* Coprescription of tamoxifen and medications that inhibit CYP2D6. *J Clin Oncol* 2010; **28:** 2768–76. Correction. *ibid.*: 3543.

Allopurinol. For reference to exacerbation of hepatotoxicity when tamoxifen was given with allopurinol, see p. 603.1.

Antibacterials. *Rifampicin* was found to decrease plasma concentrations of tamoxifen in 10 healthy subjects. This was thought to be due to induction of cytochrome P450 isoenzyme CYP3A4 by rifampicin.[1]

1. Kivistö KT, *et al.* Tamoxifen and toremifene concentrations in plasma are greatly decreased by rifampin. *Clin Pharmacol Ther* 1998; **64:** 648–54.

Anticoagulants. Cases of a potentially life-threatening interaction between tamoxifen and *warfarin*, with marked prolongation of prothrombin times, haematuria, and haematoma, have been reported.[1-3] It has been suggested that in addition to enhancement of the effects of warfarin, competition for the same metabolic enzyme systems might reduce the activity of tamoxifen against tumours,[2] but this remains speculative.

Peliosis hepatis and fatal liver haemorrhage have been reported in a patient who was receiving tamoxifen with warfarin and a liothyronine-levothyroxine preparation.[4]

1. Lodwick R, *et al.* Life threatening interaction between tamoxifen and warfarin. *BMJ* 1987; **295:** 1141.
2. Tenni P, *et al.* Life threatening interaction between tamoxifen and warfarin. *BMJ* 1989; **298:** 93.

4. Loomus GN, *et al.* A case of pelliosis hepatis in association with tamoxifen therapy. *Am J Clin Pathol* 1983; **80:** 881–3.

Antidepressants. Some antidepressants, particularly *SSRIs*, may inhibit the bioactivation of tamoxifen via the cytochrome P450 isoenzyme CYP2D6. The metabolism of tamoxifen to an active metabolite, 4-hydroxy-*N*-desmethyltamoxifen (endoxifen), may be inhibited by *paroxetine*, a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6.[1] However, the clinical consequences of this are not fully established. A case-control study[2] found that patients taking tamoxifen with known inhibitors of CYP isoenzymes, including CYP2D6, were no more likely to relapse than those not receiving a CYP inhibitor. However, a retrospective cohort study[3] found that paroxetine use during tamoxifen treatment was associated with an increased risk of death from breast cancer. The increased risk was directly related to the duration of combined use, and supports the hypothesis that irreversible CYP2D6 inhibition by paroxetine can reduce or abolish the survival advantage conferred by long-term tamoxifen treatment in patients with breast cancer. In contrast, no such risk was seen with other antidepressants (*citalopram, fluoxetine, fluvoxamine, sertraline,* and *venlafaxine*), although smaller sample sizes for some may have influenced results. Some consider that potent CYP2D6 inhibitors such as bupropion, paroxetine, and fluoxetine should be avoided in women with breast cancer taking tamoxifen, and antidepressants with a low potential to inhibit CYP2D6 (such as venlafaxine or citalopram) should be considered instead.[4-6] Caution is warranted even with moderate CYP2D6 inhibitors such as duloxetine and sertraline.[6]

For further reference to use of CYPD26 inhibitors with tamoxifen, including a slightly different classification for some of the SSRIs mentioned here, see above.

Immunosuppressants. For the results of a study *in vitro* suggesting that tamoxifen might inhibit the metabolism of *tacrolimus* by inhibiting the cytochrome P450 isoenzyme system, see under Interactions of Tacrolimus, p. 1977.3.

Neuromuscular blockers. For reference to prolonged neuromuscular blockade in a patient given *atracurium* while receiving tamoxifen, see p. 2032.2.

Pharmacokinetics

Peak plasma concentrations of tamoxifen occur 4 to 7 hours after an oral dose. It is extensively protein bound. Plasma clearance is reported to be biphasic and the terminal half-life may be up to 7 days. It is extensively metabolised by the cytochrome P450 isoenzymes CYP3A4, CYP2C9, and CYP2D6. The major serum metabolite, *N*-desmethyltamoxifen is formed mainly via CYP3A4; it has a half-life at steady state of about 14 days. 4-Hydroxytamoxifen is a minor metabolite. *N*-Desmethyltamoxifen and 4-hydroxytamoxifen are further metabolised (via CYP2D6 and the CYP3A family, respectively) to 4-hydroxy-*N*-desmethyltamoxifen (endoxifen). Several of the metabolites are stated to have similar pharmacological activity to the parent compound, and endoxifen has been proposed as an alternative treatment to avoid differences in metabolism (see Metabolism, p. 864.1). Tamoxifen is excreted slowly in the faeces, mainly as conjugates. Small amounts are excreted in urine. Tamoxifen appears to undergo enterohepatic circulation.

Genetic factors. Tamoxifen is metabolised by the cytochrome P450 isoenzymes, and its metabolites may play a role in its antineoplastic effect. Studies have suggested that

patients with low or absent CYP2D6 activity or who are being treated with CYP2D6 inhibitors have lower concentrations of endoxifen. Patients with CYP2D6*3, *4, *5, and *6 alleles are designated as poor metabolisers, those with *9, *10, *17, *29, and *41 as intermediate metabolisers, and those with *1, *2, and *35 as extensive metabolisers.[1,2] Genetic polymorphism in the enzymes responsible for tamoxifen biotransformation has the potential to affect clinical outcomes. While a small study[3] showed a decreased risk of breast cancer recurrence in patients with the CYP2D6*4 allele when treated with tamoxifen, another[4] found that this allele was an independent predictor of a higher risk of disease relapse and a lower incidence of hot flashes in postmenopausal women with breast cancer. A further study[5] found that carriers of CYP2D6 alleles *4 or *5 showed a greater risk for breast cancer relapse. Furthermore, carriers of the CYP2C19*17 genotype had a more favourable clinical outcome. A retrospective cohort study found that poor metabolisers had an almost twofold increased risk of breast cancer recurrence compared with extensive metabolisers; those with decreased CYP2D6 activity (intermediate and poor metabolisers) also had worse disease-free survival compared with extensive metabolisers, although there was no significant difference in overall survival.[6] The Clinical Pharmacology Subcommittee of the US FDA Advisory Committee for Pharmaceutical Science has advised that availability of genotypic testing be included in licensed product information for tamoxifen.[7,8] Some have commented[8] that it would seem reasonable to confine CYP2D6 testing to situations where it might guide the choice between tamoxifen and an alternative.

It has been suggested[9] that genetic variation in uridine diphosphate glucuronosyltransferase (UGT) enzymes, which are important in the glucuronidation of tamoxifen and its metabolites, may also play a role in interindividual differences in response to the drug.

Metabolism. Tamoxifen is extensively metabolised by cytochrome P450 isoenzymes, to active metabolites that include *N*-desmethyltamoxifen, 4-hydroxytamoxifen, and 4-hydroxy-*N*-desmethyltamoxifen (endoxifen).[1,2] *In-vitro* studies suggest that both *N*-desmethyltamoxifen and 4-hydroxytamoxifen are further metabolised to endoxifen.[3] There is growing interest in how genetic polymorphism might influence the efficacy and toxicity of tamoxifen and its metabolites (see Genetic Factors, p. 863.3). Substitution of endoxifen for tamoxifen has been proposed as a treatment option for patients with breast cancer in order to avoid any effects of genetic polymorphisms as well as any interactions with cytochrome P450 isoenzyme CYP2D6 inhibitors (see under Interactions, p. 863.2). The safety, tolerability, and bioavailability of an oral formulation of endoxifen has been evaluated; a daily dose of 4 mg endoxifen citrate has been proposed as being appropriate for breast cancer prevention and therapy.[2]

$C_8H_9FN_2O_3$=200.2

CAS — 17902-23-7.

ATC — L01BC03.

ATC Vet — QL01BC03.

UNII — 1548R74NSZ.

NOTE. The name S-1 has been used for a mixture of tegafur, gimeracil, and oteracil potassium.

Pharmacopoeias. In *Chin.* and *Jpn.*

Uses and Administration

Tegafur is considered to be an orally active prodrug of fluorouracil (p. 795.3). It has been used in the management of malignant neoplasms including those of the breast, gallbladder, gastrointestinal tract, head and neck, liver, and pancreas. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Tegafur has been given orally in doses up to 1 g/m² daily. It is often given with uracil (UFT; p. 2637.3). Tegafur 300 mg/m² daily, with uracil 672 mg/m² daily, may be given in 3 divided oral doses, together with calcium folinate, in the management of metastatic colorectal cancer. Doses are given for a cycle of 28 days, followed by 7 days without treatment. The drugs should be taken 1 hour before or after meals, and doses modified according to toxicity. Doses of tegafur 1 to 3 g/m² daily for 5 days have been given **intravenously.**

Administration. Tegafur is an orally active prodrug of fluorouracil. Although it has been given as a single agent, it is more often used with drugs that modify its bioavailability and toxicity.[1] These include uracil (p. 2637.3) and gimeracil (5-chloro-2,4-dihydroxypyridine, CDHP, gimestat), which can increase fluorouracil concentrations by inhibition of dihydropyrimidine dehydrogenase, the enzyme responsible for its further catabolism,[1-4] and oteracil (oxonic acid), which inhibits another enzyme, orotate pyrimidine phosphoribosyl transferase, thought to play a role in the gastrointestinal toxicity of fluorouracil and its prodrugs.[2]

UFT consists of tegafur and uracil in the optimal molar ratio 1:4.[1] It is available for the treatment of colorectal cancer (p. 706.3)—for doses, see above. A preliminary analysis of a large study comparing oral UFT and calcium folinate therapy with intravenous fluorouracil and calcium folinate found both regimens to be well tolerated with similar levels of toxicity.[5] It is also used as adjuvant therapy for gastrointestinal and other solid tumours,[6] including being tried in hepatocellular carcinoma;[7] it appears to improve survival in patients with adenocarcinoma of the lung[8] and node-negative breast cancer.[9] The efficacy of tegafur-based adjuvant therapy in Japanese patients with stomach cancer has been reviewed.[10]

A combination of tegafur, gimeracil, and oteracil potassium in the molar ratio 10:4:10 (TS-1, *Taiho Jpn*) has been tried in gastric and colorectal cancers.[2-4,11] Initial results have suggested comparable activity to fluorouracil and calcium folinate in induction regimens but the incidence of diarrhoea and stomatitis was reduced.

Adverse Effects, Treatment, and Precautions

As for Fluorouracil, p. 797.1.

Bone-marrow depression may be less severe with tegafur but gastrointestinal toxicity is often dose-limiting and central neurotoxicity is more common. Peripheral oedema and dyspnoea occur commonly. Increases in liver function test values are common and there are reports of fatal fulminant hepatitis. Liver function should be monitored in patients with hepatic impairment given tegafur; it should not be given in severe hepatic impairment.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies tegafur as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

Tegafur should not be used with drugs that inhibit dihydropyrimidine dehydrogenase; fatalities have occurred in patients given tegafur and sorivudine (see Antivirals under Interactions of Fluorouracil, p. 797.3). For the effect of tegafur with uracil on phenytoin, see p. 544.1.

Pharmacokinetics

Tegafur is well absorbed from the gastrointestinal tract after oral doses. After an intravenous dose it is reported to have a prolonged plasma half-life of 6 to 16 hours. Tegafur appears to be slowly metabolised in the liver to fluorouracil (p. 798.1), and some intracellular conversion to fluorouracil may also occur. Tegafur crosses the blood-brain barrier and is found in the CSF.

Temoporfin (BAN, USAN, rINN)

EF-9; *meso*-Tetrahydroxyphenylchlorin; *meta*-Tetrahydroxyphenylchlorin; mTHPC; Temoporfini; Temoporfina; Témoporfine; Temoporfinum; Темопорфин.

3,3′,3″,3‴-(7,8-Dihydroporphyrin-5,10,15,20-tetrayl)tetraphenol; 7,8-Dihydro-5,10,15,20-tetrakis(3-hydroxyphenyl)porphyrin.

$C_{44}H_{32}N_4O_4$=680.8

CAS — 122341-38-2.

ATC — L01XD05.

ATC Vet — QL01XD05.

UNII — FU21S769PF.

Uses and Administration

Temoporfin is a porphyrin derivative. It is used palliatively as a photosensitiser in the photodynamic therapy (see under Porfimer Sodium, p. 849.1) of refractory squamous cell carcinoma of the head and neck (p. 708.1), that cannot be treated with radiotherapy, surgery, or systemic chemotherapy. It is also under investigation in the treatment of various other malignant neoplasms. Temoporfin is given by slow intravenous injection over at least 6 minutes, at a dose of 150 micrograms/kg. This is followed 96 hours later by activation using a laser tuned to a wavelength of 652 nanometres for about 200 seconds, sufficient to supply a dose of 20 J/cm^2. This should take place not less than 90 hours and not more than 110 hours after injection. Treatment may be repeated once after at least 4 weeks if necessary.

Liposomal formulations for topical delivery of temoporfin are under investigation.

12. Naim R. Photodynamische Therapie mit m-THPC (Foscan): Behandlung von Plattenepithelkarzinomen im Kopf-Hals-Bereich. *HNO* 2008; **56**: 490–2.

Adverse Effects and Precautions

Adverse effects of temoporfin include photosensitivity, local inflammatory reactions, and gastrointestinal disturbances. Patients should be advised to avoid direct sunlight or bright indoor light for 15 days, and to protect the injection site from light for at least 3 months if extravasation has occurred.

Porphyria. Licensed product information states that the use of temoporfin is contra-indicated in patients with porphyria.

Interactions

Use of temoporfin with other drugs causing photosensitivity should be avoided as the reaction may be increased; this has been reported with topical fluorouracil.

Pharmacokinetics

Peak plasma concentrations of temoporfin occur about 2 to 4 hours after intravenous infusion. Thereafter, elimination is bi-exponential, with a terminal plasma half-life of about 65 hours. Plasma protein binding is about 85%. *Animal* data indicate that temoporfin is metabolised in the liver and excreted in the faeces via the bile.

CAS — 85622-93-1.

ATC — L01AX03.

ATC Vet — QL01AX03.

UNII — YF1K15M17Y.

Pharmacopoeias. In *US.*

USP 36: (Temozolomide). A white to light pink or light tan powder. Sparingly soluble in water; practically insoluble in toluene; soluble in dimethyl sulfoxide.

Uses and Administration

Temozolomide is a prodrug that is converted to MTIC (see Pharmacokinetics, p. 866.1), the active metabolite of dacarbazine (p. 776.1). MTIC acts as an alkylating agent. Temozolomide is licensed for the treatment of malignant gliomas (below) such as glioblastoma multiforme and anaplastic astrocytoma, and metastatic malignant melanoma (below).

Temozolomide may be given orally or intravenously. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

In adult patients with *newly diagnosed* **glioblastoma multiforme**, temozolomide is given initially with focal radiotherapy (the *concomitant phase*) in an oral or intravenous dose of 75 mg/m^2 daily for 42 days. Treatment may be interrupted or stopped depending on toxicity. Complete blood counts should be monitored weekly. Four weeks after completing the concomitant phase, temozolomide *monotherapy* is begun at an oral or intravenous dose of 150 mg/m^2 once daily for 5 days of a 28-day cycle. In cycle 2, the dose is increased to 200 mg/m^2 for 5 days, if toxicity allows. If the dose cannot be increased in cycle 2, it should not be increased in subsequent cycles. The dose used at cycle 2 is then given every 28 days, toxicity allowing. Up to 6 cycles of temozolomide monotherapy may be given.

The usual oral dose for *recurrent or progressive* malignant gliomas in adults previously untreated with chemotherapy is 200 mg/m^2 once daily for 5 days, repeated every 28 days. In patients who have received previous courses of chemotherapy the initial oral or intravenous dose is 150 mg/m^2 once daily for 5 days, for the first cycle of therapy, but may be increased to 200 mg/m^2 for subsequent courses if there is no haematological toxicity.

An oral dose of 200 mg/m^2 once daily for 5 days every 28 days is also used for metastatic **malignant melanoma**.

Administration. References[1,2] to the use of temozolomide in dose-dense regimens, designed to maximise exposure to the drug and consequent efficacy. In contrast to the original 5-day regimen (150 to 200 mg/m^2 daily for 5 days of a 28-day cycle) used in glioma, these have included 75 mg/m^2 daily for 6 to 7 weeks[1] (this is now recommended by licensed product information for the initial phase of glioma treatment) and regimens in which 150 mg/m^2 was given for 5 or 7 days of a 14-day cycle, or 100 mg/m^2 for 21 days of a 28-day cycle.[1] However, the increased dose intensity may be associated with increased adverse effects and the clinical benefits are still uncertain.

2. Neyns B, *et al.* Dose-dense temozolomide regimens: antitumor activity, toxicity, and immunomodulatory effects. *Cancer* 2010; **116**: 2868–77.

Administration in children. In the UK, temozolomide may be given to children aged 3 years or older for the treatment of malignant glioma, such as glioblastoma multiforme or anaplastic astrocytoma, that recurs or progresses after standard therapy. It is given orally in the same dose as that used for adults (see Uses and Administration, above).

Malignant neoplasms. Temozolomide has been studied[1-9] particularly in the management of malignant neoplasms of the brain (p. 701.2). In the UK, guidance has been issued[10] on its use in patients with recurrent progressive malignant glioma who have failed first-line chemotherapy treatment with other agents (either because of lack of efficacy or because of adverse effects). A systematic review[11] concluded that temozolomide is an effective primary therapy for newly diagnosed glioblastoma multiforme; it prolongs survival and delays progression. For recurrent disease, data from a single study indicate that it delays progression but does not affect overall survival. Another review[12] concluded that although there was good evidence for the use of temozolomide in both high- and low-grade gliomas, value could not be shown for other brain tumours, including metastases.

MELANOMA. Temozolomide has been studied[1-3] as a treatment for advanced metastatic melanoma (p. 714.3). A phase III study compared the overall survival-time in 305 patients treated with either oral temozolomide or intravenous dacarbazine in standard doses for up to 12 cycles of therapy. Temozolomide was found to be at least equivalent to dacarbazine in these patients, and there were no major differences in adverse effects.[2] However, median survival-times were short in both groups (7.7 months and 6.4 months respectively). Another phase III study comparing temozolomide alone or with interferon alfa in 282 patients also found modest median survival-times of 8.4 and 9.7 months respectively.[4] Studies in *animals* have investigated isolated limb infusion of temozolomide, plus hyperthermia, for regional therapy of melanoma of the extremities.[5]

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2. Myelosuppression is common with temozolomide and is dose-limiting. Blood counts should be obtained before the start of treatment and monitored throughout. The nadir of cell counts usually occurs 21 to 28 days after treatment, with recovery within the next 1 to 2 weeks. Patients over 70 years of age are thought to be more susceptible to severe myelosuppression. Prolonged pancytopenia may result in aplastic anaemia, and fatalities have been reported. Opportunistic infections can occur; pneumocystis pneumonia has been reported in patients also given radiotherapy or corticosteroids, or during a longer dosing regimen of temozolomide. Prophylaxis against pneumocystis pneumonia should be given to all patients receiving temozolomide with radiotherapy, regardless of lymphocyte count.

Nausea and vomiting are very common; antiemetic therapy may be given before or during treatment. Other common adverse effects include constipation, diarrhoea, anorexia, alopecia, fatigue, headache, rashes, convulsions, and insomnia or somnolence. Anxiety, depression, confusion, dizziness, hemiparesis, aphasia, dysphagia, peripheral neuropathy, paraesthesia, neurological and/or speech disorders, tremor, and concentration or memory impairment can occur, as can visual field defects, blurred vision, diplopia, hearing impairment, or tinnitus. Deafness has been reported. Vascular disorders such as haemorrhage, deep venous thrombosis, and peripheral oedema can occur; pulmonary embolism has been reported. Other commonly reported adverse effects include dyspnoea, coughing, dry skin, pruritus, arthralgia and/or myalgia, urinary incontinence, fever, pain, and dysgeusia. Liver enzyme values can

increase, and hyperglycaemia may occur. Cushingoid disorders have occurred uncommonly. Hypersensitivity reactions, including rare cases of anaphylaxis, can occur. Toxic epidermal necrolysis, Stevens-Johnson syndrome, and erythema multiforme have been reported rarely. Cases of interstitial pneumonitis have also been reported. Temozolomide has carcinogenic, mutagenic, and teratogenic potential. Use in pregnancy should be avoided, and men should be advised not to father a child for up to 6 months after receiving the final dose; sperm preservation before treatment should be considered as temozolomide may cause irreversible infertility.

Carcinogenicity. Antineoplastic drugs such as alkylating agents are associated with the development of secondary malignancies (see Carcinogenicity, p. 726.2). Myelodysplastic syndrome and myeloid leukaemia have been reported in patients treated with regimens containing temozolomide. Three patients with glioma developed malignant lymphoma after treatment with temozolomide.[1]

1. Neyns B, *et al.* Non-Hodgkin's lymphoma in patients with glioma treated with temozolomide. *J Clin Oncol* 2008; **26**: 4518–19. Correction. *ibid.* 2009; **27**: 3070.

Effects on the lungs. After completing 2 cycles of temozolomide therapy for glioblastoma multiforme, an 88-year-old man presented with a 4-week history of fever, weakness, shortness of breath, and non-productive cough. Auscultation of the lungs revealed inspiratory crackles without wheezing or rub. Drug-associated organising pneumonitis was suspected, and temozolomide therapy was stopped. Prednisolone was started, with prophylaxis against *Pneumocystis jirovecii*, and the patient improved dramatically.[1] Others have subsequently reported temozolomide-associated hypersensitivity pneumonitis.[2]

2. Koschel D, *et al.* Hypersensitivity pneumonitis associated with the use of temozolomide. *Eur Respir J* 2009; **33**: 931–4.

Hepatitis. Hepatitis B reactivation has been associated with the use of temozolomide plus radiotherapy.[1,2] In one case, corticosteroid treatment may have played a role in reactivation,[1] and in another case, which was fatal, hepatotoxicity from valproic acid or temozolomide itself could have contributed.[2]

1. Chheda MG, *et al.* Hepatitis B reactivation during glioblastoma treatment with temozolomide: a cautionary note. *Neurology* 2007; **68**: 955–6.
2. Grewal J, *et al.* Fatal reactivation of hepatitis B with temozolomide. *N Engl J Med* 2007; **356**: 1591–2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies temozolomide as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

Valproic acid decreases oral clearance of temozolomide by about 5%; the clinical significance is unknown.

Pharmacokinetics

Temozolomide is rapidly and completely absorbed from the gastrointestinal tract and peak plasma concentrations occur 0.5 to 1.5 hours after a dose. Food reduces the rate and extent of absorption. Temozolomide readily crosses the blood-brain barrier and can be detected in the CSF. The plasma elimination half-life is about 1.8 hours. Plasma protein binding is about 10 to 20%. Temozolomide undergoes spontaneous hydrolysis to its active metabolite 5-(3-methyl-triazen-1-yl)-imidazole-4-carboxamide (MTIC), which is then further hydrolysed to 5-amino-imidazole-4-carboxamide (AIC) and methylhydrazine. Temozolomide is largely eliminated by the kidneys, about 5 to 10% as unchanged drug.

Temsirolimus *(BAN, USAN, rINN)*

CCI-779; Temsirolimusum; Темсиролимус.

(3*S*,6*R*,7*E*,9*R*,10*R*,12*R*,14*S*,15*E*,17*E*,19*E*,21*S*,23*S*,26*R*,27*R*,34a*S*)-9,10,12,13,14,21,22,23,24,25,26,27,32,33,34,34a-Hexadecahydro-9,27-dihydroxy-3-[(1*R*)-2-[(1*S*,3*R*,4*R*)-4-hydroxy-3-methoxycyclohexyl]-1-methylethyl]-10,21-dimethoxy-6,8,12,14,20,26-hexamethyl-23,27-epoxy-3*H*-pyrido[2,1-*c*][1,4]oxaazacyclohentriacontine-1,5,11,28,29(4*H*,6*H*,31*H*)-pentone 4′[2,2-bis(hydroxymethyl)propionate].

$C_{56}H_{87}NO_{16}$=1030.3

CAS — 162635-04-3.

ATC — L01XE09.

ATC Vet — QL01XE09.

UNII — 624KN6GM2T.

Incompatibility. The formulation of temsirolimus injection contains polysorbate 80, which increases the rate of extraction of the plasticiser di-2-ethylhexylphthalate (DEHP) from PVC. In order to minimise exposure to DEHP, the infusion should be given in glass, polyolefin, or polyethylene containers, through non-DEHP giving sets with an in-line polyethersulfone filter of not greater than 5 micrometres.

Uses and Administration

Temsirolimus is an ester analogue of sirolimus (p. 1970.2) that is used for the treatment of advanced renal cell carcinoma and relapsed and/or refractory mantle cell lymphoma. It is given intravenously, diluted in 250 mL sodium chloride 0.9% and infused over 30 to 60 minutes, preferably via an infusion pump.

For **renal cell carcinoma**, temsirolimus 25 mg is given once weekly. Treatment should be interrupted and the dose reduced if toxicity occurs. US licensed product information recommends withholding the dose if the absolute neutrophil count falls below 1000 cells/mm³, or the platelet count falls below 75 000 cells/mm³, or if grade 3 toxicity occurs. Once these have resolved to grade 2 or less, temsirolimus may be restarted with the dose reduced by 5 mg weekly, to a dose no lower than 15 mg weekly.

Use of strong inhibitors or inducers of CYP3A4 may increase or decrease exposure to sirolimus, the active metabolite of temsirolimus. If no alternative is available, US licensed product information suggests dose adjustments for renal cell carcinoma patients. A reduction of temsirolimus to 12.5 mg weekly should be considered if it is given with a strong CYP3A4 inhibitor. Once the inhibitor is stopped, a washout period of about 1 week should be allowed before temsirolimus is increased back to the original dose. A dose increase of temsirolimus to 50 mg weekly should be considered if it is given with a strong CYP3A4 inducer; once the inducer is stopped, temsirolimus should be decreased to the original dose.

In the UK, temsirolimus is also licensed for **mantle cell lymphoma**; the recommended dose is 175 mg once weekly for 3 weeks followed by 75 mg once weekly thereafter. Treatment should be interrupted and the dose reduced for absolute neutrophil counts below 1000 cells/mm³ and/or platelet counts below 50 000 cells/mm³. Once these counts have returned to these levels or higher, temsirolimus may be restarted with the weekly dose reduced in the following way:

- last dose 175 mg, reduce to 75 mg
- last dose 75 mg, reduce to 50 mg
- last dose 50 mg, reduce to 25 mg

If neutrophil and platelet counts are not maintained at or above these levels on the new dose, then treatment should be withheld and the next lower dose given once the counts have recovered. Inhibitors and inducers of CYP3A4 should be avoided in patients given temsirolimus for mantle cell lymphoma.

Temsirolimus treatment may continue until disease progression or toxicity occurs.

For doses in patients with hepatic impairment see below.

Administration in hepatic impairment. Temsirolimus is mainly metabolised in the liver, and should be used with caution in patients with hepatic impairment. In the treatment of renal cell carcinoma, UK licensed product information considers that no dose adjustment is required for mild or moderate hepatic impairment (Child-Pugh class A or B). For severe impairment (Child-Pugh class C) and a baseline platelet count ≥100 000 cells/mm³, a reduced dose of temsirolimus 10 mg intravenously once weekly is recommended. Temsirolimus is contra-indicated for treatment of mantle cell lymphoma in patients with moderate or severe hepatic impairment.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Temsirolimus is metabolised to sirolimus; for adverse effects of sirolimus, see p. 1971.2. Additional adverse effects reported with temsirolimus include lymphopenia, myalgia, hypocalcaemia, anorexia, asthenia, nail disorders, dry skin, pruritus, and conjunctivitis. Cataracts have occurred in patients given temsirolimus with interferon alfa. Effects on the nervous system include insomnia, anxiety, depression, dysgeusia, paraesthesia, dizziness, and ageusia. Although hepatotoxicity has not been reported with temsirolimus, raised liver transaminase concentrations are common.

Hypersensitivity reactions to temsirolimus may be life-threatening; symptoms include anaphylaxis, dyspnoea, flushing, and chest pain. Antihistamines should be given about 30 minutes before the start of the infusion. If the patient develops a hypersensitivity reaction, the infusion should be stopped and the patient observed for 30 to 60 minutes. If appropriate, treatment may be restarted about 30 minutes after a further dose of an antihistamine and/or an H_2-antagonist. The infusion may be restarted at a slower infusion rate (up to 60 minutes) and completed within 6 hours of preparation. Cases of fatal bowel perforation have occurred; patients presented with fever, abdominal pain, metabolic acidosis, bloody stools, diarrhoea, and/or acute abdomen. Patients with CNS tumours and/or those given anticoagulants may be at increased risk of developing intracranial bleeding, which may be fatal.

Serum glucose, cholesterol, and triglycerides should be monitored before and during treatment with temsirolimus.

Effects on the lungs. Eight out of 22 patients given temsirolimus developed pulmonary abnormalities compatible with drug-induced pneumonitis. Dyspnoea and dry cough were the most common symptoms, although 4 patients were asymptomatic. The risk of developing pulmonary toxicity is increased in those with abnormal pretreatment pulmonary function, or a history of lung disease.[1] A retrospective review[2] found that 29% of patients developed radiographically diagnosed temsirolimus-related pneumonitis; radiographic changes were not necessarily associated with symptoms. The onset of drug-related pneumonitis occurred within the first 8 weeks of temsirolimus treatment in 60% of patients.

1. Duran I, *et al.* Characterisation of the lung toxicity of the cell cycle inhibitor temsirolimus. *Eur J Cancer* 2006; **42**: 1875–80.
2. Maroto JP, *et al.* Drug-related pneumonitis in patients with advanced renal cell carcinoma treated with temsirolimus. *J Clin Oncol* 2011; **29**: 1750–6.

Interactions

Both temsirolimus and its main active metabolite, sirolimus, are metabolised by cytochrome P450 isoenzyme CYP3A4, and inducers or inhibitors of CYP3A4 may affect exposure, see Interactions, under Sirolimus, p. 1972.1. If the use of alternative drugs is not feasible, dose adjustments of temsirolimus may be necessary, see Uses and Administration, above.

References.

1. Boni J, *et al.* Pharmacokinetic profile of temsirolimus with concomitant administration of cytochrome P450-inducing medications. *J Clin Pharmacol* 2007; **47**: 1430–9.
2. Boni JP, *et al.* Differential effects of ketoconazole on exposure to temsirolimus following intravenous infusion of temsirolimus. *Br J Cancer* 2008; **98**: 1797–1802.

Pharmacokinetics

Temsirolimus is mainly metabolised by cytochrome P450 isoenzyme CYP3A4 to 5 metabolites; sirolimus is the main active metabolite. The mean half-life of temsirolimus is about 17 hours. Exposure to sirolimus may be much greater than that of temsirolimus, due principally to the longer half-life of sirolimus (see p. 1972.1). Elimination is mainly in faeces; about 5% is recovered in the urine.

Preparations

Proprietary Preparations (details are given in Volume B)

$C_{32}H_{32}O_{13}S$=656.7

CAS — 29767-20-2.

ATC — L01CB02.

ATC Vet — QL01CB02.

UNII — 957E6438QA.

Stability. Precipitation occurred repeatedly in preparations for infusion containing teniposide 200 micrograms/mL in either glucose 5% or sodium chloride 0.9% injection, although previously such preparations had been used uneventfully.[1] Dilution of teniposide solutions to 100 micrograms/mL or less reduced the frequency of the problem, which could not be attributed to a change in formulation and remained unexplained.

1. Strong DK, Morris LA. Precipitation of teniposide during infusion. *Am J Hosp Pharm* 1990; 47: 512,518.

Uses and Administration

Teniposide is an antineoplastic agent with general properties similar to those of etoposide (p. 790.2). It is given as monotherapy or part of a combination regimen for refractory non-Hodgkin's lymphoma (p. 696.3), and with other antineoplastic agents in the treatment of refractory acute lymphoblastic leukaemia (p. 692.3). Teniposide is also used in solid tumours including neuroblastoma (p. 716.2), and has been used in retinoblastoma (p. 717.2).

Teniposide is given by slow intravenous infusion over at least 30 to 60 minutes, as a solution of up to 1 mg/mL in sodium chloride 0.9% or glucose 5%. Dosage regimens vary.

For non-Hodgkin's **lymphoma**, the following monotherapy regimens have been used:

- 30 mg/m² daily for 10 days
- 30 mg/m² daily every five days
- 50 to 100 mg/m² once weekly

Doses in combination regimens have generally been given once weekly, at 60 to 70 mg/m².

In the treatment of refractory acute lymphoblastic **leukaemia**, the following combination regimens have been used:

- 165 mg/m² twice weekly for 8 to 9 doses, with cytarabine
- 250 mg/m² weekly for 4 to 8 weeks, with vincristine and prednisone

For **neuroblastoma**, doses as a single agent range from 130 to 180 mg/m² once weekly.

Adverse Effects, Treatment, and Precautions

As for Etoposide, p. 791.2. There is some evidence that teniposide may be a more potent mutagen and carcinogen than etoposide.

Breast feeding. US licensed product information states that it is unknown whether teniposide is excreted in human milk. It has been suggested[1] that breast feeding be withheld for 30 to 48 hours after a dose.

1. *et al.*, eds. *Drugs during pregnancy and lactation: treatment options and risk assessment.* 2nd ed. London: Elsevier, 2007.

Hypersensitivity. Haemolytic anaemia and acute renal failure with tubular necrosis has been reported in a patient who developed an antibody to teniposide.[1] As with etoposide (p. 791.3) hypersensitivity or infusion reactions occur, sometimes with the first dose, and may be severe;[2,3] the frequency may be as high as 13% in neuroblastoma patients.[2] Although it has been suggested that hypersensitivity reactions might be due to the polyoxyl castor oil in the injection vehicle,[2] studies *in vitro* suggest that it is the drug rather than the vehicle that is responsible.[3]

1. Habibi B, *et al.* Immune hemolytic anemia and renal failure due to teniposide. *N Engl J Med* 1982; 306: 1091–3.

3. Carstensen H, *et al.* Teniposide-induced hypersensitivity reactions in children. *Lancet* 1989; ii: 55.

Pregnancy. A 32-year-old woman was diagnosed with Burkitt's lymphoma at 22 weeks of gestation. She was treated with combination chemotherapy, including doxorubicin, vincristine, teniposide, cyclophosphamide, and prednisolone; courses were given every 2.5 or 3 weeks depending on haematological recovery, for a total of 6 courses. At 35 weeks, she was given intrathecal methotrexate for a total of 7 doses, and bleomycin for a total of 4 doses. The infant was healthy, fully developed, with no physical abnormalities, and had a normal heart, and a normal blood count.[1]

1. Lowenthal RM, *et al.* Normal infant after combination chemotherapy including teniposide for Burkitt's lymphoma in pregnancy. *Med Pediatr Oncol* 1982; 10: 165–9.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Salicylic acid, sulfamethizole, and tolbutamide may affect the protein binding of teniposide, potentially increasing free teniposide in plasma and resulting in toxicity; caution is advised when giving any of these drugs with teniposide.

Antiepileptics. Clearance of teniposide was markedly increased by *phenytoin* or *phenobarbital*; the resultant decrease in systemic exposure to the antineoplastic might reduce its efficacy, and increased dosage would be needed in patients receiving these drugs to guarantee equivalent exposure.[1]

1. Baker DK, *et al.* Increased teniposide clearance with concomitant anticonvulsant therapy. *J Clin Oncol* 1992; 10: 311–15.

Ciclosporin. Use of ciclosporin with teniposide has been reported[1] to produce a decrease in the clearance of the latter, with increased terminal half-life, peak plasma concentrations, and toxicity.

Pharmacopoeias. In *US*.

USP 36: (Testolactone). A white to off-white, practically odourless, crystalline powder. Soluble 1 in 4050 of water; soluble in alcohol and in chloroform; slightly soluble in benzyl alcohol; insoluble in ether and in petroleum spirit. Store in airtight containers.

Profile

Testolactone is a derivative of testosterone (see p. 2305.1). It is reported to be an aromatase inhibitor that reduces peripheral oestrogen synthesis but has no significant androgenic activity. It has been given orally in the palliative treatment of advanced breast cancer in postmenopausal women (p. 702.1).

It is unsuitable for men with breast cancer.

Peripheral neuropathies have occurred in patients given testolactone; gastrointestinal disturbances, pain or oedema of the extremities, hypertension, malaise, maculopapular erythema, and glossitis have also been reported.

Congenital adrenal hyperplasia. For mention of the use of testolactone with flutamide to block androgenic effects in congenital adrenal hyperplasia, see p. 1603.2.

Precocious puberty. Encouraging results have been reported using testolactone in the treatment of 5 girls with precocious puberty (p. 2254.1) due to the McCune-Albright syndrome.[1] Testolactone is an aromatase inhibitor and blocks the synthesis of oestrogens from androgens. Long-term therapy (for up to 5 years) was associated with continued benefit in many patients; however, signs of puberty were not always completely suppressed, in some cases perhaps because of difficulties in maintaining the dosage regimen.[2] Encouraging results were also obtained using testolactone with spironolactone in the treatment of familial precocious puberty in boys, although neither agent was successful when used alone.[3] Again, signs of a reduced response to longer-term therapy have occurred; in this case control was restored by addition of a gonadorelin analogue.[4] Another study[5] in 10 boys who were treated for at least 6 years with spironolactone and testolactone, with deslorelin added at the onset of secondary central precocious puberty, found normalisation in growth rate and bone maturation, and improvements in predicted adult height.

Preparations

Pharmacopoeial Preparations

USP 36: Testolactone Tablets.

Thalidomide *(BAN, USAN, rINN)*

E-217; K-17; NSC-66847; Talidomid; Talidomida; Talidomidi; Thalidomidum; Талидомид.

2-Phthalimidoglutarimide.

$C_{13}H_{10}N_2O_4$=258.2

CAS — 50-35-1.

ATC — L04AX02.

ATC Vet — QL04AX02.

UNII — 4Z8R6ORS6L.

Pharmacopoeias. In *US*.

USP 36: (Thalidomide). A white to off-white powder. Sparingly soluble in water, in dehydrated alcohol, in acetone, in butyl acetate, in ethyl acetate, in glacial acetic acid, and in methyl alcohol; practically insoluble in chloroform, in ether, and in benzene; very soluble in dimethylformamide, in dioxan, and in pyridine. Store in airtight containers. Protect from light.

Stability. An extemporaneously prepared oral suspension of thalidomide 20 mg/mL was reported to be stable for at least 35 days when stored in amber plastic bottles under refrigeration (3 degrees to 5 degrees). The contents of capsules (*Thalomid; Celgene, USA*) were suspended in a 1:1 mixture of *Ora-Plus* and *Ora-Sweet* (*Paddock, USA*). Appropriate precautions should be taken during preparation and handling, because of the risks associated with this drug.[1]

Uses and Administration

Thalidomide has immunomodulating, anti-inflammatory, and anti-angiogenic activities. It should always be given under appropriately supervised and controlled conditions because of the teratogenic risks and other potential adverse effects (see Adverse Effects and Precautions, p. 869.2). Thalidomide is given orally. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Thalidomide is used in the treatment of **multiple myeloma** (see Malignant Neoplasms, p. 868.3). In disease that is refractory to standard therapies, it is given as monotherapy in an initial oral dose of 200 mg once daily. The dose may be increased by 100 mg at weekly intervals up to a maximum dose of 400 mg daily, as tolerated. Thalidomide may be used with melphalan and prednisone in patients with newly diagnosed multiple myeloma who are over 65 years of age or ineligible for high-dose chemotherapy; thalidomide in a dose of 200 mg daily is given continuously for a maximum of 12 treatment cycles of 6 weeks each. Thalidomide may also be used with dexamethasone in the treatment of patients with newly diagnosed multiple myeloma. Thalidomide 200 mg is given once daily, with dexamethasone 40 mg given orally on days 1 to 4, 9 to 12, and 17 to 20 of a 28-day cycle. Four cycles of a thalidomide and dexamethasone regimen may be used as induction therapy before high-dose chemotherapy with autologous stem cell rescue.

Thalidomide is also used for the treatment of acute cutaneous manifestations of moderate to severe type 2 (erythema nodosum leprosum) **lepra reactions** (see Leprosy, p. 188.3), but should not be given as monotherapy if moderate to severe neuritis is present; in such cases, corticosteroid therapy should also be given and continued

until neuritis improves. Thalidomide may also be used for maintenance therapy for prevention and suppression of the cutaneous manifestations of recurrent type 2 lepra reactions. It is of no value in type 1 lepra reactions. It may be given orally in usual initial doses of 100 to 300 mg once daily. In severe cases up to 400 mg daily may be given. The dose should be reduced gradually by 50 mg every 2 to 4 weeks once a satisfactory response has been achieved. An alternative regimen is to start treatment with 100 mg once daily, and if symptoms are not controlled, increase the dose by increments of 100 mg at weekly intervals up to a maximum of 400 mg once daily.

Thalidomide should preferably be given at bedtime and at least 1 hour after the evening meal.

Thalidomide has been used in several other conditions whose aetiology may involve the immune system, such as treatment and prevention of graft-versus-host disease, treatment and prevention of recurrent aphthous stomatitis in severely and terminally immunocompromised patients, treatment of the clinical manifestations of both tuberculous and non-tuberculous mycobacterial infection, treatment of myelodysplastic syndrome and treatment of HIV-associated wasting syndrome, Kaposi's sarcoma, and Crohn's disease. It has also been used in the treatment of primary brain malignancies. Thalidomide is being investigated in some other malignancies.

Action. The mechanism of action of thalidomide is not completely understood, although investigations have shown that it has anti-inflammatory and immunomodulating effects, including inhibition of the synthesis of tumour necrosis factor (TNF)-α. However, this inhibition is incomplete and selective, and increased plasma-TNF-α concentrations have been seen in some patient groups. Other immunomodulatory and anti-inflammatory properties include inhibition of leucocyte chemotaxis into the site of inflammation and reduction of phagocytosis by polymorphonuclear leucocytes. Thalidomide also appears to modulate interleukins, although results of investigations into its effect on specific interleukins and interferon gamma have so far been equivocal. Effects on CD4+ cells and variable effects on other mediators of intercellular reactions have also been implicated. Thalidomide also inhibits angiogenesis, which may have implications in solid tumours and other diseases.

Behçet's syndrome. Thalidomide was effective for the treatment of oral and genital ulceration and follicular lesions in a randomised, double-blind, placebo-controlled study[1] in 96 male patients with Behçet's syndrome (p. 1601.1). It was also noted that the development of new oral and genital ulcers was prevented, although relapses may occur on cessation of therapy. Thalidomide has also been reported[2,3] to be of benefit for severe oral and genital ulceration in children with Behçet's syndrome unresponsive to other treatments. Thalidomide also improved symptoms in a woman with Behçet's syndrome who had recurrent perforating intestinal ulcers.[4]

Cachexia. For the use of thalidomide in HIV-associated wasting, see HIV-associated Complications, below, and in cancer-related cachexia, see Malignant Neoplasms, below.

Gastrointestinal bleeding. Thalidomide has been used to control refractory bleeding in patients with gastrointestinal vascular malformations including angiodysplasia. Studies in small groups of patients have shown reductions in the number and size of angiodysplasias and in transfusion requirements. Doses of 50 to 200 mg orally daily have generally been used.[1-3] At least 8 weeks of treatment may be needed for a beneficial effect; the optimum duration of therapy is unknown but thalidomide has been continued for up to 6 months.[1] However, adverse effects may limit its use.[1,3]

3. Garrido A, *et al.* Thalidomide in refractory bleeding due to gastrointestinal angiodysplasias. *Rev Esp Enferm Dig* 2012; **104**: 69–71.

Graft-versus-host disease. A review[1] of studies investigating the use of thalidomide in chronic graft-versus-host disease (see Haematopoietic Stem Cell Transplantation, p. 1937.1) concluded that although thalidomide appeared to be of benefit in some patients unresponsive to other treatments, doses greater than 200 mg daily are poorly tolerated in most patients. Giving thalidomide as prophylaxis led to poor survival, possibly through interfering with development of tolerance. Thalidomide was not of benefit when given as treatment for newly diagnosed disease.

HIV-associated complications. It has been proposed that thalidomide's inhibitory activity against TNF-α may explain its anti-HIV effect. However, there are conflicting reports as both decreased and increased TNF-α levels, as well as unchanged levels, have been seen in HIV-patients.[1] Nevertheless, thalidomide has shown some promise as a therapeutic agent for some AIDS-related diseases. It is an effective treatment for severe ulceration of the mouth (p. 1814.2), oropharynx, and oesophagus in patients with HIV-infection.[2-5] Of concern though is the finding that modest increases in plasma HIV RNA levels have been seen in some patients, which correlated with increases in TNF-α levels.[2,4] Thalidomide has also been tried with some success in HIV-infected patients with prurigo nodularis,[6] alopecia areata[7] (p. 1682.3), and hypertrophic genital herpes[8] (p. 955.2). It has also proved to be of benefit in HIV-associated wasting[9] (p. 959.1), and has shown promise in high doses for the treatment of AIDS-related Kaposi's sarcoma[10] (p. 718.1). Thalidomide was also of benefit in 3 patients with severe idiopathic HIV-associated colitis.[11]

Inflammatory bowel disease. Small open-label studies[1-3] have shown efficacy of thalidomide in patients with refractory Crohn's disease (see under Inflammatory Bowel Disease, p. 1811.3). In many of those patients already receiving corticosteroids the dosage could be reduced and in some corticosteroids could be stopped completely. Reduction of TNF-α and interleukin-12 by thalidomide may be responsible for its clinical effects in Crohn's disease.[4] Thalidomide has also been reported[5] to be of benefit in children and young adults with intractable inflammatory bowel disease (both Crohn's disease and ulcerative colitis).

Kaposi's sarcoma. See under HIV-associated complications, above and under Malignant Neoplasms, below.

Lupus erythematosus. Thalidomide has been found to be of benefit in lupus erythematosus, including chronic discoid lupus erythematosus,[1,2] lupus erythematosus profundus,[3,4] SLE[5] (p. 1613.3), and cutaneous lupus erythematosus.[6-11] The beneficial effect of thalidomide on cutaneous lupus erythematosus may be partly mediated through protection against UV-induced inflammation.[11]

Malignant neoplasms. Thalidomide has shown benefit in the treatment of patients with multiple myeloma (p. 699.2).[1] In relapsed or refractory disease, a review[2] of uncontrolled studies showed that thalidomide monotherapy may achieve complete or partial responses in about 29% of patients, and found at 12 months after starting therapy an overall survival rate of about 60% and event-free survival of about 35%. The response improves when dexamethasone is added, increasing the complete or partial response rate to about 46% without a significant increase in toxicity.[3] The combination of thalidomide and dexamethasone has also been used in newly-diagnosed patients, with response rates of at least 63% reported.[4,5] This combination may be used as induction therapy before autologous haematopoietic stem cell transplantation.[4] After transplantation, thalidomide has been studied for maintenance therapy and found to reduce the risk for disease progression, but the effect on overall survival has been mixed.[7] It has been suggested that the lowest effective maintenance dose is 50 mg orally daily, that therapy should be given for 1 year or less to limit the risk of significant toxicity, and that thalidomide should not be used in patients with FISH-defined poor-risk cytogenetics; however, the situation for elderly patients is less clear.[7] Improved response rates have been found when thalidomide was added to cycles of melphalan and prednisone in newly-diagnosed elderly patients (when transplantation is generally unsuitable), extending survival-time by about 20% (about 6 to 7 months).[8]

Thalidomide has also been tried in the treatment of several non-plasma cell malignancies with variable results.[9] It has shown promise in patients with recurrent high-grade gliomas[10] (p. 701.2) and is under investigation for non-AIDS-related Kaposi's sarcoma[11,12] (p. 718.1), metastatic melanoma[13] (p. 714.3), myelofibrosis with myeloid metaplasia,[14-16] and androgen-independent prostate cancer[17,18] (p. 712.3).

Thalidomide has shown some benefit in the treatment of cancer-related cachexia (see under Megestrol, p. 2289.3) in patients with pancreatic cancer.[19]

Mouth ulceration. See under Behçet's syndrome p. 868.1 and under HIV-associated complications, p. 868.2.

Oesophageal ulceration. Thalidomide has been shown to be of benefit in the treatment of idiopathic oesophageal ulcers in patients with AIDS (see under HIV-associated complications, p. 868.2). Thalidomide has also been reported to have healed an oesophageal ulcer refractory to other treatments in an immunocompetent patient,[1] and in an immunocompromised patient after liver transplant.[2]

Rheumatic disorders. Beneficial responses to thalidomide have been reported in the treatment of refractory rheumatoid arthritis[1] and adult-onset Still's disease.[2] Thalidomide also improved symptoms in 2 children with systemic onset juvenile rheumatoid arthritis, in whom other therapy, including etanercept, had been ineffective.[3] Efficacy was also shown in a further 11 children with refractory disease who were able to reduce their use of prednisone.[4]

Skin disorders. Thalidomide has shown efficacy in several severe dermatological disorders refractory to conventional therapies.[1,2] A review[3] of studies of thalidomide in the treatment of severe type 2 (erythema nodosum leprosum) lepra reactions concluded that it is an effective alternative to corticosteroid therapy. It has also been investigated in other severe skin disorders and beneficial responses have been reported in erythema multiforme[4,5] (p. 1684.3), pruritus associated with uraemia,[6] Langerhans-cell histiocytosis[7] (p. 692.1), epidermolysis bullosa and its variants,[8-10] prurigo nodularis,[11,12] pyoderma gangrenosum[13,14] (p. 1688.3), and Schnitzler's syndrome.[15] Thalidomide has been reported[16] to be of benefit in the treatment of erythema nodosum-like lesions attributed to immune reconstitution inflammatory syndrome that developed in a patient after initiation of antibacterial therapy for Whipple's disease.

Adverse Effects and Precautions

For general discussions, see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Thalidomide was withdrawn from use as a hypnotic in the early 1960s after it was discovered that it produced teratogenic effects when given in early pregnancy. These effects, which could develop after a single dose, involved mainly malformations of the limbs and defects of the ears, eyes, and internal organs. Death at or shortly after birth was also common. Further abnormalities and problems, including effects on the CNS, developed in later life.

Thalidomide was reintroduced in 1998 for use as an immunomodulator but because of its severe teratogenic effects, it should not be used in women of child-bearing potential, or if such use is absolutely essential then stringent contraceptive measures must be used, including the simultaneous use of 2 reliable forms of contraception for at least 4 weeks before, during, and for 4 weeks after, thalidomide therapy. A pregnancy test must be carried out before starting thalidomide treatment (preferably within 24 hours, and no more than 3 days before), and regular tests carried out during treatment. If pregnancy occurs during thalidomide therapy the drug must be stopped immediately and the patient given appropriate evaluation and counselling. As thalidomide is present in semen, male patients receiving thalidomide should use barrier methods of contraception even after successful vasectomy if their partner is of child-bearing potential. Patients should not donate blood or sperm during thalidomide therapy, or for 4 weeks after stopping.

The other major adverse effect of thalidomide is peripheral neuropathy, which can be severe and irreversible, and dose modifications should be considered. If there is no loss of function (grade 1), the patient should be monitored and doses reduced if symptoms worsen. If function deteriorates but daily living activities are not compromised (grade 2), the dose should be reduced or treatment interrupted and the patient monitored; treatment should be discontinued if there is no improvement, or it may be restarted if neuropathy resolves. Treatment should be discontinued when the neuropathy interferes with daily activities (grade 3) or is disabling (grade 4).

Venous thromboembolism has been reported in a significant number of patients receiving thalidomide for multiple myeloma, particularly in those also receiving chemotherapeutic drugs, including dexamethasone. Arterial thromboembolic events, including myocardial infarction and stroke, have also occurred, especially in patients with pre-existing risk factors for these; thromboprophylaxis should be considered, particularly in the first few months of treatment (see Effects on the Cardiovascular System, below).

Thalidomide is a centrally active hypnotic sedative and frequently causes drowsiness and somnolence; affected patients should not drive or operate machinery. Other common adverse effects include constipation, dizziness, and orthostatic hypotension. Hypersensitivity reactions have occurred. An erythematous macular rash may develop, usually 2 to 10 days after initiation of therapy. Stevens-Johnson syndrome and toxic epidermal necrolysis have also been reported, and therefore thalidomide should be stopped if a rash develops and only restarted after appropriate clinical evaluation. Thalidomide therapy should not be resumed if the rash is exfoliative, purpuric, or bullous, or if Stevens-Johnson syndrome or toxic epidermal necrolysis is suspected. Neutropenia and an increase in the viral load in HIV-infected patients have also been reported; thalidomide therapy should not be started in neutropenic patients. Bradycardia, heart failure, renal failure, seizures, worsening of Parkinson's disease symptoms, and hearing impairment or deafness, have also been reported. Patients with a high tumour burden before treatment are at increased risk of tumour lysis syndrome.

Although human data for breast feeding while taking thalidomide are lacking, licensed product information recommends that it should be avoided in view of the potential for serious adverse effects in the infant.

Effects on the cardiovascular system. Use of thalidomide in patients with malignant neoplastic disease has been associated with an increased risk of **venous** thromboembolic events such as deep-vein thrombosis. There were 27 spontaneous reports of thromboembolic events in the first 18 months of thalidomide returning to the US market in July 1998; 26 of these were in patients with malignancies.[1] A review[2] of thromboembolic events associated with thalidomide identified 67 such reports from a total of 2075 adverse events reported to the FDA between October 1998 and June 2001; a further 29 cases were identified from clinical study data. Deep-vein thrombosis occurred in 48 of these patients, pulmonary embolism in 25, and 23 developed both. The most common primary diagnoses among these patients were multiple myeloma and renal cell carcinoma. However, it should be noted that patients with cancer are known to be at increased risk of venous thromboembolism and some chemotherapeutic regimens may further increase this risk. The contribution of thalidomide to the development of venous thromboembolism remains to be fully evaluated in controlled studies. Further reviews[3,4] of reports of venous thromboembolism associated with thalidomide concluded that the incidence of venous thromboembolism in patients with multiple myeloma is higher when thalidomide is given with chemotherapeutic drugs such as dexamethasone, melphalan, or doxorubicin.

Patients given thalidomide have also been reported to be at increased risk of **arterial** thromboembolic events such as myocardial infarction and stroke. This risk appeared to be greatest in the first 5 months of treatment, and most patients who had such effects had pre-existing thromboembolic risk factors. It is recommended that measures should be taken to reduce modifiable risk factors such as hypertension, hyperlipidaemia, and smoking in those given thalidomide, and that candidates for thalidomide treatment be given appropriate thromboprophylaxis at least for the first 5 months, especially those with thromboembolic risk factors additional to their underlying pathology.[5]

Studies suggest that prophylactic use of a low-molecular-weight heparin (enoxaparin),[6] low-dose aspirin,[7] or low-dose warfarin[8] may reduce the incidence of deep-vein thrombosis in patients with multiple myeloma receiving thalidomide and chemotherapeutic drugs. A comparison of these 3 drugs in patients who did not have any other clear indication for prophylaxis showed them to be equally effective in reducing serious thromboembolic events, acute cardiovascular events, and sudden death.[9]

Bradycardia has been associated with thalidomide therapy in some patients, although symptoms may be managed by a reduction in dose.[10,11] See also under Effects on the Endocrine System, p. 870.1.

Effects on the endocrine system. Amenorrhoea has been reported[1,2] in women taking thalidomide for severe dermatological conditions; menses resumed 2 to 3 months after stopping thalidomide.[2]

Hypothyroidism has been associated with thalidomide use in patients with multiple myeloma,[3,4] and it was suggested[3] that some adverse effects of thalidomide, such as bradycardia and constipation, may be manifestations of hypothyroidism.

Severe hyperglycaemia has been reported[5] in a 70-year-old man 4 weeks after starting thalidomide for multiple myeloma. Plasma-glucose concentrations returned to normal after treatment with insulin and an oral antidiabetic and he continued with thalidomide therapy.

5. Pathak RD, *et al.* Thalidomide-associated hyperglycemia and diabetes: case report and review of literature. *Diabetes Care* 2003; 26: 1322–3.

Effects on the gastrointestinal tract. Bowel perforation requiring surgery has been reported[1] in 3 patients taking thalidomide for malignant neoplasms. A fourth case of acute abdominal pain and suspected bowel perforation is also described but the patient died of a cardiac arrest before surgery.

1. McClay H, Cervi P. Thalidomide and bowel perforation: four cases in one hospital. *Br J Haematol* 2008; 140: 360–1.

Effects on the liver. Hepatitis has been reported[1] in a 58-year-old woman taking thalidomide for end-stage plasma cell leukaemia. In another report of hepatotoxicity,[2] a 76-year-old woman with multiple myeloma being treated with thalidomide and dexamethasone developed jaundice and acute increases in liver enzymes, which returned to normal when thalidomide was stopped. Fatal fulminant hepatic failure with encephalopathy that appeared to be associated with thalidomide developed in a 64-year-old woman being treated for multiple myeloma.[3]

3. Hamadani M, *et al.* Thalidomide-induced fulminant hepatic failure. *Mayo Clin Proc* 2007; 82: 638.

Effects on the lungs. Interstitial pneumonitis,[1] including interstitial pneumonia,[2] has been reported in patients taking *thalidomide* for multiple myeloma. There have also been reports of dyspnoea in women taking thalidomide for ovarian cancer; resolution of symptoms occurred on drug withdrawal and some patients were able to continue therapy when reintroduced at a reduced dose.[3]

There have also been reports of respiratory toxicity associated with *pomalidomide* therapy for multiple myeloma.[4] One patient abruptly developed dyspnoea, pyrexia, and chills about 4 months after starting pomalidomide plus dexamethasone treatment; lung infiltrates consistent with pneumonitis were noted. Pomalidomide was stopped and symptoms resolved quickly with corticosteroid treatment. Treatment was later restarted with a reduced dose of pomalidomide without recurrence of symptoms. Another patient developed dyspnoea 16 months after starting pomalidomide plus dexamethasone treatment. Symptoms resolved when treatment was withdrawn but recurred with 2 further rechallenges, one using a lower dose of pomalidomide.

1. Onozawa M, *et al.* Thalidomide-induced interstitial pneumonitis. *J Clin Oncol* 2005; 23: 2425–6.

4. Geyer BL, *et al.* Acute lung toxicity related to pomalidomide. *Chest* 2011; 140: 529–33.

Effects on mental function. Symptoms of dementia appeared in a patient who had been taking thalidomide for about 2 months for the treatment of multiple myeloma.[1] Dementia later resolved completely within 48 hours of stopping thalidomide.

1. Morgan AE, *et al.* Reversible dementia due to thalidomide therapy for multiple myeloma. *N Engl J Med* 2003; 348: 1821–2.

Effects on the nervous system. Peripheral neuropathy is a major adverse effect of thalidomide therapy, although the underlying mechanisms, risk factors, and optimum management are still not clear.[1] One prospective study[2] in patients with cutaneous lupus erythematosus or SLE concluded that the cumulative dose of thalidomide had no effect on the incidence of peripheral neuropathy, whereas results from a retrospective study[3] in patients with SLE or multiple myeloma showed that the risk of developing neurotoxicity as well as severity of symptoms did correlate with cumulative dose. However, the latter study[3] examined a range of doses and found that this correlation was most significant at cumulative doses over 20 g but either absent or equivocal at lower doses, which might explain the discrepancies in results between studies using different doses. Two further studies[4,5] in patients with multiple myeloma concluded that neurotoxicity was associated with duration of treatment of greater than 6 to 12 months rather than dose-intensity or total cumulative dose. Conversely, another study,[6] also in multiple myeloma patients, found electrophysiologic evidence of peripheral neuropathy in two-thirds of patients as early as 4 months from the start of treatment, and in all of them by 7 months; many patients also had clinical symptoms.

Central neurotoxicity has also been reported[7] in a patient who developed encephalopathy after receiving thalidomide monotherapy for multiple myeloma over 21 months.

7. Sohlbach K, *et al.* Encephalopathy in a patient after long-term treatment with thalidomide. *J Clin Oncol* 2006; 24: 4942–4.

Effects on sexual function. Dose-related sexual dysfunction, including loss of libido, loss of penile rigidity, and premature ejaculation, was associated with thalidomide use in 2 male patients.[1] Erectile dysfunction has been reported[2] in 6 patients within 4 weeks of starting thalidomide therapy.

2. Murphy PT, O'Donnell JR. Thalidomide induced impotence in male hematology patients: a common but ignored complication? *Haematologica* 2007; 92: 1440.

Effects on the skin. Toxic epidermal necrolysis has been reported[1] in a 62-year-old woman about 5 weeks after starting thalidomide for the treatment of a glioblastoma. Although she was taking several other drugs, including dexamethasone, thalidomide was considered responsible since its use had the closest temporal relationship to the adverse effect. Toxic epidermal necrolysis has also been reported[2] in a 64-year-old patient 24 days after starting thalidomide and dexamethasone for myeloma. It was suggested that there might be an adverse interaction between thalidomide and dexamethasone. Thalidomide had previously been studied[3] for the *treatment* of toxic epidermal necrolysis, but the study was prematurely terminated because of significantly higher mortality in the thalidomide group; the causes of death were those usually attributed to the disease itself. Thalidomide had been chosen as an investigative drug because it is a potent inhibitor of TNF-α, which has been implicated in the pathogenesis of this condition. However, the authors noted that there was a tendency for plasma concentrations of TNF-α to increase after treatment with thalidomide compared with the placebo group, and postulated that thalidomide might paradoxically enhance TNF-α production in these patients.

Exacerbation of psoriasis by thalidomide, reported, in 2 patients might also have been due to an increase in TNF-α production.[4,5]

In an open-label study in 87 patients with multiple myeloma[6] comparing thalidomide given as monotherapy or given with dexamethasone, minor to moderate skin eruptions were noted in about 45% of patients in each group, and included morbilliform, seborrhoeic, maculopapular, and non-specific dermatitis. Three patients receiving thalidomide and dexamethasone developed severe skin reactions (exfoliative erythroderma, erythema multiforme, or toxic epidermal necrolysis) that required treatment to be stopped.

Migraine. Migraine attacks were associated with thalidomide use in a 36-year-old man.[1]

1. García-Albea E, *et al.* Jaqueca típica y talidomida. *Med Clin (Barc)* 1993; 100: 557.

Mutagenicity. Reports of the birth of 3 malformed infants to parents who had themselves been exposed to thalidomide *in utero*[1,2] provoked fears that thalidomide may be a mutagen. However, the limb malformations seen in the infants were not typical of mutagenesis[3] and the teratogenic effect of thalidomide was likely to be associated with interference with angiogenesis in the fetus rather than mutation.[4] Review[5] of the evidence up to 1998 concluded that there was no scientific basis for the hypothesis that thalidomide is a mutagen and birth defects appeared to be no more common in children born to thalidomide-affected parents than in the population as a whole. Further support for the counter-argument came in 2002 from a Swedish retrospective study in which malformations or functional anomalies consistent with thalidomide embryopathy were not found in 64 children born to 34 parents with thalidomide embryopathy.[6]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies thalidomide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

The sedative activity of barbiturates, alcohol, chlorpromazine, and reserpine has been reported to be enhanced by thalidomide. Use with other drugs that have the potential to cause peripheral neuropathy should be undertaken cautiously.

Antineoplastics. There may be an increased risk of deep-vein thrombosis from the use of thalidomide with *doxorubicin* (see p. 785.3). See also Effects on the Cardiovascular System, p. 869.3.

For the effect of thalidomide on the metabolism of *irinotecan*, see under Interactions of Irinotecan, p. 814.2.

Corticosteroids. For reference to a possible interaction between thalidomide and *dexamethasone*, see under Effects on the Skin, above.

Hormonal contraceptives. Thalidomide does *not* alter the metabolism of ethinylestradiol and norethisterone,[1,2] and so the efficacy of oral contraceptives should not be affected by thalidomide therapy. Nevertheless, 2 reliable forms of contraception should always be used simultaneously when taking thalidomide (see Adverse Effects and Precautions, p. 869.2), bearing in mind that the reliability of hormonal contraceptives may be compromised by drugs other than thalidomide (see p. 2242.3).

1. Trapnell CB, *et al.* Thalidomide does not alter the pharmacokinetics of ethinyl estradiol and norethindrone. *Clin Pharmacol Ther* 1998; 64: 597–602.
2. Scheffler MR, *et al.* Thalidomide does not alter estrogen-progesterone hormone single-dose pharmacokinetics. *Clin Pharmacol Ther* 1999; 65: 483–90.

Interferons. Neurological toxicity was reported[1] in 4 of 13 patients in a phase II study of thalidomide and interferon alfa-2a used together in the treatment of renal cell carcinoma. It was suggested that the membrane-destabilising properties of both drugs could have produced such serious toxicity since it exceeded that expected from either drug alone. A fifth patient had a Stevens-Johnson reaction that was also attributed to the combination. The study was halted as a result of these serious adverse effects.

Severe bone marrow depression has been reported[2] in a patient given thalidomide with peginterferon alfa-2b that was also attributed to the combined effect of the 2 drugs.

1. Nathan PD, *et al.* Unexpected toxicity of combination thalidomide and interferon alfa-2a treatment in metastatic renal cell carcinoma. *J Clin Oncol* 2002; **20**: 1429–30.
2. Gómez-Rangel JD, *et al.* Pegylated-interferon induced severe bone marrow hypoplasia in a patient with multiple myeloma receiving thalidomide. *Am J Hematol* 2003; **74**: 290–1.

Pharmacokinetics

Thalidomide is slowly absorbed from the gastrointestinal tract; peak plasma concentrations occur within about 3 to 6 hours of an oral dose. It crosses the placenta and is distributed into the semen. The exact metabolic route and fate of thalidomide is unknown, although it appears to undergo non-enzymatic hydrolysis in plasma. The elimination half-life is about 5 to 7 hours.

Thiotepa *(BAN, rINN)*

NSC-6396; TESPA; Thiophosphamide; Thiotépa; Thiotepum; Tiotepa; Triethylenethiophosphoramide; TSPA; WR-45312; Tiotrena.

Phosphorothioic tri(ethyleneamide); Tris(aziridin-1-yl)phosphine sulphide.

$C_6H_{12}N_3PS$=189.2

CAS — 52-24-4.

ATC — L01AC01.

ATC Vet — QL01AC01.

UNII — 905Z5W3GKH.

Pharmacopoeias. In *Br., Chin., Fr., Jpn,* and *US.*

BP 2014: (Thiotepa). Fine white, crystalline flakes. M.p. 52 degrees to 57 degrees. Freely soluble in water, in alcohol, and in chloroform. Store at 2 degrees to 8 degrees. At higher temperatures it polymerises and becomes inactive.

USP 36: (Thiotepa). Fine white, crystalline flakes, having a faint odour. M.p. 52 degrees to 57 degrees. Soluble 1 in 13 of water, 1 in about 8 of alcohol, 1 in about 2 of chloroform, and 1 in about 4 of ether. Store at 2 degrees to 8 degrees in airtight containers. Protect from light.

Incompatibility. Lyophilised thiotepa 1 mg/mL in glucose 5% was incompatible when mixed with solutions of cisplatin or minocycline hydrochloride.[1]

1. Trissel LA, Martinez JF. Compatibility of thiotepa (lyophilized) with selected drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1996; **53**: 1041–5.

Stability. A solution of a lyophilised thiotepa preparation 500 micrograms/mL in glucose 5% was considered to be stable (less than 10% loss of thiotepa) for 8 hours at both 4 degrees and 23 degrees.[1] After 24 hours losses ranged between about 10 and 17%. A higher thiotepa concentration (5 mg/mL) was stable for 3 days at 23 degrees and 14 days at 4 degrees. Another study found that solutions containing 1 or 3 mg/mL of thiotepa in sodium chloride 0.9% were stable for 24 hours at 25 degrees and 48 hours at 8 degrees, but solutions containing 0.5% thiotepa needed to be used immediately.[2]

1. Xu QA, *et al.* Stability of thiotepa (lyophilized) in 5% dextrose injection at 4 and 23 degreesC. *Am J Health-Syst Pharm* 1996; **53**: 2728–30.
2. Murray KM, *et al.* Stability of thiotepa (lyophilized) in 0.9% sodium chloride injection. *Am J Health-Syst Pharm* 1997; **54**: 2588–91.

Uses and Administration

Thiotepa is an ethyleneimine compound whose antineoplastic effect is related to its alkylating action. It has generally been replaced by cyclophosphamide (p. 771.1) or other drugs. It is not a vesicant and may be given by all parenteral routes, as well as directly into tumour masses.

Thiotepa has been given parenterally in the palliative treatment of various solid tumours, including those of breast and ovary (p. 702.1 and p. 711.2). It may also be given intravenously with other antineoplastic drugs, with or without total body irradiation, as a conditioning therapy before autologous or allogeneic haematopoietic progenitor cell transplantation (HPCT). Instillations of thiotepa may be used in the adjuvant treatment of superficial tumours of the bladder (p. 700.2) and in the control of malignant effusions (p. 700.1). It has also been given intrathecally to patients with malignant meningeal disease, and has been used, in the form of eye drops, as an adjunct to the surgical removal of pterygium, to prevent recurrence (see p. 831.2). Thiotepa has also been used in the treatment of condylomata acuminata (p. 1689.3).

Thiotepa is given in a variety of dosage schedules for the **palliative treatment** of various solid tumours. In general, initial doses to suit the individual patient are followed by maintenance doses given at intervals of 1 to 4 weeks. Blood counts are recommended before and during therapy and should continue for at least 3 weeks after stopping. Thiotepa should not be given if the white cell or platelet counts fall below acceptable levels (see also Bone-marrow Depression, p. 730.3) and treatment should be stopped if the white cell count falls rapidly. Dosage should be reduced in patients with lesser degrees of leucopenia.

Intramuscular and intravenous dosage regimens vary considerably; several regimens have used courses of 15 mg daily for 4 days. In the USA a licensed dose of 300 to 400 micrograms/kg may be given intravenously at 1- to 4-week intervals. A solution containing 1 mg/mL in sterile water has been tried intrathecally in doses of up to 10 mg given on alternate days, for up to 4 doses (see also Administration, below).

The following doses, given by intravenous infusion over 2 to 4 hours, are recommended for use as **conditioning therapy:**

- for haematological diseases:
  - 125 to 300 mg/m² daily, given as a single infusion, for 2 to 4 days before *autologous* HPCT to a maximum cumulative dose of 900 mg/m² for the entire conditioning treatment, *or*
  - 185 to 481 mg/m² daily, given in one or two infusions, for 1 to 3 days before *allogeneic* HPCT to a maximum cumulative dose of 555 mg/m² for the entire conditioning treatment
- for solid tumours:
  - 120 to 250 mg/m² daily, given in one or two infusions, for 2 to 5 days before autologous HPCT to a maximum cumulative dose of 800 mg/m² for the entire conditioning treatment

For doses of thiotepa given as conditioning therapy in children, see below.

In the treatment of **bladder cancer** thiotepa in doses up to 60 mg may be instilled in 30 to 60 mL of sterile water or sodium chloride 0.9% into the bladder of a patient previously dehydrated for 8 to 12 hours, and retained if possible for 2 hours. The instillation may be repeated weekly for up to 4 weeks. Similar instillations have been given at intervals of 1 to 2 weeks, for up to 8 instillations in the prophylaxis of recurrence after surgical removal of bladder cancer. Single doses of 90 mg in 100 mL of sterile water have also been used prophylactically. For **malignant effusions**, doses of up to 60 mg of thiotepa in 20 to 60 mL of sterile water may be instilled after aspiration; in the USA the licensed dose is 600 to 800 micrograms/kg, a dose similar to that suggested for injection directly into tumours. Thiotepa for local use may be mixed with solutions of procaine and adrenaline.

Thiotepa 0.05% in sterile Ringer's solution has been instilled as eye drops every 3 hours for up to 6 weeks after surgical removal of **pterygium** in order to reduce the likelihood of recurrence.

A dose of 60 mg in a gel has been instilled weekly into the urethra for the treatment of **condylomata acuminata** (genital warts). Topical application of thiotepa has also been used for condylomata.

Administration. Neurotoxicity of intrathecal chemotherapy has been variously attributed to preservatives, volume, osmolality, and pH of the preparation; common practice is to prepare intrathecal chemotherapy with preservative-free diluent and limit the volume of the final solution, usually to 5 mL. A study evaluated pH and osmolality for thiotepa intrathecal solutions (in various diluents) at concentrations commonly used in practice: 1, 2, and 5 mg/mL. The concentration of thiotepa or the diluent used did not significantly change the pH of the injection; however, osmolality was generally lower than the physiological range of the CSF.[1]

1. de Lemos ML, *et al.* Evaluation of osmolality and pH of various concentrations of methotrexate, cytarabine, and thiotepa prepared in normal saline, sterile water for injection, and lactated Ringer's solution for intrathecal administration. *J Oncol Pharm Pract* 2009; **15**: 45–52.

Administration in children. Thiotepa may be given with other antineoplastic drugs, with or without total body irradiation, to children as a conditioning therapy before autologous or allogeneic haematopoietic progenitor cell transplantation (HPCT). The following doses, given by intravenous infusion over 2 to 4 hours, are recommended:

- for haematological diseases: 125 to 250 mg/m² daily, given in one or two infusions, for 1 to 3 days before *allogeneic* HPCT to a maximum cumulative dose of 375 mg/m² for the entire conditioning treatment
- for solid tumours: 150 to 350 mg/m² daily, given as a single infusion, for 2 to 3 days before *autologous* HPCT to a maximum cumulative dose of 1050 mg/m² for the entire conditioning treatment

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bone-marrow depression may be delayed; the nadir of white cell and platelet counts may occur up to 30 days after thiotepa has been stopped. Bone-marrow depression has been reported after intravesical as well as parenteral use, and has occasionally been prolonged or fatal.

Gastrointestinal disturbances, fatigue, weakness, headache and dizziness, hypersensitivity reactions, blurred vision and conjunctivitis may occur. Amenorrhoea and impaired fertility have also been reported. Local irritation, and rarely frank chemical or haemorrhagic cystitis may follow intravesical instillation. Depigmentation of periorbital skin has occurred after the use of thiotepa eye drops. As with other alkylating agents, thiotepa is potentially mutagenic, teratogenic, and carcinogenic.

Thiotepa should be given with extreme care, if at all, to patients with pre-existing impairment of hepatic, renal, or bone-marrow function.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies thiotepa as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Pharmacokinetics

The absorption of thiotepa from the gastrointestinal tract is incomplete and unreliable; variable absorption also occurs from intramuscular injection sites. Absorption through serous membranes such as the bladder and pleura occurs to some extent. After intravenous doses it is rapidly cleared from plasma, with an elimination half-life of about 2.4 hours. It is extensively metabolised: triethylenephosphoramide (TEPA), the primary metabolite, and some of the other metabolites have cytotoxic activity and are eliminated more slowly than the parent compound. It is excreted in the urine: less than 2% of a dose is reported to be present as unchanged drug or its primary metabolite.

CAS — 154-42-7 (anhydrous tioguanine); 5580-03-0 (tioguanine hemihydrate).

ATC — L01BB03.

ATC Vet — QL01BB03.

UNII — FTK8U1GZNX (thioguanine); WIX31ZPX66 (anhydrous thioguanine).

Pharmacopoeias. In *Br., Chin.,* and *US.*

BP 2014: (Tioguanine). A pale yellow, crystalline powder. Practically insoluble in water, in alcohol, and in chloroform; dissolves in dilute solutions of alkali hydroxides.

USP 36: (Thioguanine). It is anhydrous or contains one-half molecule of water of hydration. A pale yellow, odourless or practically odourless, crystalline powder. Insoluble in water and in chloroform; soluble 1 in 7700 of alcohol; freely

soluble in dilute solutions of alkali hydroxides. Store in airtight containers.

Uses and Administration

Tioguanine is an analogue of the naturally occurring purine, guanine, and is an antimetabolite antineoplastic with actions and uses similar to those of mercaptopurine (p. 821.1). It appears to cause fewer gastrointestinal reactions but cross-resistance exists so that patients who do not respond to one are unlikely to respond to the other.

Tioguanine is given *orally*, usually with other antineoplastics, in the induction and consolidation of remissions in acute myeloid leukaemia (p. 693.1). It has also been used in other malignancies including acute lymphoblastic leukaemia (p. 692.3) and chronic myeloid leukaemia (p. 694.2). *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Doses of between 100 and 200 mg/m² daily have been given at various stages of treatment for short term cycles. A dose of 2 mg/kg daily increased after 4 weeks to 3 mg/kg daily if there is no response and toxicity allows, may be given in those rare cases when single agent therapy is considered appropriate.

Blood counts should be made frequently, particularly during induction and when tioguanine is given with other antineoplastics. Therapy should be withdrawn at the first sign of severe bone-marrow depression. Tioguanine is not recommended for maintenance or similar long-term continuous therapy because of the high risk of hepatotoxicity (see Effects on the Liver, below).

Tioguanine has been given *intravenously* as the sodium salt.

Administration in children. Tioguanine is given orally in the treatment of acute childhood leukaemias in the same doses as those used for adults (see Uses and Administration, above).

Administration in the elderly. UK licensed product information states that tioguanine has been used in elderly patients with acute leukaemia at the same doses as those used for younger patients, and that there are no dosage recommendations based on age alone. US licensed product information states that dose selection for elderly patients should be made cautiously, in view of the greater possibility of decreased hepatic, renal, or cardiac function, and suggests that initial doses be at the lower end of the dosing range.

Administration in hepatic or renal impairment. UK licensed product information states that reduced doses should be considered in patients with hepatic or renal impairment, but makes no specific dose recommendations. US licensed product information makes no recommendations for dose adjustment in hepatic or renal impairment, aside from advising caution in elderly patients who might have reduced hepatic or renal function (see Administration in the Elderly, above).

Psoriasis. A report of the use of tioguanine, in oral doses ranging from 20 mg twice weekly to 120 mg daily, in the management of patients with refractory psoriasis.[1] Dramatic improvement occurred in 14 of 18 patients, but a further 2 were unable to tolerate the drug. Myelosuppression was the principal toxic effect and it was suggested that thiopurine methyltransferase activity could be measured as a basis to determine initial dosage and the risk of toxicity. For the conventional management of psoriasis see p. 1688.1.

1. Mason C, Krueger GG. Thioguanine for refractory psoriasis. *J Am Acad Dermatol* 2001; **44**: 67–72.

Adverse Effects, Treatment, and Precautions

As for Mercaptopurine, p. 821.2.

In some patients, gastrointestinal reactions are reported to be less frequent than with mercaptopurine.

Effects on the blood. For the view that it may be possible to predict those individuals likely to have severe bone-marrow depression with tioguanine based on measurement of the activity of thiopurine methyltransferase or the concentration of tioguanine nucleotide, see under Azathioprine, p. 1946.2.

Effects on the liver. The use of tioguanine has been limited by reports of hepatic veno-occlusive disease attributed to the drug.[1-4] The manufacturer (*GlaxoSmithKline*) has stated that, in most cases, liver toxicity is reversible upon withdrawal of chemotherapy. A comparison with mercaptopurine in the maintenance treatment of children with acute lymphoblastic leukaemia found that of 95 patients who developed veno-occlusive disease, 82 were receiving tioguanine, representing about 11% of all patients assigned to the drug.[5] In addition, although tioguanine was associated with fewer CNS relapses, patients in the tioguanine arm were more likely to develop fatal infections.

Centrilobular hepatic necrosis has also been reported; reports are confounded by the use of high doses of tioguanine, other antineoplastics, oral contraceptives, and chronic alcohol abuse.

Handling and disposal. For reference to a method for the destruction of tioguanine in wastes, see Mercaptopurine, p. 821.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies tioguanine as probably not porphyrinogenic: it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

Unlike mercaptopurine (p. 821.3), normal doses of tioguanine may be used with allopurinol.

Several cases of portal hypertension with hepatic nodular regenerative hyperplasia have been reported in patients who received tioguanine with busulfan (see p. 756.1).

It has been suggested that daunorubicin might enhance the hepatotoxicity of tioguanine (see p. 779.3).

Pharmacokinetics

Tioguanine is incompletely and variably absorbed from the gastrointestinal tract; on average about 30% of a dose is absorbed after oral doses. It is rapidly activated in the body by intracellular conversion to its nucleotide, thioguanylic acid and its thioguanosine phosphate derivatives. With repeated doses increasing amounts of the nucleotide are incorporated into DNA. Very little unchanged tioguanine has been detected circulating in the blood but the half-life of the nucleotide in the tissues is prolonged. Tioguanine is inactivated mainly by methylation to aminomethylthiopurine; small amounts are deaminated to thioxanthine, and may go on to be oxidised by xanthine oxidase to thiouric acid, but inactivation is essentially independent of xanthine oxidase and is not affected by inhibition of the enzyme.

It is excreted in the urine almost entirely as metabolites; only negligible amounts of tioguanine have been detected. Tioguanine does not appear to cross the blood-brain barrier to a significant extent; very little is found in CSF after normal clinical doses. It crosses the placenta.

Tirapazamine *(USAN, rINN)*

SR-4233; Tirapazamina; Tirapazaminum; Win-59075; Тирапазамин.
3-Amino-1,2,4-benzotriazine 1,4-dioxide.
$C_7H_6N_4O_2$=178.2
CAS — 27314-97-2.
UNII — 1UD32YRS9G.

Profile

Tirapazamine is reported to be reduced in hypoxic cells to an active anion that causes DNA strand breaks. It sensitises hypoxic tumour cells to the cytotoxic activity of other drugs. It is under investigation for its cytotoxic actions, alone or with cisplatin or radiotherapy. Adverse effects reported with tirapazamine include nausea and vomiting, diarrhoea, rashes, muscle cramps and fatigue; myelosuppression is said to be rare.

Tivozanib *(USAN, rINN)*

AV-951 (tivozanib hydrochloride); KI-8951; Tivozanibum; Тивозаниб.
1-[2-Chloro-4-[(6,7-dimethoxyquinolin-4-yl)oxy]phenyl]-3-(5-methyl-1,2-oxazol-3-yl)urea.
$C_{22}H_{19}ClN_4O_5$=454.9
CAS — 475108-18-0.
UNII — 172030934T.

Profile

Tivozanib is an orally active tyrosine kinase inhibitor that targets vascular epidermal growth factor receptors 1, 2, and 3. It is under investigation for the treatment of renal cell carcinoma and other solid tumours.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

Topotecan Hydrochloride

(BANM, USAN, pINNM)

Hidrocloruro de topotecán; Nogitecan Hydrochloride; SKF 104864A; SKFS-104864-A; Topotecán, hidrocloruro de Topotécane, Chlorhydrate de; Topotecani Hydrochloridum Topotekaanihydrokloridi; Topotekanhydroklorid; Топотекана Гидрохлорид.
(*S*)-10-Dimethylaminomethyl-4-ethyl-4,9-dihydroxy-1*H*-pyrano[3′,4′:6,7]indolizino[1,2*b*]quinoline-3,14(4*H*,12*H*)-dione hydrochloride.
$C_{23}H_{23}N_3O_5$,HCl=457.9
CAS — 123948-87-8 (topotecan); 119413-54-6 (topotecan hydrochloride).
ATC — L01XX17.
ATC Vet — QL01XX17.
UNII — 956S425ZCY.

Incompatibility. Topotecan hydrochloride was found to degrade to 88.7% of its original concentration over 24 hours when mixed with ticarcillin sodium or potassium clavulanate. It was also found to be incompatible with dexamethasone sodium phosphate and fluorouracil.

When mixed with mitomycin solution an immediate colour change took place and concentrations of mitomycin fell by 15 to 20% over 4 hours. The pH of the mixtures remained constant at 3.3 to 3.5.

1. Mayron D, Gennaro AR. Stability and compatibility of topotecan hydrochloride with selected drugs. *Am J Health-Syst Pharm* 1999; 56: 875–81.

Uses and Administration

Like irinotecan (p. 812.3), topotecan is a semisynthetic derivative of the alkaloid camptothecin that exerts its antineoplastic activity by inhibition of topoisomerase I. It is used in the treatment of metastatic carcinoma of the ovary refractory to other therapy (see p. 711.2) and in relapsed small cell lung cancer (p. 710.2) after standard therapy. Topotecan is given with cisplatin in the treatment of metastatic, recurrent, or persistent carcinoma of the cervix (p. 704.2) that is not amenable to curative treatment with surgery and/or radiation therapy. Topotecan is also under investigation in the management of myelodysplastic syndromes.

Topotecan is given as the hydrochloride but doses are expressed in terms of the base. Topotecan hydrochloride 1.09 mg is equivalent to about 1 mg of topotecan. Topotecan may be given orally or intravenously. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* When given by intravenous infusion, topotecan is diluted in sodium chloride 0.9% or glucose 5%; a final concentration of between 25 and 50 micrograms/mL is specified in the UK.

In **ovarian** and **small cell lung cancer**, topotecan hydrochloride may be given *intravenously* in an initial dose equivalent to topotecan 1.5 mg/m², infused over 30 minutes, on days 1 to 5 of a 21-day course. A minimum of 4 courses should be given, in the absence of tumour progression, and provided that blood counts and haemoglobin have recovered adequately (see also Bone-marrow Depression, p. 730.3). If severe neutropenia occurs in any course, or if the platelet count falls below 25 000 cells/mm³, the dose in the subsequent courses may be reduced by 250 micrograms/m² to 1.25 mg/m² daily, and subsequently to 1 mg/m² daily if necessary. Alternatively, in the event of severe neutropenia, a granulocyte colony-stimulating factor may be given from day 6 of the course, 24 hours after topotecan dosage is complete. If severe toxicity recurs once the dose has been reduced to 1 mg/m² withdrawal of topotecan may be required. Dosage should also be reduced in patients with renal impairment (see below).

Topotecan may also be given *orally* for small cell lung cancer. The recommended dose is 2.3 mg/m² once daily for 5 consecutive days, repeated every 21 days. If neutropenia occurs, or if the platelet count falls below 25 000 cells/mm³, or for patients with severe diarrhoea, the daily dose should be reduced by 400 micrograms/m²(to 1.9 mg/m² daily, and subsequently to 1.5 mg/m² daily if necessary) for subsequent courses.

In **cervical cancer**, topotecan is given in an intravenous dose of 750 micrograms/m², infused over 30 minutes, on days 1, 2, and 3 of a 21-day course; cisplatin 50 mg/m² is given by intravenous infusion after topotecan on day 1. Dosage adjustments for subsequent courses are specific for each drug; for cisplatin, see p. 766.2. If severe neutropenia occurs, or if the platelet count falls below 25 000 cells/mm³, the topotecan dose should be reduced to 600 micrograms/m², and subsequently to 450 micrograms/m² if necessary. Alternatively, in the event of severe febrile neutropenia, granulocyte colony-stimulating factor may be given from day 4 of the course, 24 hours after completion of the topotecan infusion.

Administration. In an attempt to reduce haematological toxicity, various schedule modifications of topotecan have been investigated, one of the most commonly studied being a regimen of intravenous topotecan 4 mg/m² over 30 minutes, once weekly for 3 weeks, followed by a week of rest.[1] A pharmacokinetic study found this dose to be well tolerated in patients with advanced solid tumours, although clinical efficacy was not assessed.[1] A study compared the conventional schedule of topotecan (see Uses and Administration, above), at a reduced dose of 1.25 mg/m² on days 1 to 5 of a 21-day cycle, with a weekly schedule of 4 mg/m² on days 1, 8 and 15 of a 28-day cycle in patients with platinum-resistant ovarian cancer.[2] Haematological toxicity was less with the weekly regimen. Slightly lower efficacy in terms of response rates and progression-free survival was seen with the weekly regimen, although these differences were not statistically significant, and there was no notable differences in overall survival between the two regimens. The authors concluded that weekly topotecan is a viable treatment option in this setting, allowing therapy to be geared towards goals of management.[2]

Administration in renal impairment. Licensed product information for *intravenous* topotecan recommends the following for patients with **ovarian** or **small cell lung cancer** according to creatinine clearance (CC):
- mild renal impairment (CC 40 to 60 mL/minute): no dosage adjustment
- moderate renal impairment (CC 20 to 39 mL/minute): 750 micrograms/m² daily for 5 consecutive days

For patients with small cell lung cancer given *oral* topotecan, the following is suggested:
- mild renal impairment (CC 50 to 80 mL/minute): no dosage adjustment
- moderate renal impairment (CC 30 to 49 mL/minute): 1.8 mg/m² once daily for 5 consecutive days

Data are insufficient to make dose recommendations in patients with severe renal impairment.

In patients with **cervical cancer**, treatment with topotecan and cisplatin should only be started in those with a serum creatinine of 1.5 mg or less per 100 mL.

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Neutropenia is very common with topotecan and is usually dose-limiting. The nadir of white cell count usually occurs about 9 to 12 days after a dose. Febrile neutropenia, sepsis, and neutropenic colitis can occur; fatalities have been reported. Thrombocytopenia, anaemia, and leucopenia also occur commonly. Topotecan should not be given to those patients with pre-existing bone-marrow depression, and blood counts should be monitored regularly. Gastrointestinal disturbances and anorexia are also common with topotecan, and may be severe; oral topotecan is associated with severe diarrhoea.

Interstitial lung disease has been reported, and can be fatal; underlying risk factors include pulmonary fibrosis, lung cancer, thoracic radiation, and use of other drugs toxic to the lungs or of colony-stimulating factors. Patients should be monitored for signs and symptoms such as cough, fever, dyspnoea, or hypoxia, and treatment should be stopped if interstitial lung disease is suspected.

Other adverse effects include fatigue and weakness, alopecia, malaise, pruritus, pyrexia, and hyperbilirubinaemia. Hypersensitivity reactions including rashes have been reported; anaphylaxis, angioedema, and urticaria may occur rarely.

Licensed product information recommends that topotecan should not be given to patients with severe hepatic or renal impairment, due to a lack of data in these patients. Its use in breast feeding is contra-indicated for the same reason. Topotecan has been reported to produce fetal death and malformations in *animals*.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies topotecan as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/08/11)

Interactions

For a report of topotecan reducing the clearance of docetaxel, see Antineoplastics, p. 782.2.

Greater myelosuppression is seen when topotecan is used with other cytotoxic drugs, which may require dosage reductions of either drug. However, with platinum drugs, there is a sequence-dependent interaction: giving a platinum drug on the first day of topotecan dosage requires lower doses of each, compared with giving it on the fifth day.

Granulocyte colony-stimulating factor can prolong the duration of neutropenia if given with topotecan, so if used, it should not be started until, 24 hours after topotecan dosage is complete.

Ciclosporin has been reported to increase exposure to topotecan.

Pharmacokinetics

Topotecan is rapidly absorbed after oral doses; peak plasma concentrations occur after about 1 to 2 hours. The oral bioavailability is about 40%. Food does not appreciably affect topotecan pharmacokinetics. Topotecan is widely distributed after intravenous doses. Plasma protein binding is about 35%. The drug undergoes reversible hydrolysis of the lactone ring to the inactive hydroxy acid form; only small amounts are demethylated in the liver. A significant proportion of a dose is excreted in urine. The terminal half-life has been reported to be 2 to 3 hours for the intravenous formulation, and 3 to 6 hours for the oral formulation.

Toremifene Citrate (BANM, USAN, rINNM) ⊗

Citrato de toremifeno; FC-1157a; Toremifen Sitrat; Torémifène, Citrate de; Toremifeni Citras; Toremifeno, citrato de; Торемифена Цитрат.

2-[*p*-[(*Z*)-4-Chloro-1,2-diphenyl-1-butenyl]phenoxy]-*N*,*N*-dimethylethylamine citrate.

$C_{26}H_{28}ClNO.C_6H_8O_7$=598.1

CAS — 89778-26-7 (toremifene); 89778-27-8 (toremifene citrate).

ATC — L02BA02.

ATC Vet — QL02BA02.

UNII — 2498Y7B3QT.

Uses and Administration

Toremifene is a selective oestrogen receptor modulator with properties similar to those of tamoxifen (p. 860.2). It is used in the treatment of metastatic breast cancer (p. 702.1) in postmenopausal women with oestrogen-receptor positive tumours.

Toremifene is given orally as the citrate, but doses are calculated in terms of the base; 88.4 mg of toremifene citrate is equivalent to about 60 mg of toremifene. A dose of toremifene 60 mg once daily is used.

Toremifene is also under investigation for the prevention of prostate cancer in men with high-grade intraepithelial neoplasia, as well as for the treatment of adverse effects related to androgen deprivation therapy.

Mastalgia. For reports of efficacy with toremifene in the management of mastalgia, see under Danazol, p. 2265.1.

Adverse Effects and Precautions

As for Tamoxifen Citrate, p. 861.2. Increased sweating occurs very commonly with toremifene.

Use of toremifene is contra-indicated in patients with pre-existing endometrial hyperplasia, or in those with severe thromboembolic disease or severe hepatic impairment. Toremifene has been shown to prolong the QT interval in a dose-dependent manner. Its use is therefore contra-indicated in patients with QT prolongation, electrolyte disturbances (especially uncorrected hypokalaemia), or in those with bradycardia, heart failure, or a history of arrhythmias. Toremifene should also be used with caution in those with conditions such as myocardial ischaemia, as treatment may lead to an increased risk for ventricular arrhythmias such as torsade de pointes and cardiac arrest; if cardiac arrhythmia occurs during therapy, toremifene should be stopped and an ECG should be performed. Patients with bone metastases should be monitored for signs and symptoms of hypercalcaemia.

Breast feeding. Licensed product information states that toremifene is excreted in the milk of *rats*, and that bodyweight gain of the rat offspring was seen during lactation. It is unknown whether the drug is excreted in human milk, and use is contra-indicated during breast feeding. It has been suggested[1] that breast feeding be withheld for a minimum of 25 to 30 days after a dose.

1. *et al.*, eds. *Drugs during pregnancy and lactation: treatment options and risk assessment.* 2nd ed. London: Elsevier, 2007.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies toremifene as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Interactions

Toremifene is metabolised by cytochrome P450 isoenzyme CYP3A4, and potent enzyme-inducing drugs such as phenytoin, phenobarbital and carbamazepine, can increase toremifene metabolism, thereby lowering the serum concentration; dose adjustment of toremifene may be needed. Conversely, azole antifungals and macrolide antibacterials may theoretically inhibit toremifene metabolism by inhibiting the isoenzyme.

Toremifene should not be used with drugs that prolong the QT interval, such as antiarrhythmics, antipsychotics (such as phenothiazines, pimozide, sertindole, haloperidol, and sultopride), certain antimicrobials (such as moxifloxacin, erythromycin, pentamidine, and antimalarials, particularly halofantrine), certain antihistamines (terfenadine, astemizole, mizolastine) and other drugs such as cisapride, vincamine, bepridil, and diphemanil.

Use with drugs that decrease renal calcium excretion, such as thiazide diuretics, may increase the incidence of hypercalcaemia. Use with coumarin anticoagulants should be avoided as there is a risk of increased bleeding time.

Antibacterials. *Rifampicin* was found to decrease plasma concentrations of toremifene in 9 subjects. This was thought to be due to induction of cytochrome P450 isoenzyme CYP3A4 by rifampicin.[1]

1. Kivistö KT, *et al.* Tamoxifen and toremifene concentrations in plasma are greatly decreased by rifampin. *Clin Pharmacol Ther* 1998; 64: 648–54.

Pharmacokinetics

Toremifene citrate is well absorbed from the gastrointestinal tract and peak plasma concentrations of toremifene occur within 3 hours. Food intake may delay peak plasma concentrations by up to 2 hours but has no effect on the extent of absorption. Plasma concentration declines biexponentially; the mean distribution half-life is about 4 hours and the elimination half-life is about 5 days. It is extensively bound to plasma proteins, mainly albumin. Toremifene is metabolised principally by the cytochrome P450 isoenzyme CYP3A4. The main metabolite is *N*-demethyltoremifene, which is reported to have similar anti-oestrogenic activity but weaker anti-tumour activity than toremifene; it is even more extensively bound to plasma proteins. Minor metabolites of toremifene include (deaminohydroxy)-toremifene, 4-hydroxytoremifene, and *N,N*-didemethyltoremifene; concentrations of these are considered to be too low to have biological effects. Toremifene undergoes enterohepatic circulation and is eliminated mainly in the faeces as metabolites. About 10% is excreted in the urine.

Reviews.

Tositumomab *(rINN)*

B-1; Tositumomabum; Тозитумомаб.

Immunoglobulin G2a anti-(human antigen CD 20) (mouse monoclonal clone B1R1 γ2a-chain), disulfide with mouse monoclonal clone B1R1 λ_a-chain, dimer.

CAS — 192391-48-3.

UNII — 0343IGH41U.

Uses and Administration

Tositumomab is an anti-B1 monoclonal antibody that is directed against the CD20 antigen found on the surface of B lymphocytes. It is radiolabelled with iodine-131 (p. 2225.3) for the treatment of patients with CD20 antigen-expressing, relapsed or refractory, low-grade, follicular, or transformed non-Hodgkin's lymphoma (p. 696.3), and including those patients who have disease refractory to rituximab.

The regimen consists of a dosimetric step, followed 7 to 14 days later by a therapeutic step. The dosimetric step consists of 450 mg of tositumomab given intravenously in 50 mL sodium chloride 0.9% over 60 minutes. Tositumomab 35 mg radiolabelled with iodine-131 is then given intravenously in 30 mL sodium chloride 0.9% over 20 minutes. This is followed by whole body imaging to determine whether biodistribution is acceptable, and to allow calculation of the therapeutic dose of radiolabelled tositumomab. In the therapeutic step, tositumomab 450 mg is given again, and followed by the calculated dose of radiolabelled tositumomab.

The rate of infusion may be halved for mild to moderate infusional toxicity, and stopped if this is severe; the infusions may be restarted at half the rate once toxicity resolves. Patients are pretreated with thyroid protective agents at least 24 hours before the first radiolabelled dose of tositumomab; treatment is continued until 2 weeks after the radiolabelled therapeutic dose. Analgesics and antihistamines are also given orally 30 minutes before doses of tositumomab.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 721.1, p. 730.2, and p. 732.2.

Infusion reactions suggestive of a cytokine release syndrome, and other hypersensitivity reactions including anaphylaxis, have been reported with tositumomab. Prolonged and severe neutropenia, thrombocytopenia, and anaemia occur commonly; full blood counts should be monitored weekly for up to 12 weeks. Other adverse effects include gastrointestinal disturbances, dehydration, abdominal pain, pleural effusion, and increased susceptibility to infection. Delayed adverse effects such as the development of secondary malignancies, leukaemia, or myelodysplastic syndrome may occur. Patients receiving the radiolabelled regimen may be susceptible to hypothyroidism and pretreatment with thyroid blocking drugs is recommended (see Uses and Administration, above); levels of thyroid-stimulating hormone should be measured before treatment and annually thereafter.

Hypersensitivity. A report of successful use of tositumomab in a patient who had repeated infusion reactions to rituximab[1] suggests a possible lack of cross-sensitivity between the 2 anti-CD20 antibodies.

1. Hayslip J, Fenning R. Safe administration of iodine-131 tositumomab after repeated infusion-related reactions to rituximab. *Oncologist* 2007; 12: 338–40.

Trabectedin *(BAN, USAN, rINN)*

Ecteinascidin-743; ET-743; NSC-648766; Trabectedina; Trabectédine; Trabectedinum; Трабектедин.

(1′*R*,6*R*,6a*R*,7*R*,13*S*,14*S*,16*R*)-6′,8,14-Trihydroxy-7′,9-dimethoxy-4,10,23-trimethyl-19-oxo-3′,4′,6,7,12,13,14,16-octahydrospiro[6,16-(epithiopropanooxymethano)-7,13-imino-6a*H*-1,3-dioxolo[7,8]isoquino[3,2-*b*][3]benzazocine-20,1′(2′*H*)-isoquinolin]-5-yl acetate.

$C_{39}H_{43}N_3O_{11}S$=761.8

CAS — 114899-77-3.

ATC — L01CX01.

ATC Vet — QL01CX01.

UNII — ID0YZQ2TCP.

Uses and Administration

Trabectedin is a novel DNA-binding agent derived from the marine tunicate, *Ecteinascidia turbinata*. It is used for the treatment of advanced soft-tissue sarcomas, after failure of anthracyclines or ifosfamide, or in patients for whom these drugs are unsuitable. It is also licensed for use with liposomal doxorubicin in the treatment of relapsed platinum-sensitive ovarian cancer.

For treatment of **soft-tissue sarcomas**, the recommended dose is 1.5 mg/m², given as an intravenous infusion over 24 hours.

For the treatment of **ovarian cancer** trabectedin is given in a dose of 1.1 mg/m² as an intravenous infusion over 3 hours immediately following an infusion of pegylated liposomal doxorubicin 30 mg/m².

Treatment may be repeated at 3-week intervals as long as clinical benefit persists, provided haematological, hepatic, and renal function parameters are met. If these baseline criteria are not met, treatment must be delayed for up to 3 weeks, until the criteria are met. If severe toxicity occurs at any time between cycles, the dose for subsequent cycles must be reduced (see Administration in Subsequent Cycles, p. 875.1).

If trabectedin is given via a central venous line, which is the preferred method, the dose should be diluted in at least 50 mL of sodium chloride 0.9% or glucose 5%. If central access is unfeasible, and it is given peripherally, the dose should be diluted in at least 1 litre of diluent. Dexamethasone 20 mg is given intravenously 30 minutes before treatment with trabectedin (or before liposomal doxorubicin in patients treated for ovarian cancer), to reduce nausea and hepatotoxicity.

Administration in hepatic impairment. Licensed product information states that there are no studies of trabectedin in hepatic impairment and data are unavailable to recommend doses in these patients. However, since systemic exposure is likely to be increased in these patients, thus increasing the risk of hepatotoxicity, caution is advised and dose adjustments may be needed. Trabectedin should not be given to patients with hyperbilirubinaemia.

Administration in renal impairment. Licensed product information for trabectedin states that no dose adjustments are needed when used as monotherapy in patients with mild or moderate renal impairment, but that trabectedin should not be used in patients with severe renal impairment (creatinine clearance less than 30 mL/min) as no data are available for this population. For similar reasons, combination therapy is not recommended in those with creatinine clearance less than 60 mL/min.

Administration in subsequent cycles. Initial criteria for administration of trabectedin are:
- absolute neutrophil count: at least 1500 cells/mm³
- platelet count: at least 100 000 cells/mm³
- bilirubin: less than or equal to upper limit of normal (ULN)
- alkaline phosphatase, alanine aminotransferase, and aspartate aminotransferase: less than or equal to 2.5 X ULN
- albumin: 25 mg/mL or more
- creatine phosphokinase: less than or equal to 2.5 X ULN
- haemoglobin: 9 g/dL
- creatinine clearance: at least 30 mL/minute for monotherapy or 60 mL/minute for combination therapy with liposomal doxorubicin

These baseline criteria must also be met before re-treating the patient in subsequent cycles. If serious toxicity occurs between cycles, e.g neutropenia of less than 500 cells/mm³ lasting more than 5 days or associated with fever or infection, thrombocytopenia below 25 000 cells/mm³, bilirubin above the ULN or alkaline phosphatase > 2.5 X ULN, or increase in aminotransferases above 2.5 X ULN for monotherapy or 5 X ULN for combination therapy, then subsequent doses must be reduced as follows:
- for **soft-tissue sarcoma** the dose of trabectedin is reduced from 1.5 mg/m² to 1.2 mg/m² initially, and then to 1 mg/m² if necessary. If severe toxicity still continues, stopping treatment should be considered
- for **ovarian cancer**, the initial dose of 1.1 mg/m² is reduced to 900 micrograms/m² (with a reduction in liposomal doxorubicin dose to 25 mg/m²), and then to 750 micrograms/m² (with liposomal doxorubicin 20 mg/m²). Again, consideration should be given to stopping treatment if further reduction is necessary

Once a dose has been reduced for toxicity, re-escalation in subsequent cycles is inadvisable.

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2. Neutropenia, thrombocytopenia, anaemia, and leucopenia are very common with trabectedin; febrile neutropenia often occurs. Full blood counts should be performed at baseline, weekly for the first 2 cycles, and then once between cycles thereafter. Dose reductions may be needed in those with haematological toxicity. Hepatobiliary disorders are also very common, and include hyperbilirubinaemia and alterations in liver function tests, which are mostly transient. Patients with liver disease should be closely monitored, and trabectedin should not be given to those with hyperbilirubinaemia.

Other very common adverse effects include gastrointestinal disturbances, anorexia, headache, and fatigue. Antiemetic prophylaxis with dexamethasone should be given to all patients. Peripheral sensory neuropathy, paraesthesia, dysgeusia, dizziness, pyrexia, and oedema are common, as are dyspnoea, cough, alopecia, myalgia, arthralgia, dehydration, hypokalaemia, hypotension, and flushing. Injection site reactions can occur, and the use of a central line is recommended.

Deaths associated with trabectedin treatment have often involved a combination of adverse events including pancytopenia, febrile neutropenia, and in some cases sepsis, hepatic involvement, renal failure, and rhabdomyolysis.

Trabectedin may cause serious birth defects if given during pregnancy, although data are limited. Women and men of fertile age are advised to use effective contraception during treatment, and for 3 and 5 months, respectively, after stopping treatment. Breast feeding is contra-indicated due to lack of data, and should be avoided for the duration of treatment and for 3 months after therapy is stopped.

Extravasation. A report[1] of severe local tissue inflammation and necrosis in 2 patients, associated with extravasation of trabectedin from central venous access devices. Both patients had full thickness injuries that required surgical debridement of affected skin, subcutaneous tissue, and pectoral muscle, suggesting that trabectedin should be considered a vesicant.

1. Theman TA, *et al.* Recognition of a new chemotherapeutic vesicant: trabectedin (ecteinascidin-743) extravasation with skin and soft tissue damage. *J Clin Oncol* 2009; 27: e198–e200.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies trabectedin as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

Trabectedin is metabolised by the cytochrome P450 isoenzyme CYP3A4, and drugs that inhibit this enzyme (such as azole antifungals, macrolide antibacterials, or ritonavir) may increase blood concentrations of trabectedin. Equally, inducers of CYP3A4 (such as rifampicin, phenobarbital, and St John's wort) may decrease systemic exposure to trabectedin. Trabectedin is a substrate of P-glycoprotein, and use with P-glycoprotein inhibitors (such as ciclosporin and verapamil) may alter trabectedin pharmacokinetics, although the clinical significance of this interaction has not been established. Alcohol and other hepatotoxic drugs should be avoided during trabectedin treatment due to possible potentiation of hepatotoxicity. Use with live attenuated vaccines is not recommended, and use with yellow fever vaccine is specifically contra-indicated. For the effect of trabectedin on phenytoin, see p. 544.1.

Pharmacokinetics

Trabectedin is extensively distributed in the tissues. Plasma protein binding is about 94 to 98%. It is metabolised in the liver, mainly by cytochrome P450 isoenzyme CYP3A4. The terminal half-life is about 180 hours. Trabectedin is excreted mainly in the faeces, with a small amount in the urine, of which less than 1% is unchanged drug.

Trabedersen *(BAN, rINN)*

AP-12009; TGF-β2 antisense oligonucleotide; Trabédersen; Trabedersén; Trabedersenum; Transforming growth factor-β2-specific phosphorothioate antisense oligodeoxynucleotide; Трабедерсен.

2′-Deoxy-*P*-thiocytidylyl-(3′→5′)-2′-deoxy-*P*-thioguanylyl-(3′→5′)-2′-deoxy-*P*-thioguanylyl-(3′→5′)-2′-deoxy-*P*-thiocytidylyl-(3′→5′)-2′-deoxy-*P*-thioadenylyl-(3′→5′)-*P*-thiothymidylyl-(3′→5′)-2′-deoxy-*P*-thioguanylyl-(3′→5′)-*P*-thiothymidylyl-(3′→5′)-2′-deoxy-*P*-thiocytidylyl-(3′→5′)-*P*-thiothymidylyl-(3′→5′)-2′-deoxy-*P*-thioadenylyl-(3′→5′)-*P*-thiothymidylyl-(3′→5′)-*P*-thiothymidylyl-(3′→5′)-*P*-thiothymidylyl-(3′→5′)-2′-deoxy-*P*-thioguanylyl-(3′→5′)-2′-deoxyadenosine.

CAS — 925681-61-4.

NOTE. The name Oncomun has been used as a trade mark for trabedersen.

Profile

Trabedersen is an antisense oligonucleotide that specifically suppresses the production of transforming growth factor-beta-2, an immunosuppressive protein produced by tumour cells. It is under investigation for the treatment of high-grade glioma (see Malignant Neoplasms of the Brain, p. 701.2) and other neoplasms such as pancreatic cancer.

Trametinib *(USAN, pINN)*

GSK-1120212; Tramétinib; Trametinibum; Траметиниб.

N-(3-[3-Cyclopropyl-5-[(2-fluoro-4-iodophenyl)amino]-6,8-dimethyl-2,4,7-trioxo-3,4,6,7-tetrahydropyrido[4,3-*d*]pyrimidin-1(2*H*)-yl]phenyl)acetamide.

$C_{26}H_{23}FIN_5O_4$=615.4

CAS — 871700-17-3.

UNII — 33E86K87QN.

Trametinib Dimethyl Sulfoxide *(USAN, pINNM)*

GSK-1120212B.

$C_{26}H_{23}FIN_5O_4.C_2H_6OS$=693.5

CAS — 1187431-43-1.

UNII — BSB9VJ5TUT.

Profile

Trametinib is an inhibitor of mitogen-activated extracellular kinases (MEK 1 and 2) that is used in the treatment of unresectable or metastatic melanoma (p. 714.3) with BRAF V600E or V600K mutations; it should not be used in patients who have previously been treated with a BRAF inhibitor. It is given as the compound trametinib dimethyl sulfoxide but doses are expressed as the non-solvated base; 2 mg of trametinib is equivalent to about 2.25 mg trametinib dimethyl sulfoxide. The usual oral dose is equivalent to 2 mg once daily; tablets should be swallowed whole and taken on an empty stomach. A missed dose should not be taken within 12 hours of the next dose. Doses may need to be withheld or reduced if toxicity occurs. Where dose adjustment is required, reductions are made in steps of 500 micrograms. Treatment is continued until disease progression or unacceptable toxicity occurs. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Commonly reported adverse effects with trametinib are skin reactions such as rash, dry skin, and pruritus, paronychia, lymphoedema, hypertension, haemorrhage, and gastrointestinal disturbances, particularly diarrhoea. Severe skin toxicity, cardiomyopathy, interstitial lung disease, retinal pigment epithelial detachment, and retinal vein occlusion have also occurred. Trametinib should be avoided during pregnancy and women of child-bearing potential should use contraception during and for 4 months after treatment.

Trastuzumab *(BAN, USAN, rINN)*

Anticuerpo monoclonal HER2; HER-2 Monoclonal Antibody; rhuMAb HER2; Trastutsumabi; Trastuzumabum; Трастузумаб.

Immunoglobulin G1 (human-mouse monoclonal rhuMab HER2 γ1-chain anti-human $p185^{c\text{-}erbB2}$ receptor), disulfide with human-mouse monoclonal rhuMab HER2 light chain, dimer.

CAS — 180288-69-1.

ATC — L01XC03.

ATC Vet — QL01XC03.

UNII — P188ANX8CK.

Trastuzumab Emtansine *(USAN, rINN)*

Ado-trastuzumab Emtansine; PRO-132365; RG-3502; T-DM1; Trastuzumab-DM1; Trastuzumab Emtansina; Trastuzumab-

MCC-DM1; Trastuzumabum Emtansinum; Трастузумаб Эмтанзин.
CAS — 1018448-65-1.
UNII — SE2KH7T06F.

NOTE. Trastuzumab emtansine contains trastuzumab covalently linked to the microtubule inhibitory drug DM1, via the stable thioether linker MCC (4-[*N*-maleimidomethyl] cyclohexane-1-carboxylate). Emtansine refers to the MCC-DM1 complex.

Trastuzumab and trastuzumab emtansine are not interchangeable.

Uses and Administration

Trastuzumab is a humanised monoclonal antibody directed against a cell surface protein produced by the human epidermal growth factor receptor 2 (HER2) gene. HER2 protein is overexpressed in about one-third of all breast cancers. Trastuzumab is used in the treatment of breast cancer (p. 702.1) with such characteristics. It is also used with combination chemotherapy in HER2-positive metastatic gastric cancer (p. 706.1). Trastuzumab emtansine (also called ado-trastuzumab emtansine) consists of trastuzumab conjugated to DM1, a maytansine derivative and cytotoxic microtubule inhibitor. It is used in the treatment of metastatic HER2-positive breast cancer.

Note that trastuzumab and trastuzumab emtansine are not interchangeable.

Trastuzumab is generally given in either a weekly or 3-weekly infusion schedule. Doses should be added to 250 mL of sodium chloride 0.9% for intravenous infusion. The initial dose is given over 90 minutes and subsequent doses may be given over 30 to 90 minutes. Alternatively, for some indications, it may be given subcutaneously once every 3 weeks; injection sites should be alternated between thighs, and the dose injected over 2 to 5 minutes. Preparations for subcutaneous injection contain recombinant human hyaluronidase and are not suitable for intravenous use.

- Weekly infusion schedule: 4 mg/kg initially, followed after 1 week by a maintenance dose of 2 mg/kg at weekly intervals.
- 3-Weekly infusion schedule: 8 mg/kg initially, followed after 3 weeks by a maintenance dose of 6 mg/kg once every 3 weeks.
- 3-Weekly subcutaneous schedule: 600 mg once every 3 weeks (no loading dose is required).

In metastatic breast cancer, trastuzumab may be given alone or with a taxane or an aromatase inhibitor. It is given in either a weekly or 3-weekly schedule, and continued until disease progression.

In the adjuvant treatment of early breast cancer, trastuzumab may be given in a weekly schedule with docetaxel or paclitaxel for 12 weeks, starting after 4 cycles of the AC regimen (doxorubicin and cyclophosphamide). Alternatively, weekly trastuzumab may be given with docetaxel and carboplatin for 18 weeks. One week after the completion of either of these treatment courses, trastuzumab may be continued at 6 mg/kg by infusion every 3 weeks. A 3-weekly trastuzumab regimen may also be given as adjuvant monotherapy after multimodal therapy including surgery, chemotherapy, and radiotherapy if applicable. In locally advanced disease, a 3-weekly trastuzumab regimen has been used with neoadjuvant chemotherapy followed by adjuvant trastuzumab; however, the concurrent use of trastuzumab with anthracyclines should be limited to chemotherapy-naive patients and only using low-dose anthracycline regimens. Trastuzumab therapy is given for 1 year in total or until disease recurs, whichever occurs first.

In metastatic adenocarcinoma of the stomach or gastro-oesophageal junction, trastuzumab is given in a 3-weekly infusion schedule with cisplatin and either capecitabine or 5-fluorouracil. Treatment is continued until disease progression.

If the patient misses an infusion dose of trastuzumab by 1 week or less, then the usual maintenance dose should be given as soon as possible, without waiting until the next planned cycle. Subsequent cycles are then given according to the previous schedule.

If the infusion dose is missed by more than 1 week, a re-loading dose of trastuzumab should be given, and subsequent maintenance doses given thereafter.

If a subcutaneous dose is missed, it should be given as soon as possible; the interval between doses should not be less than 3 weeks.

Trastuzumab emtansine (ado-trastuzumab emtansine) is given alone in the treatment of metastatic breast cancer. A dose of 3.6 mg/kg is given every 3 weeks until disease progression or there is unacceptable toxicity. The dose should be added to 250 mL of sodium chloride 0.9% for intravenous infusion. The first dose is infused over 90 minutes; subsequent doses may be given over 30 minutes if tolerated.

If a dose of trastuzumab emtansine is missed or delayed, it should be given as soon as possible and the schedule adjusted to keep an interval of 3 weeks between subsequent doses.

The dose of trastuzumab or trastuzumab emtansine may need to be delayed or reduced because of toxicity (see Administration in Subsequent Cycles, below).

Administration. Intrathecal trastuzumab has been tried in the treatment of leptomeningeal carcinomatosis in HER2-positive metastatic breast cancer. A review[1] of 17 case reports found that it had been given as monotherapy or in various regimens with other systemic or intrathecal treatments. Individual doses of trastuzumab ranged from 4 to 150 mg, and total doses ranging from 35 to 1110 mg (mean 399.8 mg) were reported. Slightly higher doses were recorded in 4 of the patients given intrathecal trastuzumab readministration beyond CNS progression (mean dose of 560 mg and cumulative dose of 1040 mg). Clinical and radiological improvement was reported in more than half of the patients and overall survival was prolonged to a median of 13.5 months compared with 5.9 months for published historical groups. Treatment was well tolerated.

1. Zagouri F, *et al.* Intrathecal administration of trastuzumab for the treatment of meningeal carcinomatosis in HER2-positive metastatic breast cancer: a systematic review and pooled analysis. *Breast Cancer Res Treat* 2013; 139: 13–22.

Administration in subsequent cycles. *Trastuzumab* infusion may need to be slowed or stopped in patients who develop infusion reactions. Parenteral treatment may need to be withheld or stopped if ventricular function deteriorates.

Similarly, *trastuzumab emtansine* infusion should be slowed or stopped for infusion reactions. The dose may need to be delayed or reduced for other adverse effects. The dose may be reduced step-wise from 3.6 mg/kg to 3 mg/kg, then to 2.4 mg/kg; if a further dose reduction is needed then trastuzumab emtansine should be stopped. The following modifications have been recommended in patients who develop increases in serum transaminases, hyperbilirubinaemia, or thrombocytopenia:

- serum transaminases > 2.5 to ≤ 5 X upper limit of normal (ULN): continue trastuzumab emtansine at the same dose
- serum transaminases > 5 to ≤ 20 X ULN: withhold until recovery to at least ≤ 5 X ULN and then reduce the dose by one step
- serum transaminases > 20 X ULN: permanently stop trastuzumab emtansine
- total bilirubin > 1.5 to ≤ 3 X ULN: withold until recovery to at least < 1.5 X ULN, then treat at the same dose
- total bilirubin > 3 to ≤ 10 X ULN: withold until recovery to at least < 1.5 X ULN, then reduce the dose by one step
- total bilirubin > 10 X ULN: permanently stop trastuzumab emtansine
- serum transaminases > 3 X ULN and total bilirubin > 2 X ULN: permanently stop trastuzumab emtansine
- patients diagnosed with nodular regenerative hyperplasia: permanently stop trastuzumab emtansine
- platelets 25 000 to < 50 000 cells/mm³: withhold until ≥ 75 000 cells/mm³ and then treat at the same dose
- platelets < 25 000 cells/mm³: withhold until ≥ 75 000 cells/mm³ and then reduce the dose by one step

In patients with left ventricular dysfunction, trastuzumab emtansine should be withheld if left ventricular ejection fraction is less than 40%, or between 40% and 45% and also 10% or more points below baseline. Treatment should be stopped if there is symptomatic congestive heart failure, or if function has not recovered in less than 3 weeks to within 10% points from baseline or to more than 40%.

Trastuzumab emtansine should be withheld in patients who develop grade 3 or 4 peripheral neuropathy, and permanently stopped in those who develop pulmonary toxicity.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 716.1, p. 730.2 and p. 732.2.

Trastuzumab has been associated with fatal hypersensitivity reactions, infusion reactions characteristic of a cytokine release syndrome, and pulmonary events including acute respiratory distress syndrome. These usually occur after the first dose of trastuzumab and are more common in patients with reduced lung function. Systemic and local reactions have occurred after subcutaneous injection. Use of trastuzumab is contra-indicated in patients with severe dyspnoea at rest. Cardiac dysfunction and congestive heart failure may also occur and left ventricular function should be monitored before and during therapy. The risk of cardiotoxicity is increased if trastuzumab is given with anthracyclines or cyclophosphamide (see below).

There is an increase in the incidence of leucopenia, thrombocytopenia, anaemia, and febrile neutropenia when trastuzumab is given with chemotherapy, but it infrequently causes myelosuppression when used alone. Diarrhoea occurs in about 25% of patients given trastuzumab as monotherapy; the incidence increases with combination therapy. Other gastrointestinal disturbances are common, as are chills, fever, headache, arthralgia, myalgia, and rashes. Asthenia, chest pain, and renal or liver disorders have also been reported.

The adverse effects of trastuzumab are also reported for *trastuzumab emtansine*. However, thrombocytopenia and hepatotoxicity are very common and may require dose adjustment. Peripheral neuropathy is also commonly reported with trastuzumab emtansine; it is generally a sensory neuropathy and may be severe in a small percentage of patients.

Effects on the heart. Cardiac events related to the use of trastuzumab include asymptomatic decreases in left ventricular ejection fraction, tachycardia, palpitations, dyspnoea, and chest pain. Congestive heart failure may develop.[1] Complete left bundle branch block, mimicking an acute coronary syndrome, has also been seen.[2]

In a pivotal comparative study,[3] an increased incidence of cardiac adverse events prompted a retrospective analysis. This independent review identified cardiac dysfunction in 27% of patients given trastuzumab, an anthracycline, and cyclophosphamide, compared with only 8% given an anthracycline and cyclophosphamide. In patients given trastuzumab and paclitaxel, 13% developed cardiac dysfunction compared with 1% of patients given paclitaxel alone, although all these patients had previously received an anthracycline. The incidence of severe dysfunction was highest in those patients given trastuzumab, an anthracycline, and cyclophosphamide.

Further analysis[4] of this and 6 other studies found that, in a total of 1219 patients, 10 heart-related deaths had been reported, and that 9 of these were patients who had taken trastuzumab. However, the risk of developing cardiotoxicity was less when trastuzumab was given alone than when given with anthracyclines. Advanced age was found to be a significant risk factor, whereas giving trastuzumab and the anthracycline at different times appeared to decrease the rate of cardiotoxicity.

Licensed product information for trastuzumab warns that patients who have previously had anthracyclines may also be at increased risk of cardiotoxicity with trastuzumab treatment. Furthermore, because the half-life of trastuzumab is about 4 to 5 weeks, trastuzumab may persist in the circulation for up to 20 to 25 weeks, and patients given anthracyclines after stopping trastuzumab may still be at increased risk of cardiotoxicity. If anthracyclines are used, the patient's cardiac function should be carefully monitored. Patients with pre-existing cardiovascular disease should also be treated with caution.

However, the majority of patients who develop congestive heart failure improve with standard treatment, including the use of ACE inhibitors, beta blockers, cardiac glycosides and diuretics.[1,5,6] Cardiotoxicity may improve even in those patients who continue with trastuzumab therapy.[5,6] A small retrospective study found that cardiotoxicity appeared to be largely reversible once trastuzumab was stopped, and that therapy might even be restarted. Findings from myocardial biopsy suggested that, while the mechanism of cardiotoxicity with trastuzumab remained uncertain, it differed from that with anthracyclines.[7] A retrospective review[8] of 173 patients with metastatic breast cancer who were treated with trastuzumab-based therapy for at least 1 year found that 28% of patients had a cardiac event; 10.9% had grade 3 cardiotoxicity, including 1 cardiac-related death. However, cardiotoxicity, whether symptomatic or not, was generally

reversible, with or without specific therapy, suggesting that maintenance or re-treatment with trastuzumab may be feasible in those patients for whom no alternative therapeutic options are available.

Analysis of symptomatic heart failure with trastuzumab suggests a lower incidence than that previously reported with retrospective data; however, this may be due to over-reported events in pivotal studies and the more recent exclusion of patients at risk of cardiotoxicity.[5] Analysis from a large study of patients given adjuvant chemotherapy with or without 1 year of trastuzumab found a cumulative incidence of cardiac events (defined as confirmed New York Heart Association class III or IV cardiac dysfunction, or cardiac death) with trastuzumab of 4.1% at 3 years. The difference in cumulative incidence was 3.3% when compared with the control group.[9] Additional follow-up to 7 years included some further reports of cardiac events in both groups, but the late development of heart failure in patients given trastuzumab was uncommon.[10] Cardiac function returned to the normal range in the majority of patients who had stopped trastuzumab because of dysfunction, although some decline from baseline persisted. In similar studies,[11,12] follow-up analyses at around 3 years also confirmed a higher incidence of cardiac events in patients given 1 year of trastuzumab therapy, but it remained low and cardiac dysfunction appeared to be reversible.

Reviews[13,14] have concluded that trastuzumab-induced cardiotoxicity is not dose-related and is generally reversible once the drug is stopped. However, others[15,16] have challenged the concept that cardiotoxicity is reversible, and the need for longer-term follow-up data, especially with respect to asymptomatic left ventricular dysfunction, has been emphasised.[13,15] As well as routine monitoring of cardiac function and for symptoms of heart failure, some suggest that increases in serum concentrations of troponin I during trastuzumab treatment are predictive of cardiotoxicity, and that further investigation of troponin I monitoring is warranted.[16]

Effects on the liver. A 54-year-old African American woman was treated with 8 weeks of trastuzumab therapy. Her liver enzyme concentrations were normal before treatment was started but increased until trastuzumab had to be stopped, after which they returned to normal. Upon re-challenge, liver enzyme concentrations increased again. Liver function tests with close monitoring are advised during trastuzumab therapy.[1]

1. Srinivasan S, *et al.* Trastuzumab-induced hepatotoxicity. *Ann Pharmacother* 2008; **42**: 1497–1501.

Metastatic disease. There is some suggestion that patients treated with trastuzumab for metastatic breast cancer have a higher incidence of cerebral metastases. This may reflect increased survival of patients given trastuzumab, and the lack of CNS penetration by the drug,[1,2] or tumours overexpressing human epidermal growth receptor 2 (HER2) may be more likely to metastasise to the CNS.[2] A comparison[1] of trastuzumab-treated patients with a control group found that, although trastuzumab reduced the incidence of bone metastases, the development of brain metastases was similar in both groups. However, trastuzumab improved overall survival in all patients developing metastases, including those with brain metastases. A retrospective review[2] found an association between the development of cerebral metastases and both hormone-receptor negative status and the presence of visceral disease.

For the intrathecal use of trastuzumab in leptomeningeal carcinomatosis in metastatic breast cancer, see Administration under Uses and Administration, p. 876.2.

2. Clayton AJ, *et al.* Incidence of cerebral metastases in patients treated with trastuzumab for metastatic breast cancer. *Br J Cancer* 2004; **91**: 639–43.

Peripheral vascular toxicity. A woman developed a painless prominence of the veins in her left arm and hand 3 days after receiving trastuzumab via a left hand vein. The veins were thickened and rope-like on palpation but there was no tenderness, oedema, or skin changes; there was no evidence of thrombus. She had previously received intravenous chemotherapy into left hand veins without sequelae. Biopsy suggested venous wall injury. Cardiac function was preserved, suggesting the mechanism of vascular injury was unrelated to cardiac dysfunction. Trastuzumab therapy was stopped permanently and her symptoms gradually resolved over the course of a year.[1]

1. Pansegrau GK, *et al.* Trastuzumab-associated peripheral vascular toxicity. *J Clin Oncol* 2007; **25**: 1438–40.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies trastuzumab as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11).

Pregnancy. Fetal exposure to *trastuzumab* in 18 pregnancies (19 newborns) has been reviewed.[1] The duration of maternal trastuzumab treatment ranged from 1 to 31 weeks, with a mean duration of 14.8 weeks, and it was given either alone or with other antineoplastics. Oligohydramnios and anhydramnios were the most commonly reported adverse events, affecting 11 of the 15 pregnancies exposed to trastuzumab in the second or third trimester. There was a trend towards an increase in risk with a longer duration of trastuzumab use. However, oligohydramnios seemed to be reversible after stopping the drug. There appeared to be no significant difference between weekly and 3-weekly exposure in relation to oligohydramnios and anhydramnios. Some cases showed intra-uterine growth restriction, dystrophy, and pulmonary hypoplasia. Conditions reported at birth in 9 neonates included respiratory distress, renal failure, and infection; 4 of these infants died within 6 months. The remaining 10 neonates were healthy at birth and at follow-up.

No adverse effects were found in the 3 cases exposed to trastuzumab during the first trimester only (up to 6 weeks of gestational age).[1] The authors suggested that this might be related to the poor trans-placental transfer of monoclonal antibodies during early pregnancy compared with later gestation. Also, the inhibitory effect of trastuzumab on epidermal growth factor receptors in the fetal kidney, which might inhibit amniotic fluid production, would only be significant after month 4 (before this the amniotic fluid is produced maternally). Nevertheless, the limited number of reports precludes any definite conclusion about the safety of trastuzumab in the first trimester.

Licensed product information advises the use of contraception during trastuzumab therapy and for at least 6 months after stopping treatment.

Information about fetal exposure to *trastuzumab emtansine* is lacking. However, in addition to the potential effects of trastuzumab, the cytotoxic component DM1 is expected to cause embryo-fetal toxicity.

1. Zagouri F, *et al.* Trastuzumab administration during pregnancy: a systematic review and meta-analysis. *Breast Cancer Res Treat* 2013; **137**: 349–57.

Interactions

For reports of trastuzumab enhancing the effect of warfarin, see p. 1532.2.

Based on *in-vitro* studies, it is suggested that the concomitant use of strong inhibitors of the cytochrome P450 isoenzyme CYP3A4 and trastuzumab emtansine should be avoided if possible, because of the potential for an increased exposure to the DM1 component.

Pharmacokinetics

The pharmacokinetics of *trastuzumab* are non-linear, and clearance decreases with increasing dose. The half-life after short-duration intravenous infusions was found to be about 2 days after weekly 10-mg doses and 12 days after 500-mg doses. It has also been reported to be about 6 days with the recommended weekly infusion schedule (4 mg/kg initially, followed by 2 mg/kg weekly), and about 16 days with the 3-weekly infusion schedule (8 mg/kg initially, followed by 6 mg/kg every 3 weeks). However, limited sampling may underestimate terminal half-life. Population pharmacokinetic modelling, based on pooled data in a two-compartment model to take account of accumulation with long-term dosing, estimates a terminal elimination half-life of about 28.5 days. When given subcutaneously, trastuzumab peak plasma concentrations occur about 3 days after injection, but with high interindividual variability ranging from 1 to 14 days. It has an estimated bioavailability of about 82%.

Detectable concentrations of the cell surface protein of the HER2 receptor (shed antigen) have been found in patients' serum; those patients with higher baseline values for shed antigen had lower serum trough concentrations of trastuzumab, although target trastuzumab concentrations were still achieved after weekly dosing, and no relationship to clinical response was seen.

Trastuzumab emtansine has a shorter half-life than trastuzumab, of about 4 days. The small molecule component, DM1, is metabolised via the cytochrome P450 isoenzymes CYP3A4 and CYP3A5 and is a substrate of P-glycoprotein.

Treosulfan *(BAN, rINN)*

Dihydroxybusulphan; NSC-39069; Treosulfaani; Tréosulfan; Treosulfano; Treosulfanum; Треосульфан.

L-Threitol 1,4-dimethanesulphonate.

$C_6H_{14}O_8S_2$=278.3

CAS — 299-75-2.

ATC — L01AB02.

ATC Vet — QL01AB02.

UNII — CO61ER3EPI.

Profile

Treosulfan is an antineoplastic agent related to busulfan (p. 754.3), which is reported to act by alkylation after conversion *in vivo* to epoxide compounds. It is used palliatively or as an adjunct to surgery mainly in the treatment of ovarian cancer (p. 711.2).

Treosulfan may be given orally, intravenously, or intraperitoneally. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Treosulfan 1 g daily is licensed for *oral* use in 4 divided doses for 2 or 4 weeks followed by the same period without treatment. Alternatively 1.5 g daily in 3 divided doses may be given for 1 week, followed by 3 weeks without therapy. The cycle is then repeated, the dose being adjusted if necessary according to the effect on bone marrow. Doses of 3 to 8 g/m² may instead be given *intravenously* every 1 to 3 weeks. Doses larger than 3 g/m² should be given by infusion at a rate of 3 g/m² every 5 to 10 minutes. Doses up to 1.5 g/m² have been given *intraperitoneally*. Lower doses

should be used if treatment with other antineoplastic drugs or radiotherapy is being given.

Regular blood counts should be made and treatment should be interrupted if the white cell or platelet counts fall below acceptable levels (see also Bone-marrow Depression, p. 730.3). Because bone-marrow depression may be cumulative the interval between blood counts should be reduced after the second course of treatment with treosulfan.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Ger.*: Ovastat.

Trofosfamide *(rINN)*

A-4828; NSC-109723; Trilophosphamide; Trofosfamid; Trofosfamida; Trofosfamidi; Trofosfamidum; Trophosphamide; Z-4828; Трофосфамид.

3-(2-Chloroethyl)-2-[bis(2-chloroethyl)amino]tetrahydro-2*H*-1,3,2-oxazaphosphorine-2-oxide.

$C_9H_{18}Cl_3N_2O_2P$=323.6

CAS — 22089-22-1.

ATC — L01AA07.

ATC Vet — QL01AA07.

UNII — H64JRU6GJ0.

Profile

Trofosfamide is a derivative of cyclophosphamide (p. 771.1) and has the same general properties. It is used in the treatment of malignant disorders in usual initial oral doses of 300 to 400 mg daily. Doses of 50 to 150 mg daily have been given for maintenance therapy.

Uses. References[1-10] to the use of trofosfamide, including its investigational use with pioglitazone and rofecoxib as antiangiogenic therapy.[4,5,7]

Tumour Necrosis Factor

Factor de necrosis tumoral; TNF.

Tasonermin *(BAN, rINN)*

Tasonermini; Tasonermina; Tasonermine; Tasonerminum; TNFα-1a; Тазонермин.

$C_{774}H_{1225}N_{215}O_{231}S_5$=17350.8

CAS — 94948-59-1.

ATC — L03AX11.

ATC Vet — QL03AX11.

UNII — 23CA79S88F.

Profile

Tumour necrosis factor is a cytokine of which 2 forms have been identified with similar biological properties: TNFα or cachectin, which is produced mainly by macrophages, and TNFβ or lymphotoxin, which is produced by lymphocytes. Various recombinant forms of TNFα, both human and mouse, are available: the names sonermin and sertenef have been used for such products.

The antitumour effects of tumour necrosis factor *in vitro* and in *animals* have prompted investigation of recombinant TNFα in the treatment of cancer either alone or with other cytokines such as interleukin-2 or the interferons. Tasonermin is a recombinant TNFα used with melphalan (p. 819.1) for soft tissue sarcomas. It is given by mildly hyperthermic isolated limb perfusion at a total dose of 3 mg for an upper limb and 4 mg for a lower limb.

Leakage of tasonermin into the systemic circulation should not exceed 10%, as severe toxicity may occur. Local adverse effects include skin reactions, oedema, and pain; less commonly, vascular thrombosis, onycholysis, or severe tissue damage have occurred. Systemic effects include fever, chills, nausea and vomiting, arrhythmias, hepatotoxicity, and infections. Shock or hypotension, neurological disorders, thrombocytopenia, leucopenia, acute renal failure, and hypersensitivity reactions have all been reported.

Pharmacopoeias. In *Chin.* and *Jpn.*

Profile

Ubenimex is a peptide derived from *Streptomyces olivoreticuli*. It is reported to have antineoplastic and immunostimulant properties. It has been used in the adjuvant treatment of acute myeloid leukaemia and is under investigation for the treatment of lung cancer. Adverse effects include gastrointestinal and hepatic function disturbances, skin rashes, headache, and paraesthesias.

$C_{34}H_{36}F_3NO_{13}$=723.7

CAS — 56124-62-0.

ATC — L01DB09.

ATC Vet — QL01DB09.

UNII — 2C6NUM6878.

Pharmacopoeias. In *US.*

USP 36: (Valrubicin). An orange to orange-red crystalline powder. Very slightly soluble in water, in hexane, and in petroleum spirit; soluble in dehydrated alcohol, in acetone, in dichloromethane, and in methyl alcohol. Store in airtight containers. Protect from light.

Uses and Administration

Valrubicin is a semisynthetic analogue of the anthracycline doxorubicin (p. 782.3). It is used for carcinoma *in situ* (CIS) of the bladder (p. 700.2) refractory to BCG vaccine, when surgery is contra-indicated, although only about 20% of such patients exhibit a complete response. A dose of 800 mg is given intravesically once a week for 6 weeks. Valrubicin is diluted with sodium chloride 0.9% to a total volume of 75 mL. The solution should be retained for 2 hours if possible before voiding.

Because of the risk of metastasis, cystectomy should be reconsidered for patients with CIS who do not respond completely to valrubicin treatment after 3 months.

References.

1. Steinberg G, *et al.* Efficacy and safety of valrubicin for the treatment of Bacillus Calmette-Guerin refractory carcinoma in situ of the bladder. *J Urol (Baltimore)* 2000; **163**: 761–7.
2. Kuznetsov DD, *et al.* Intravesical valrubicin in the treatment of carcinoma in situ of the bladder. *Expert Opin Pharmacother* 2001; **2**: 1039–13.

Adverse Effects, Treatment, and Precautions

Increased urinary frequency and urgency, dysuria, bladder spasm and pain may follow intravesical use of valrubicin due to local irritation of the bladder, and usually resolve within 1 to 7 days of treatment. Gross haematuria has occurred rarely but should be distinguished from drug-induced red coloration of the urine. Abdominal pain and nausea may occur.

Myelosuppression similar to that seen with other anthracyclines (see Adverse Effects of Doxorubicin, p. 784.1) is possible if significant systemic exposure occurs. Therefore valrubicin should not be given to patients with a perforated bladder or compromised bladder mucosa.

Because of the risk of metastasis, cystectomy should be reconsidered for patients with carcinoma *in situ* who do not respond completely to valrubicin treatment after 3 months.

Pharmacokinetics

On intravesical use valrubicin penetrates the bladder wall but systemic absorption is low in patients who have an intact bladder mucosa. The drug is almost entirely excreted by voiding after the installation period.

Vandetanib (BAN, USAN, rINN)

AZD-6474; Vandétanib; Vandetanibum; ZD-6474; Вандетаниб.

N-(4-Bromo-2-fluorophenyl)-6-methoxy-7-[(1-methylpiperidin-4-yl)methoxy]quinazolin-4-amine.

$C_{22}H_{24}BrFN_4O_2$=475.4

CAS — 338992-00-0; 443913-73-3.

ATC — L01XE12.

ATC Vet — QL01XE12.

UNII — YO460OQ37K.

NOTE. The name Zactima has been used as a trade mark for vandetanib.

Uses and Administration

Vandetanib is a tyrosine kinase inhibitor targeted at receptors for vascular endothelial growth factor and epidermal growth factor. It is used for the treatment of symptomatic or progressive medullary thyroid cancer (p. 716.1) in patients with unresectable locally advanced or metastatic disease. The recommended dose is 300 mg orally once daily. Treatment is continued until patients no longer benefit, or unacceptable toxicity occurs. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* If a daily dose of vandetanib is missed, no catch-up dose is recommended if it is less than 12 hours before the next dose. In the event of severe toxicity, treatment is interrupted until toxicity resolves or improves; dosage may be resumed at 200 mg once daily; doses may be reduced further to 100 mg once daily if needed. For use in hepatic and renal impairment, see below. In the event of a corrected QT interval (QTcF) greater than 500 milliseconds, treatment should be interrupted until the QTcF returns to less than 450 milliseconds; treatment is resumed at a reduced dose.

Vandetanib is also under investigation in the treatment of other solid malignancies.

Administration. As for Gefitinib, p. 800.3.

Administration in hepatic impairment. A pharmacokinetic study[1] in subjects given a single oral dose of vandetanib 800 mg found that hepatic impairment was associated with reduced peak plasma concentrations, especially in those with severe disease, but that the area under the concentration-time curve was unaltered. Exposure to *N*-desmethylvandetanib (see Pharmacokinetics, below) was reduced in subjects with hepatic impairment, consistent with impaired oxidative drug metabolism. It was concluded that, while hepatic impairment would not affect the magnitude of steady-state exposure, the time taken to achieve it would be increased, especially in those with severe disease. The authors concluded that no dose adjustment would be needed in patients with hepatic impairment.

US licensed product information states that data are limited in patients with hepatic impairment (serum bilirubin > 1.5 times the upper limit of normal) and that vandetanib is not recommended for use in patients with moderate (Child-Pugh class B) or severe (Child-Pugh class C) hepatic impairment, as safety and efficacy have not been established.

1. Weil A, *et al.* Pharmacokinetics of vandetanib in subjects with renal or hepatic impairment. *Clin Pharmacokinet* 2010; 49: 607–18.

Administration in renal impairment. A pharmacokinetic study[1] in subjects given a single oral dose of vandetanib 800 mg found that renal impairment resulted in statistically significant increased exposure and reduced plasma clearance. Mean area under the concentration-time curve values were 46%, 62%, and 79% higher in subjects with mild, moderate, and severe renal impairment, respectively.

US licensed product information states that the initial dose of vandetanib (see Uses and Administration, above) should be reduced to 200 mg orally once daily in patients with moderate or severe renal impairment (creatinine clearance < 50 mL/min).

1. Weil A, *et al.* Pharmacokinetics of vandetanib in subjects with renal or hepatic impairment. *Clin Pharmacokinet* 2010; 49: 607–18.

Adverse Effects, Treatment, and Precautions

The most common adverse effects with vandetanib are gastrointestinal disturbances, abdominal pain, rash, acne, headache, fatigue, and decreased appetite. Diarrhoea can be severe, and routine anti-diarrhoeals are recommended; vandetanib may need to be interrupted, and treatment resumed at a reduced dose upon improvement. Hypertension is also common, and hypertensive crisis has been reported; dose reduction or interruption of therapy may be needed, and if blood pressure cannot be controlled, vandetanib should not be restarted. Other adverse effects include hypocalcaemia, proteinuria, pancreatitis, blurred vision, and depression. Electrolyte abnormalities, decreased glucose, increased alanine aminotransferase (ALT) concentrations, increased bilirubin, and increased creatinine can occur.

Vandetanib can prolong the QT interval; because of the drug's long half-life (see Pharmacokinetics, below), this and other adverse effects may not resolve quickly. ECG monitoring is recommended at baseline, after 2 to 4 weeks, again at 8 to 12 weeks after starting treatment, and every 3 months thereafter. Torsade de pointes, ventricular tachycardia, and sudden death have been reported. Vandetanib therapy should not be started in patients whose corrected QT interval (QTcF) is greater than 450 milliseconds (see also Uses and Administration, above), and the drug should not be given to those with a history of torsade de pointes, congenital long QT syndrome, bradyarrhythmias, or uncompensated cardiac failure. It should also not be given if the patient has hypocalcaemia, hypokalaemia, or hypomagnesaemia, which should be corrected before starting therapy with vandetanib, and periodically monitored.

Severe skin reactions, including Stevens-Johnson syndrome, have occurred with vandetanib; fatalities have been reported. Treatment involves stopping therapy and the use of systemic corticosteroids. If vandetanib is restarted, a reduced dose should be used. Mild to moderate reactions can include rash, dry skin, dermatitis, pruritus, photosensitivity reactions, and palmar-plantar erythrodysesthesia syndrome; these may be treated with topical and systemic corticosteroids, oral antihistamines, and topical and systemic antibacterial therapy. Sunscreens and protective clothing are advised if the patient is exposed to sunlight; this should continue for 4 months after vandetanib therapy is stopped.

Fatalities due to cardiac failure, ischaemic cerebrovascular events, or serious haemorrhage have been reported in patients taking vandetanib; therapy should be stopped. Interstitial lung disease has also occurred, in some cases fatal, and patients should be advised to report any new or worsening respiratory symptoms. Therapy may need to be interrupted or stopped permanently in severe cases; corticosteroids and antibacterials may be indicated for management.

Reversible posterior leukoencephalopathy syndrome (RPLS) has also been seen, and this diagnosis should be considered if patients present with seizures, headache, visual disturbances, or confusion. Therapy may need to be stopped if RPLS occurs.

Patients who are treated with vandetanib and who have had a thyroidectomy have required higher doses of thyroid hormone replacement therapy; thyroid stimulating hormone concentrations should be measured at baseline, at 2 to 4 weeks, at 8 to 12 weeks, and every 3 months thereafter.

Vandetanib may be fetotoxic; women should be advised to avoid pregnancy during treatment and for at least 4 months after the last dose.

Interactions

Vandetanib is metabolised by the cytochrome P450 isoenzyme CYP3A4. Inducers of this isoenzyme can reduce plasma vandetanib concentrations and use with potent CYP3A4 inducers (such as dexamethasone, carbamazepine, phenytoin, phenobarbital, rifabutin, rifampicin, and rifapentine) should be avoided. St John's wort can decrease vandetanib exposure unpredictably and use together is not recommended. No significant interaction was seen between vandetanib and the potent CYP3A4 inhibitor itraconazole in healthy subjects. Vandetanib can prolong the QT interval and use with antiarrhythmic drugs (such as amiodarone, disopyramide, dofetilide, procainamide, and sotalol) and other drugs that prolong the QT interval (such as chloroquine, clarithromycin, dolasetron, granisetron, haloperidol, methadone, moxifloxacin, and pimozide) should be avoided.

Pharmacokinetics

Absorption of vandetanib after oral ingestion is slow, with peak plasma concentrations occurring at about 6 hours (range 4 to 10 hours) after dosing. Steady-state concentrations occur at about 3 months. Plasma protein binding is about 90%. Vandetanib is metabolised by cytochrome P450 isoenzyme CYP3A4, mainly to *N*-desmethylvandetanib, and by flavin-containing mono-oxygenase enzymes FM01 and FM03 to vandetanib-*N*-oxide. The plasma half-life is about 19 days. Vandetanib and its metabolites are slowly excreted in the urine and faeces. Exposure to vandetanib is increased by renal impairment. Japanese and Chinese patients have been reported to have higher exposure to vandetanib compared with Caucasian patients.

Veltuzumab (USAN, rINN)

Immu-106; Veltuzumabum; Вептузумаб.

Immunoglobulin G1, anti-(human CD20 (antigen)) (human-mouse monoclonal hA20 heavy chain), disulfide with human-mouse monoclonal hA20 κ-chain, dimer.

CAS — 728917-18-8.

UNII — BPD4DGQ314.

Profile

Veltuzumab is a humanised monoclonal antibody that targets CD20 receptors on B-lymphocytes. It is under investigation for the treatment of chronic lymphocytic leukaemia, non-Hodgkin's lymphoma, idiopathic thrombocytopenia purpura, and rheumatoid arthritis.

Vemurafenib (USAN, rINN)

PLX-4032; RG-7204; RO-5185426; Vémurafénib; Vemurafenibum; Вемурафениб.

N-[3-[5-(4-Chlorophenyl)-1*H*-pyrrolo[2,3-*b*]pyridin-3-carbonyl]-2,4-difluorophenyl]propane-1-sulfonamide.

$C_{23}H_{18}ClF_2N_3O_3S$=489.9

CAS — 918504-65-1.

UNII — 207SMY3FQT.

Uses and Administration

Vemurafenib is a BRAF kinase inhibitor that is used for the treatment of unresectable or metastatic melanoma (p. 714.3) with $BRAF^{V600}$ mutation. The recommended oral dose is 960 mg twice daily. A missed dose may be taken up to 4 hours before the next dose. Tablets should be swallowed whole and not crushed or chewed. Vemurafenib may be taken with or without food, but regularly taking both daily doses on an empty stomach should be avoided as this may reduce its exposure (see Pharmacokinetics, p. 880.2). *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* Treatment is continued until disease progression or unacceptable toxicity occurs. The dose may need to be modified or withheld if toxicity occurs, see Administration in Subsequent Cycles, p. 880.1.

Vemurafenib is also under investigation for the treatment of thyroid cancer.

Administration in subsequent cycles. Oral doses of vemurafenib may need to be withheld, reduced, or treatment stopped if toxicity occurs.

- For grade 3 or intolerable grade 2 adverse effects: withhold treatment until effects have resolved to ≤grade 1. Treatment may be resumed at a dose of 720 mg twice daily after the first occurrence; after the second occurrence treatment should be resumed at 480 mg twice daily. If the same adverse effect recurs for a third time, vemurafenib should be permanently stopped.
- For grade 4 adverse effects: either permanently stop vemurafenib, or withhold until effects have resolved to ≤ grade 1 and then resume treatment at a dose of 480 mg twice daily. If the same adverse effect recurs for a second time, vemurafenib should be permanently stopped.
- For those with a QTc > 500 milliseconds during treatment: vemurafenib should be withheld and risk factors for QT interval prolongation controlled. Once the QTc has recovered to < 500 milliseconds, treatment may be resumed at a dose of 720 mg twice daily after the first occurrence; after the second occurrence treatment should be resumed at 480 mg twice daily. If QT interval prolongation recurs for a third time, vemurafenib should be permanently stopped. If, after risk factors for QT interval prolongation have been controlled, the QTc is still > 500 milliseconds and there is > 60 milliseconds increase from pretreatment values, vemurafenib should be permanently stopped.

Adverse Effects, Treatment, and Precautions

The most common adverse effects with vemurafenib are arthralgia, alopecia, fatigue, nausea, rash, photosensitivity, pruritus, and skin papilloma. Patients should avoid sun exposure, wear protective clothing, and apply sunscreen when outdoors to avoid photosensitivity. For intolerable grade 2 erythema, dose modifications are recommended, see Administration in Subsequent Cycles, above. Other effects on the skin include dry skin, actinic keratosis, palmar-plantar erythrodysesthesia syndrome, keratosis pilaris, seborrhoeic keratosis, and erythema nodosum. Stevens-Johnson syndrome and toxic epidermal necrolysis have occurred rarely; treatment should be permanently stopped in those who have a severe skin reaction.

Cutaneous squamous cell carcinomas have been reported in patients treated with vemurafenib, usually early in the course of treatment with a median time to first appearance of 7 to 8 weeks. Non-cutaneous squamous cell carcinoma, basal cell carcinoma, and new primary cases of malignant melanoma have also occurred. Monitoring for malignancies should be undertaken before, during, and for up to 6 months after treatment.

Hypersensitivity reactions include anaphylaxis, rash, erythema, and hypotension; treatment should be permanently stopped in those who have a severe reaction.

QT prolongation has been seen with vemurafenib, and treatment is not recommended in those with long QT syndrome, uncorrected electrolyte abnormalities, or those taking other medicines known to prolong the QT interval. ECG and electrolytes should be monitored before starting vemurafenib and after changing the dose. ECGs should also be checked 15 days after the start of treatment, monthly during the first 3 months of treatment, and then every 3 months thereafter (or more often if needed). Treatment should not be started in those with a QTc > 500 milliseconds; the dose may need to be withheld or reduced, or vemurafenib stopped, in those with a prolonged QT interval during treatment, see Administration in Subsequent Cycles, above.

Abnormalities in liver function tests have occurred during vemurafenib treatment, and liver function should be measured before starting treatment, and monthly during treatment or as needed. Vemurafenib may need to be withheld, the dose reduced, or treatment stopped if abnormalities occur, see Administration in Subsequent Cycles, above.

Effects on the eyes include blurred vision, iritis, photophobia, retinal vein occlusion, and uveitis. Patients should be monitored for signs of uveitis; treatment with corticosteroid and mydriatic eye drops may be required if uveitis occurs.

Other adverse effects that have occurred with vemurafenib include myalgia, musculoskeletal pain, oedema, fever, headache, dysgeusia, gastrointestinal disorders, cough, dizziness, peripheral neuropathy, Bell's palsy, folliculitis, vasculitis, and atrial fibrillation.

References.

1. Sinha R, *et al.* Cutaneous adverse events associated with vemurafenib in patients with metastatic melanoma: practical advice on diagnosis, prevention and management of the main treatment-related skin toxicities. *Br J Dermatol* 2012; 167: 987–94.

Interactions

In-vitro studies indicate that vemurafenib is a substrate of the cytochrome P450 isoenzyme CYP3A4, and therefore inhibitors or inducers of this enzyme may alter vemurafenib concentrations. Caution is required when vemurafenib is used with strong CYP3A4 inhibitors or inducers.

Vemurafenib is also a moderate CYP1A2 inhibitor, a weak CYP2D6 inhibitor, and a CYP3A4 inducer; use is not recommended with drugs that are metabolised via these routes and have a narrow therapeutic window. Exposure to caffeine (a CYP1A2 substrate) and dextromethorphan (a CYP2D6 substrate) was increased when given with vemurafenib, and a reduced dose of CYP1A2 and CYP2D6 substrates may be required if they must be given with vemurafenib. Exposure to midazolam (a CYP3A4 substrate) was decreased with vemurafenib.

Pharmacokinetics

When vemurafenib is taken orally at usual doses, peak plasma concentrations occur after about 3 to 4 hours and steady state is achieved in 15 to 22 days. Regularly taking vemurafenib on an empty stomach may lead to significantly lower steady state exposure than when taken with or just after food. Vemurafenib is highly protein bound (> 99%) to albumin and α-1 acid glycoprotein. *In-vitro* studies have shown that vemurafenib is a substrate and an inhibitor of P-glycoprotein. Only 5% of a dose of vemurafenib is metabolised; 94% of the dose is excreted in the faeces and 1% in the urine. The median elimination half-life is about 57 hours.

USP 36: (Verteporfin). Store at a temperature between -25 degrees and -10 degrees in airtight containers.

Uses and Administration

Verteporfin is a photosensitiser used in photodynamic therapy (see under Porfimer Sodium, p. 849.1). It is used to treat neovascular (wet) age-related macular degeneration (see below). After intravenous dosage verteporfin accumulates preferentially in the endothelial cells of actively growing blood vessels, including those in the choroid. When activated by laser light it produces local vascular occlusion and this inhibits neovascularisation and reduces the decline in visual acuity. It is given by intravenous infusion over 10 minutes at a dose of 6 mg/m^2. This is followed 15 minutes after the start of the infusion by activation using a laser tuned to a wavelength of 689 nanometres and delivered to the eye via a fibre optic device and a slit lamp, together with a suitable contact lens. The recommended light dose is 50 J/cm^2, given over 83 seconds. Therapy may be repeated every 3 months for recurrent choroidal neovascular leakage. Verteporfin has also been investigated in the photodynamic therapy of a variety of other disorders including malignant neoplasms.

Age-related macular degeneration. Age-related macular degeneration (AMD) is a degenerative disease usually occurring in people over the age of 50 years.[1-3] The central portion of the retina (the macula) deteriorates[2,4,5] and it is a major cause of severe visual loss in people over 60 years old in North America and Europe.[4,6] There are two main types of AMD.[2,4,6-9]

- In geographic atrophy or *non-neovascular* or *non-exudative (dry) AMD*, which occurs at an early stage of AMD, the retinal pigment epithelium is lost completely in localised areas, causing a gradual loss of central vision in the affected eye(s). It is characterised by retinal hypo- or hyperpigmentation, and yellow deposits of acellular amorphous debris beneath the retina, called drusen. These are usually large, or soft (with indistinct margins); small hard drusen occur naturally with ageing but, unlike drusen in AMD, do not progress.
- In *neovascular* or *exudative (wet) AMD*, new blood vessels develop in the choroidal layer beneath the retina; leaks or haemorrhage from these lead to macular oedema, retinal scarring, and often acute, significant loss of vision. This process of *choroidal neovascularisation* (CNV) is defined as classic or occult according to its appearance on fluorescein angiography;[2,5,8,10] the classic form is associated with more rapid progression than the occult form.[2,8] CNV lesions are also classified according to their location relative to the fovea.[1,2,11] Although the neovascular form accounts for only about 20% of all cases of AMD, the risk of severe visual loss with this form is much higher than with dry AMD.[1,8,12] However, about 10 to 20% of patients with dry AMD can progress to the neovascular form,[1,9] and both forms can occasionally co-exist in the same patient.[10]

Risk factors, besides older age, include a family history of the disorder, polymorphisms in either the complement factor H (CFH) or age-related maculopathy susceptibility 2 (ARMS2 or LOC387715) genes, smoking, white race, and increased body-mass index;[3,12,13] female sex, atherosclerosis, dietary fat or fish intake, alcohol or caffeine consumption, refractive error, iris colour, and increased exposure to sunlight have also been proposed as risk factors but have not consistently been related to development of AMD.[13]

There is currently no **treatment** that effectively prevents visual loss or improves vision in all patients with AMD.[14]

- Laser photocoagulation treatment is of proven efficacy for neovascular AMD, especially for extrafoveal CNV;[15] however, rates of recurrence are high.[1,6,13,14]
- Photodynamic therapy (see under Porfimer Sodium, p. 849.1) with verteporfin has been shown to decrease the risk of visual loss in patients with neovascular AMD, including subfoveal CNV.[1,4,8,10,11,14,16-20] Systematic reviews have noted that although photodynamic therapy with verteporfin is probably effective in preventing visual loss in those with classic and occult CNV due to AMD, the size of the effect remains in doubt.[5,21] Furthermore, the therapy can only be effective during the proliferative stage of the disease while the neovascular process is active.[5]

  In the UK, NICE guidelines considered the evidence to show a larger treatment effect in patients with classic CNV, and recommend photodynamic therapy in those patients with neovascular AMD with a confirmed diagnosis of classic, with no occult, subfoveal CNV.[2] However, other guidelines[22] on the use of verteporfin recommend that verteporfin treatment be considered for patients with minimally classic subfoveal CNV who have relatively small lesions, or where the proportion of classic CNV is increasing. For those patients with occult CNV and who are presumed to have recent disease progression, verteporfin may be considered in those with smaller lesions or lower levels of visual acuity; for those with large occult lesions, treatment may be considered if levels of visual acuity are rapidly decreasing. Patients should be followed up at least as often as every 3 months after initial therapy, and re-treated if necessary.[22] Subsequent results suggest that verteporfin is ineffective in occult lesions.[20]

  While photodynamic therapy is considered to have minimal adverse effects and a low complication rate, some have cautioned that patients should be counselled that verteporfin therapy rarely leads to an improvement in vision.[23]
- Vascular endothelial growth factor (VEGF) plays a role in the development of CNV secondary to AMD; pegaptanib and ranibizumab are VEGF inhibitors used in the treatment of neovascular (wet) AMD.[24-26] Systematic reviews[27,28] of randomised controlled studies of these drugs concluded that both show benefit in slowing or stopping the progression of disease. Greater effect was seen with ranibizumab than with pegaptanib, although head-to-head comparative studies are needed to confirm this. Use of pegaptanib is not recommended by NICE in the UK.[29] Early studies have reported benefit from the use of aflibercept.[30,31] Bevacizumab is also used, although its use is unlicensed and controversial.[6,15,32] (For further discussion, see Age-related Macular Degeneration, under Bevacizumab, p. 747.2.) Triamcinolone acetonide, a corticosteroid that may also downregulate VEGF, has been given intravitreally with variable results; combination treatment with photodynamic therapy is under investigation,[9,13,33] and initial results have been promising.[15]
- Angiogenesis inhibitors such as anecortave[3,9,13,14,33] and squalamine[15] are under investigation for neovascular AMD. Interferon alfa gave encouraging preliminary results, but controlled data showed no benefit.[9,13] Thalidomide has been tried, but studies were stopped due to adverse effects.[9,13]
- Vitamin and mineral supplements may be of use in selected patients; the AREDS study found that antoxidants (vitamin C, vitamin E, and betacarotene) plus zinc modestly benefited those with moderate to severe signs of the disease.[10,12,14] However, betacarotene

should be avoided in smokers,[3,6,9] and high doses of vitamins may have adverse effects.[12] The carotenoids, lutein and zeaxanthin, have been promoted as retinal protectants, but controlled data are lacking.[9,10,14,34,35] Some recommend that those at risk of AMD should be encouraged to stop smoking and to consume a diet including vegetables, fish, whole grains, and nuts, and to reduce consumption of fats especially vegetable oil.[7,12,34] A prospective cohort study found that a high dietary intake of vitamin E and zinc, or an above-median intake of the combination of vitamins C and E, betacarotene, and zinc were associated with a lower risk of incident AMD.[36] Daily supplementation with folic acid, pyridoxine, and cyanocobalamin during an average of 7.3 years of follow-up reduced the risk of AMD in a large cohort of women at increased risk for vascular disease; benefit emerged at about 2 years of follow-up and persisted throughout the study.[37] However, systematic reviews[38,39] have found no evidence to support the role of antoxidant vitamin and mineral supplements in the primary prevention of AMD.

- Retinal or macular surgery, and transpupillary thermotherapy have been investigated;[1,10,13,14,33] however, long-term data are lacking for surgery,[12] and use of transpupillary thermotherapy is not recommended.[15] Radiotherapy has also been tried with mixed results.[9,13] Retinal transplantation is under investigation.[6,10,14] Gene silencing with bevasiranib, a short interfering RNA (siRNA) therapeutic designed to turn off or silence the gene that produces VEGF, is also under investigation for wet AMD.[12,40,41]

Adverse Effects and Precautions

Photosensitivity will occur in all patients treated with verteporfin and patients should not be exposed to direct sunlight for 2 to 5 days after treatment. However, exposure to ambient indoor light is encouraged, as it allows gradual inactivation of any remaining drug. Headaches, injection site reactions, and visual disturbances occur frequently. Extravasation at the injection site may produce severe pain and inflammation and requires interruption of therapy. Patients who have a severe decrease in vision should not be re-treated until their vision recovers. Other reported adverse effects include hypersensitivity, infusion-related pain (mainly presenting as back pain), chest pain, gastrointestinal disturbances, atrial fibrillation, hypertension, decreased hearing, and anaemia. Verteporfin should be used with care in patients with hepatic impairment and may be contra-indicated if impairment is severe.

Porphyria. Licensed product information states that the use of verteporfin is contra-indicated in patients with porphyria. However, the Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies verteporfin as not porphyrinogenic: it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/11/11)

Interactions

Use of verteporfin with other drugs causing photosensitivity should be avoided as the reaction may be increased.

Pharmacokinetics

After intravenous doses, elimination of verteporfin is bi-exponential, with a terminal plasma elimination half-life of about 5 to 6 hours. Protein binding is about 90%. It is metabolised in the liver. It is excreted in faeces via the bile, mostly as unchanged drug, with less than 1% of a dose recovered in the urine.

$C_{46}H_{58}N_4O_9.H_2SO_4$=909.1

CAS — 865-21-4 (vinblastine); 143-67-9 (vinblastine sulfate).

ATC — L01CA01.

ATC Vet — QL01CA01.

UNII — N00W22YO2B.

Description. Vinblastine sulfate is the sulfate of an alkaloid, vincaleukoblastine, extracted from *Catharanthus roseus* (*Vinca rosea*) (Apocynaceae).

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 8: (Vinblastine Sulfate). A white or slightly yellowish, very hygroscopic, crystalline powder. It loses not more than 15% of its weight on drying. Freely soluble in water; practically insoluble in alcohol. A 0.15% solution in water has a pH of 3.5 to 5.0. Store at a temperature not exceeding -20 degrees in airtight glass containers. Protect from light.

USP 36: (Vinblastine Sulfate). A white or slightly yellow, odourless, hygroscopic, amorphous or crystalline powder. It loses not more than 15% of its weight on drying. Freely soluble in water. A 0.15% solution in water has a pH of 3.5 to 5.0. Store at a temperature between -25 degrees and -10 degrees in airtight containers. Protect from light.

Stability. Between about 5 and 20% of active drug was lost from solution when a solution of vinblastine sulfate 3 micrograms/mL in glucose 5% injection was stored for 48 hours in a range of intravenous burette giving sets, the highest loss being from cellulose propionate sets and the lowest from one made from methacrylate butadiene styrene.[1] Similarly, storage in PVC tubing led to a 42 to 44% loss from solution whereas only about 6% was lost over the 48 hours in polybutadiene tubing. The losses appeared to be due to drug sorption, and were therefore greater from the tubing which had a greater surface-area-to-volume ratio than the burettes.

1. McElnay JC, *et al.* Stability of methotrexate and vinblastine in burette administration sets. *Int J Pharmaceutics* 1988; **47**: 239–47.

Uses and Administration

Vinblastine sulfate is an antineoplastic vinca alkaloid that apparently acts by binding to the microtubular proteins of the spindle and arresting mitosis at the metaphase; it is thus specific for the M phase of the cell cycle. It also interferes with amino acid metabolism and possibly nucleic acid synthesis, and has some immunosuppressant activity. Multidrug resistance may occur.

Vinblastine sulfate is used, usually with other antineoplastics, in the treatment of Hodgkin's disease and other lymphomas, for some inoperable malignant neoplasms including those of the breast, bladder, and kidney, and in non-small cell lung cancer, choriocarcinoma, and Kaposi's sarcoma; vinblastine has also been used in the management of Langerhans-cell histiocytosis and advanced mycosis fungoides. It was formerly used with bleomycin and cisplatin (PVB) for testicular cancer, but other regimens are now preferred. See the cross-references given below.

Vinblastine sulfate is given by **intravenous** injection. Care should be taken to avoid extravasation and the intravenous injection may be given over 1 minute into a freely-running infusion of sodium chloride 0.9% if preferred. However, UK guidelines recommend that for adults and adolescents, the required dose should be supplied in a 50 mL infusion bag of sodium chloride 0.9% and infused intravenously over 5 to 10 minutes. (For adolescents treated in specialised paediatric units, see Administration in Children, p. 882.1.)

The usual dose of vinblastine sulfate is about 6 mg/m², not more often than once every 7 days. Single doses starting at 3.7 mg/m² and increasing at weekly intervals, over 4 weeks, to a usual maximum dose of 11.1 mg/m² have been given; doses have been increased above this, but should not exceed 18.5 mg/m². If a maintenance dose is required, it may be given every 7 days provided white cell counts permit (see below), and should be the maximum dose that the patient is able to tolerate without serious leucopenia occurring.

For doses in children, see p. 882.1.

White cell counts should be made before each injection and some sources suggest a repeat dose should not be given

unless the count has risen to at least 4000 cells/mm³ (but see also Bone-marrow Depression, p. 730.3). Dosage reduction is recommended in patients with hepatic impairment (see below).

Administration. Administration errors have occurred with the vinca alkaloids (see Administration Error, below). For UK guidelines on dilution of vinca alkaloids to avoid inadvertent intrathecal use, see p. 883.2.

Administration in children. Doses of vinblastine sulfate in children vary according to the disease treated, the schedule used, and whether it is used as a single agent or as part of a combination chemotherapy regimen. The usual dose is about 6 mg/m² given intravenously, not more often than once every 7 days. Single doses starting at 2.5 mg/m² and increasing at weekly intervals, over 4 weeks, to a usual maximum dose of 7.5 mg/m² have been given; doses have been increased above this, but should not exceed 12.5 mg/m².

UK guidelines state that doses of vinca alkaloids may be given via a syringe to children and adolescents treated in paediatric units.[1] For adolescents treated in adolescent or adult units, recommendations for administration are as for adults (see Uses and Administration, p. 881.3).

1. NHS National Patient Safety Agency. Rapid Response Report NPSA/2008/RRR004 (issued 11th August, 2008): using vinca alkaloid minibags (adult/adolescent units). Available at: http://www.nrls.npsa.nhs.uk/EasySiteWeb/getresource.axd?AssetID=60290&type=full&servicetype=Attachment (accessed 29/09/09)

Administration in hepatic impairment. Licensed product information states that the dose of vinblastine should be reduced by 50% in patients having a direct serum bilirubin value above 3 mg per 100 mL.

Blood disorders, non-malignant. The vinca alkaloids vinblastine and vincristine have been used in the treatment of auto-immune blood disorders such as immune thrombocytopenia (p. 1606.1). There are also reports of the haemolytic-uraemic syndrome/thrombotic thrombocytopenic purpura responding to treatment with intravenous injection of vincristine.[1-3] For further details on the treatment of thrombotic microangiopathies, see under Plasma, p. 1159.1. Vincristine has been given with normal immunoglobulin in the management of a patient with life-threatening thrombocytopenia due to sarcoidosis.[4] Vincristine has also been used for life-threatening haemangioma (p. 1605.3).

4. Larner AJ. Life threatening thrombocytopenia in sarcoidosis. *BMJ* 1990; 300: 317–19.

Histiocytic syndromes. The value of systemic chemotherapy in patients with Langerhans-cell histiocytosis (p. 692.1) is uncertain; however, it is certainly widely used in extensive disease, vinblastine being one of the drugs often employed.[1,2]

1. The French Langerhans' Cell Histiocytosis Study Group. A multicentre retrospective survey of Langerhans' cell histiocytosis: 348 cases observed between 1983 and 1993. *Arch Dis Child* 1996; 75: 17–24.
2. Gadner H, *et al.* A randomized trial of treatment for multisystem Langerhans' cell histiocytosis. *J Pediatr* 2001; 138: 728–34. Correction. *ibid.*; 139: 170.

Malignant neoplasms. Vinblastine plays an important role in the ABVD regimen in patients with Hodgkin's disease (p. 696.1). It also formed part of the effective, if toxic, PVB regimen used to treat germ cell (ovarian or testicular) cancer, p. 711.2 and p. 715.1 respectively, although other regimens tend now to be preferred. The vinca alkaloids are also active in gestational trophoblastic tumours (p. 691.2), and vinblastine is also used in the therapy of invasive bladder cancer (p. 700.2); it may be used in the adjuvant or palliative treatment of non-small-cell lung cancer (p. 710.2) and in the palliative care of advanced breast cancer (p. 702.1). It has been used in malignancies of the kidney (p. 708.3). Vinca alkaloids are also used to treat Kaposi's sarcoma (p. 718.1).

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bone-marrow depression, especially leucopenia, is the most common adverse effect with vinblastine and tends to be dose-limiting. Maximum depression occurs 5 to 10 days after a dose with recovery in a further 7 to 14 days. Leucopenia may be more severe in patients with cachexia or extensive skin ulceration: vinblastine should not be used in elderly patients with these conditions. Stomatitis, gastrointestinal bleeding, and abdominal pain may occur; nausea and vomiting respond to treatment with antiemetics.

The vinca alkaloids can produce central and peripheral (including autonomic) neurotoxicity, although these effects are less frequent with vinblastine. Symptoms include malaise, weakness, headache, depression, paraesthesia and numbness, loss of deep tendon reflexes, peripheral neuropathies, constipation and adynamic ileus, jaw pain, and convulsions. Damage to the eighth cranial nerve may result in vestibular and auditory toxicity leading to dizziness, nystagmus, vertigo, and partial or total deafness. A routine prophylactic regimen against constipation is recommended in patients receiving high doses of vinblastine. Overdosage has caused permanent damage to the CNS. Intrathecal use of the vinca alkaloids is contra-indicated because of the likelihood of fatal neurotoxicity (see Administration Error, below).

Other reported effects include skin reactions, alopecia, ischaemic cardiotoxicity, hypertension, dyspnoea and bronchospasm, and bone and tumour pain. A syndrome of inappropriate secretion of antidiuretic hormone has occurred at high doses, and may be relieved by fluid restriction and, if necessary, a suitable diuretic. Rare cases of anaphylaxis and anaphylactoid-type reactions have been reported with the vinca alkaloids.

Vinblastine is irritant to the skin and mucous membranes and extravasation may cause necrosis, cellulitis, and sloughing. The application of warmth and local injection of hyaluronidase may be of benefit in relieving the effects of extravasation. By analogy with its use in the management of vincristine overdosage (see p. 883.2), folinic acid has been suggested for use in overdosage with vinblastine.

Vinblastine should not be injected into an extremity with impaired circulation because of an increased risk of thrombosis. It should be given with caution and at reduced dosage to patients with hepatic impairment (see under Uses, above).

Administration error. *Intrathecal doses of vinca alkaloids, including vinblastine, result in ascending paralysis and death.* For reference to the successful treatment of inadvertent intrathecal dosage of vincristine, and UK guidelines on dilution of vinca alkaloids to avoid intrathecal use, see p. 883.2.

Handling and disposal. A method for the destruction of vincristine or vinblastine *wastes* using sulfuric acid and potassium permanganate.[1] Residues produced by degradation of either drug by this method showed no mutagenicity *in vitro*.

Urine and faeces produced for up to 4 and 7 days respectively after a dose of vinblastine should be handled wearing protective clothing.[2]

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies vinblastine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/09/11)

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Use with drugs that inhibit cytochrome P450 isoenzymes of the CYP3A subfamily may result in decreased metabolism of vinblastine and increased toxicity. Use with cisplatin has been reported to increase vinblastine plasma concentrations. For a report of the possible contribution of vinblastine to reduced plasma concentrations of phenytoin, see p. 544.1.

Analgesics. A report of enhanced hepatotoxicity in patients treated with interferon alfa and vinblastine who were given *paracetamol*.[1]

1. Kellokumpu-Lehtinen P, *et al.* Hepatotoxicity of paracetamol in combination with interferon and vinblastine. *Lancet* 1989; i: 1143.

Antibacterials. There is a report of severe vinblastine toxicity in 3 patients who received vinblastine and ciclosporin with *erythromycin*.[1] Adverse effects resolved on stopping erythromycin and recurred in 1 patient who was rechallenged with erythromycin.

1. Tobe SW, *et al.* Vinblastine and erythromycin: an unrecognised serious drug interaction. *Cancer Chemother Pharmacol* 1995; 35: 188–90.

Antineoplastics. Acute bronchospastic reactions after injection of a vinca alkaloid have been reported, usually in patients also given *mitomycin*,[1] and presenting as acute respiratory distress, cyanosis, and dyspnoea, often with the development of pulmonary infiltrates and pneumonitis.[2,3] Several fatalities due to respiratory complications have occurred. For reports of vascular toxicity and Raynaud's syndrome associated with the use of vinca alkaloids with *bleomycin* and other drugs, see Effects on the Cardiovascular System, p. 727.2.

1. Dyke RW. Acute bronchospasm after a vinca alkaloid in patients previously treated with mitomycin. *N Engl J Med* 1984; 310: 389.
2. Konits PM, *et al.* Possible pulmonary toxicity secondary to vinblastine. *Cancer* 1982; 50: 2771–4.
3. Ozols RF, *et al.* MVP (mitomycin, vinblastine, and progesterone): a second-line regimen in ovarian cancer with a high incidence of pulmonary toxicity. *Cancer Treat Rep* 1983; 67: 721–2.

Antivirals. Severe myelosuppression has occurred in patients given relatively high doses of vinblastine with *interferon alfa-n1*.

A patient who had been given vinblastine 6 mg/m² every 3 weeks had severe gastrointestinal and haematological toxicity and moderate renal failure when *HAART* with zidovudine, lamivudine, abacavir, nevirapine, and lopinavir with ritonavir was reintroduced.[1] The vinblastine dosage was eventually stabilised at 2 mg/m² during HAART without toxicity.

1. Korb R, *et al.* Life-threatening interaction between antiretroviral therapy and vinblastine in HIV-associated multicentric Castleman's disease. *Eur J Haematol* 2006; 76: 269–71.

Pharmacokinetics

Vinblastine is not reliably absorbed from the gastrointestinal tract. After intravenous use it is rapidly cleared from the blood and distributed to tissues; it is reported to be concentrated in blood platelets. It is extensively protein bound. Vinblastine is metabolised in the liver, by cytochrome P450 isoenzymes of the CYP3A subfamily, to an active metabolite desacetylvinblastine, and is excreted in faeces via the bile, and in urine; some is excreted as unchanged drug. The terminal half-life is reported to be about 25 hours. It does not cross the blood-brain barrier in significant amounts.

Description. Vincristine sulfate is the sulfate of an alkaloid, 22-oxovincaleukoblastine, obtained from *Catharanthus roseus* (*Vinca rosea*) (Apocynaceae).

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 8: (Vincristine Sulfate). A white or slightly yellowish, very hygroscopic, crystalline powder. It loses not more than 12% of its weight on drying. Freely soluble in water; slightly soluble in alcohol. A 0.1% solution in water has a pH of 3.5 to 4.5. Store at a temperature not exceeding -20 degrees in airtight glass containers. Protect from light.

USP 36: (Vincristine Sulfate). A white to slightly yellow, odourless, hygroscopic, amorphous or crystalline powder. It loses not more than 12% of its weight on drying. Freely soluble in water; slightly soluble in alcohol; soluble in methyl alcohol. A 0.1% solution in water has a pH of 3.5 to 4.5. Store at a temperature between -25 degrees and -20 degrees in airtight containers. Protect from light.

Uses and Administration

Vincristine is an antineoplastic vinca alkaloid that may act similarly to vinblastine (p. 881.3) by arresting mitosis at the metaphase.

Vincristine sulfate is used mainly in combination chemotherapy regimens for acute and chronic leukaemias, lymphomas, including Hodgkin's disease and non-Hodgkin's lymphomas, and multiple myeloma. It is also used for tumours of the breast, lung, head and neck, and soft-tissue sarcomas, as well as for paediatric solid tumours including Ewing's sarcoma, rhabdomyosarcoma, neuroblastoma, Wilms' tumour, retinoblastoma, and medulloblastoma. Vincristine has also been used in immune thrombocytopenia refractory to other agents. See also the cross-references given below.

Vincristine sulfate is given by **intravenous** injection. Care should be taken to avoid extravasation and the injection may be given over 1 minute into a freely-running intravenous infusion (usually sodium chloride 0.9%) if preferred. However, UK guidelines recommend that for adults and adolescents, the required dose should be supplied in a 50 mL infusion bag of sodium chloride 0.9% and infused intravenously over 5 to 10 minutes. (For adolescents treated in specialised paediatric units, see Administration in Children, below.)

The usual dose of vincristine sulfate is 1.4 to 1.5 mg/m^2 once weekly, up to a maximum weekly dose of 2 mg (see also Administration, below).

For doses in children, see below.

Blood counts should be carried out before giving each dose. Dosage reduction is recommended in patients with hepatic impairment (see below).

A *liposomal* formulation of vincristine is used in the treatment of patients with Philadelphia chromosome-negative acute lymphoblastic leukaemia who have had at least 2 relapses or whose disease has progressed following 2 or more anti-leukaemia therapies. Vincristine sulfate liposome injection is given by intravenous infusion (in sodium chloride 0.9% or glucose 5%) over 1 hour in a dose of 2.25 mg/m^2 once every 7 days. Doses may need to be modified if toxicity occurs. A liposomal formulation is also under investigation for metastatic uveal melanoma.

Action. Results *in vitro* suggested[1] a selective action of vincristine against lymphocytes of patients with chronic lymphocytic leukaemia; lymphocytes of healthy subjects were not so affected. A further study[2] confirmed these findings, and also found marked variation in vincristine susceptibility among individual chronic lymphocytic leukaemic cells. This suggests that vincristine may have effects other than arrest of mitosis.

1. Vilpo J, Vilpo L. Selective toxicity of vincristine against chronic lymphocytic leukaemia in vitro. *Lancet* 1996; 347: 1491–2.
2. Vilpo JA, *et al.* Selective toxicity of vincristine against chronic lymphocytic leukemia cells in vitro. *Eur J Haematol* 2000; 65: 370–8.

Administration. Although a maximum single dose of 2 mg is recommended for vincristine sulfate to reduce neurotoxicity, a review[1] has suggested that this guideline is overly rigid, since it does not take into account interindividual variations in pharmacokinetics and susceptibility to toxicity, which may be considerable. Furthermore the authors considered the evidence for effectiveness of this dosage limitation to be equivocal. They suggested beginning therapy at 1.4 mg/m^2 and adjusting subsequent doses according to toxicity.

Administration errors have occurred with the vinca alkaloids. For UK guidelines on dilution of intravenous vinca alkaloids to avoid inadvertent intrathecal use, see Administration Error, under Adverse Effects, below.

1. McCune JS, Lindley C. Appropriateness of maximum-dose guidelines for vincristine. *Am J Health-Syst Pharm* 1997; 54: 1755–8.

Administration in children. The suggested dose of vincristine sulfate for the treatment of paediatric tumours in children weighing over 10 kg is 1.4 to 2 mg/m^2, given **intravenously** once weekly, up to a maximum weekly dose of 2 mg. For those weighing 10 kg or less, the suggested initial dose is 50 micrograms/kg, given once weekly.

UK guidelines state that doses of vinca alkaloids may be given via a syringe to children and adolescents treated in paediatric units.[1] For adolescents treated in adolescent or adult units, recommendations for administration are as for adults (see Uses and Administration, above).

1. NHS National Patient Safety Agency. Rapid Response Report NPSA/2008/RRR004 (issued 11th August, 2008): using vinca alkaloid minibags (adult/adolescent units). Available at: http://www.nrls.npsa.nhs.uk/EasySiteWeb/getresource.axd?AssetID=60290&type=full&servicetype=Attachment (accessed 29/09/09)

Administration in hepatic impairment. Licensed product information states that the dose of vincristine should be reduced by 50% in patients having a serum bilirubin value above 3 mg per 100 mL (51 micromoles/litre).

Amyloidosis. For mention of regimens including vincristine used in the management of amyloidosis, see p. 819.3.

Blood disorders, non-malignant. Vincristine may be employed in the treatment of various auto-immune blood disorders, see under Vinblastine, p. 882.1.

Malignant neoplasms. Vincristine is widely used in the treatment of malignant neoplasms. It is a fundamental part of potentially curative regimens for acute lymphoblastic leukaemia, Hodgkin's disease and aggressive non-Hodgkins lymphomas (see p. 692.3, p. 696.1 and p. 696.3). It has also been used in chronic lymphocytic leukaemia (p. 693.3) and in other non-Hodgkin's lymphomas including AIDS-related lymphoma (p. 697.2), Burkitt's lymphoma (p. 697.3) and mycosis fungoides (p. 698.3). Other haematological malignancies in which it may be tried include multiple myeloma (p. 699.2). Among the solid neoplasms, vincristine is used in regimens to treat gestational trophoblastic tumours (p. 691.2), tumours of the brain (p. 701.2), head and neck (p. 708.1), Wilms' tumour (p. 709.1), small-cell lung cancer (p. 710.2), and thymoma (p. 715.3). It is also employed in regimens for neuroblastoma (p. 716.2), retinoblastoma (p. 717.2), and some sarcomas including sarcomas of bone, Kaposi's sarcoma, and rhabdomyosarcoma (see p. 717.3, p. 718.1, and p. 718.2).

Adverse Effects, Treatment, and Precautions

As for Vinblastine Sulfate, p. 882.1.

Bone-marrow depression occurs less commonly than with vinblastine but neurological and neuromuscular effects are more severe with vincristine and are dose-limiting. Walking may be impaired and the neurological effects may not be reversed for several months after the drug is stopped. Convulsions, often with hypertension, have occurred. Constipation is common and there may be abdominal pain. Urinary disturbances have occurred and alopecia is frequent.

Folinic acid has been given for the treatment of overdosage: suggested doses are as much as 100 mg of folinic acid intravenously every 3 hours for 24 hours, then every 6 hours for at least 48 hours. However, this is unlikely to be of benefit in reversing neuromuscular toxicity. For mention of the use of glutamic acid in managing the usually fatal consequences of inadvertent intrathecal dosage, see below.

Because severe constipation and impaction of faeces often occur with vincristine, laxatives or enemas may be necessary to ensure regular bowel function. Vincristine should be given with caution to patients with pre-existing neuromuscular disease and is contra-indicated in patients with the demyelinating form of Charcot-Marie-Tooth syndrome (see under Effects on the Nervous System, below). Doses may need to be adjusted in patients with hepatic impairment. Care should also be taken in elderly patients, who may be more susceptible to neurotoxicity.

A liposomal formulation of vincristine has been associated with hepatotoxicity and increased liver enzyme tests; hepatic function should be monitored.

Administration error. *Inadvertent intrathecal doses of vincristine result in ascending paralysis and death.*[1-3] However, in one case[1] treatment immediately after the error, and consisting of removal of contaminated spinal fluid and flushing with lactated Ringer's solution and fresh frozen plasma diluted in lactated Ringer's solution, plus intravenous and oral glutamic acid, was reported successful in stabilising neurological dysfunction and preventing death. A similar case of successful treatment has subsequently been reported,[4] in which immediate CSF aspiration and irrigation (with lactated Ringer's solution containing fresh frozen plasma to bind vincristine) for 6 days was combined with intravenous folate, glutamic acid, and pyridoxine.

Licensed product information therefore recommends the following treatment as soon as possible after inadvertent intrathecal injection:

- removal of as much CSF as is safely possible through the lumbar access
- CSF irrigation with lactated Ringer's solution, by continuous infusion at a rate of 150 mL/hour
- as soon as it is available, 25 mL of fresh frozen plasma should be added to every 1 litre of lactated Ringer's solution and infused at a rate of 75 mL/hour; the rate of infusion should then be adjusted to maintain a spinal fluid protein concentration of 150 mg per 100 mL

While stating that the roles of the following drugs in the reduction of neurotoxicity are uncertain, licensed product information also allows the use of:

- glutamic acid 10 g intravenously over 24 hours, followed by 500 mg orally, three times daily, for one month or until the neurological dysfunction has stabilised
- folinic acid 100 mg as an intravenous bolus, and then infused at a rate of 25 mg/hour for 24 hours, then 25 mg intravenously every six hours for 1 week
- pyridoxine 50 mg intravenously over 30 minutes, every 8 hours

While early recognition and immediate treatment with cerebrospinal fluid drainage and exchange may improve survival,[5] fatalities still occur despite these measures.[5,6] Recommendations[2,6] have been made in order to prevent further errors occurring, including restrictions on the prescription, administration, and storage of intrathecal drugs. In the UK, recommendations state that when vinca alkaloids are prescribed for adults and adolescents, syringes should not be used to administer the dose; instead, the required dose of vinca alkaloid should be supplied in a 50 mL infusion bag of sodium chloride 0.9%, and infused over 5 to 10 minutes. All vinca alkaloids should be labelled as being for intravenous use only, with a clear warning of the consequences of use by other routes. However, for children and adolescents being treated in specialised paediatric units, the use of syringes to administer vinca alkaloids is permitted.[7]

Effects on the nervous system. In its most typical form, vincristine neurotoxicity[8] manifests as a mixed sensorimotor neuropathy of the distal type. The earliest symptoms are sensory changes in the form of paraesthesias, accompanied by impairment and ultimately loss of deep tendon reflexes. In more severe forms, impairment of motor function occurs with wrist drop and foot drop, ataxia and gait abnormalities, and occasionally progressive quadriparesis.

In contrast to these peripheral neuropathies, which are usually associated with long-term usage, there may be short-term autonomic neuropathy resulting in constipation and occasionally ileus, abdominal pain, atony of the urinary bladder (which may lead to urinary retention), orthostatic hypotension, and rarely, impotence. Effects on the cranial nerves may result in ptosis, hoarseness (due to laryngeal nerve paralysis), or optic neuropathies. Effects on the CNS are rare, probably in part because of poor penetration into CSF, but include excessive release of antidiuretic hormone and consequent hyponatraemia.

Hallucinations have occurred[2] and effects on the special senses have been reported: both bilateral optic atrophy and blindness,[3] and profound neurological deafness (which was largely reversible on drug withdrawal)[4] have occurred. Convulsions associated with hypertension are another feature of vincristine toxicity.[5]

Toxicity is related to both the cumulative and the individual dose.[1] It usually begins in adults after receiving a total of 5 to 6 mg, and is significant by the time a cumulative dose of 15 to 20 mg is reached. If individual doses are low (less than 2 mg) or intervals between doses are longer than the usual week, patients can tolerate higher cumulative doses. Children tolerate vincristine better than adults, but the elderly are particularly prone to neurotoxicity. Patients with existing neurological disorders such as poliomyelitis or the Charcot-Marie-Tooth syndrome may be at increased risk of neurotoxicity.[8,9] It has been suggested that increased neurotoxicity may be associated with the use of ready-to-use solutions rather than reconstituted lyophilised preparations but this is unproven.[10-14]

There is no good treatment for the effects of vincristine on the nervous system: symptoms are largely reversible once dosage is interrupted, and should be managed with appropriate symptomatic care.[1] However, there is some suggestion that glutamic acid may be of benefit in treating neurotoxicity[15]—see also Administration Error, above. For the use of dinoprost to alleviate ileus induced by vinca alkaloids, see p. 2134.1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies vincristine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/09/11)

Pregnancy. For a report of a healthy infant born to a woman treated with a vincristine-containing chemotherapy regimen, see Pregnancy, under Teniposide, p. 867.2.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Use of vincristine with drugs that inhibit cytochromes of the CYP3A subfamily may result in decreased metabolism of vincristine and increased toxicity. If vincristine is used with asparaginase it should be given 12 to 24 hours before the enzyme: giving asparaginase with or before vincristine may reduce vincristine clearance and increase toxicity. For reports of vascular toxicity and Raynaud's syndrome associated with the use of vinca alkaloids with bleomycin and other drugs see Effects on the Cardiovascular System, p. 727.2.

Antibacterials. Severe neurotoxicity has occurred when *isoniazid* was added to the regimen of a patient receiving vincristine.[1]

1. Carrión C, *et al.* Possible vincristine-isoniazid interaction. *Ann Pharmacother* 1995; **29**: 201.

Antiepileptics. A pharmacokinetic study showed that systemic clearance of vincristine was 63% higher when it was given with *phenytoin* or *carbamazepine*, two inducers of the cytochrome P450 isoenzyme CYP3A4. The clinical significance of this finding is unknown.[1]

1. Villikka K, *et al.* Cytochrome P450-inducing antiepileptics increase the clearance of vincristine in patients with brain tumours. *Clin Pharmacol Ther* 1999; **66**: 589–93.

Antifungals. Toxicity has been reported to be increased in children who received *itraconazole* with or without nifedipine during treatment involving vincristine.[1-4] Itraconazole is presumed to potentiate the toxicity of vincristine either by inhibition of cytochrome P450 isoenzymes, thus reducing the clearance of vincristine,[1-4] or by inhibiting the P-glycoprotein efflux pump,[2,3] and increasing intracellular concentrations of vincristine. Nifedipine also decreases the clearance of vincristine, by similar mechanisms,[1,3,4] and can theoretically further potentiate toxicity.

4. Kamaluddin M, *et al.* Potentiation of vincristine toxicity by itraconazole in children with lymphoid malignancies. *Acta Paediatr* 2001; **90**: 1204–7.

Nifedipine. Vincristine toxicity may be potentiated by nifedipine, see Antifungals, above.

Pharmacokinetics

Vincristine is not reliably absorbed from the gastrointestinal tract. After intravenous injection it disappears rapidly from the blood. It is extensively protein bound and is reported to be concentrated in blood platelets. It is metabolised in the liver chiefly by the cytochrome P450 isoenzymes CYP3A4 and CYP3A5 and excreted mainly in the bile; about 70 to 80% of a dose is found in faeces, as unchanged drug and metabolites, while 10 to 20% appears in the urine. The terminal half-life is reported to be about 85 hours but may range from about 19 to 155 hours. Vincristine does not appear to cross the blood-brain barrier in significant amounts.

Vindesine Sulfate *(BANM, USAN, rINNM)*

Compound 112531 (vindesine); Desacetyl Vinblastine Amide Sulfate; LY-099094; NSC-245467 (vindesine or vindesine sulfate); Sulfato de vindesina; Vindeslinisulfaatti; Vindesina, sulfato de; Vindésine, sulfate de; Vindesine Sulphate; Vindesini Sulfas; Vindesinsulfat; Vindesin-sulfát; Vindezino sulfatas; Vindezin-szulfát; Виндезина Сульфат.

3-Carbamoyl-4-*O*-deacetyl-3-de(methoxycarbonyl)vincaleukoblastine sulfate.

$C_{43}H_{55}N_5O_7,H_2SO_4$=852.0

CAS — 53643-48-4 (vindesine); 59917-39-4 (vindesine sulfate).
ATC — L01CA03.
ATC Vet — QL01CA03.
UNII — CPH2U7DNDY.

Pharmacopoeias. In *Chin.* and *Eur.* (see p. vii).

Ph. Eur. 8: (Vindesine Sulfate). A white or almost white, hygroscopic, amorphous substance. Freely soluble in water and in methyl alcohol; practically insoluble in cyclohexane. The pH of a 0.5% solution in water is 3.5 to 5.5. Store in airtight polypropylene containers with a polypropylene cap, at a temperature not exceeding -50 degrees.

Uses and Administration

Vindesine sulfate is an antineoplastic agent derived from vinblastine (see p. 881.3); like the other vinca alkaloids it causes mitotic arrest in metaphase by binding to microtubular protein. It is used, alone or with other antineoplastics, in the treatment of refractory acute lymphoblastic leukaemia, blast crises of chronic myeloid leukaemia, malignant melanoma unresponsive to other therapy, and advanced carcinoma of the breast, unresponsive to surgery and/or hormonal therapy. See also the cross references given below.

Vindesine sulfate is given by **intravenous** injection. Care should be taken to avoid extravasation and the intravenous injection may be given over 1 to 3 minutes into a freely-running infusion (usually sodium chloride 0.9% or glucose 5%) if preferred. However, UK guidelines recommend that for adults and adolescents, the required dose should be supplied in a 50 mL infusion bag of sodium chloride 0.9% and infused intravenously over 5 to 10 minutes. (For adolescents treated in specialised paediatric units, see Administration in Children, below.) The usual starting dose of vindesine sulfate is 3 mg/m² which may be raised by increments of 500 micrograms/m² weekly providing that the granulocyte and platelet counts do not fall below 1500 cells/mm³ and 100 000 cells/mm³, respectively (see also Bone-marrow Depression, p. 730.3), and providing the patient has no acute abdominal pain; the maximum total weekly dose is 4 mg/m².

For doses in children, see below.

Blood counts should be made before each injection. It may be necessary to reduce initial doses in patients with significantly impaired hepatic function.

Administration. Administration errors have occurred with the vinca alkaloids (see Administration Error, below). For UK guidelines on dilution of vinca alkaloids to avoid inadvertent intrathecal use, see p. 883.2.

Administration in children. An initial dose of vindesine sulfate **4 mg/m² intravenously** may be given to children for the treatment of acute lymphoblastic leukaemia (resistant to other drugs). This may be increased in weekly increments of 500 micrograms/m² providing granulocyte and platelet counts do not fall below acceptable levels and provided the patient has no acute abdominal pain. The weekly dose for children usually ranges between 4 and 5 mg/m².

UK guidelines state that doses of vinca alkaloids may be given via a syringe to children and adolescents treated in paediatric units.[1] For adolescents treated in adolescent or adult units, recommendations for administration are as for adults (see Uses and Administration, above).

1. NHS National Patient Safety Agency. Rapid Response Report NPSA/2008/RRR004 (issued 11th August, 2008): using vinca alkaloid minibags (adult/adolescent units). Available at: http://www.nrls.npsa.nhs.uk/EasySiteWeb/getresource.axd?AssetID=60290&type=full&servicetype=Attachment (accessed 29/09/09)

Malignant neoplasms. Vindesine has been tried in refractory metastatic melanoma (p. 714.3), childhood acute lymphoblastic leukaemia (p. 692.3), chronic myeloid leukaemia in blastic crisis (p. 694.2), and neuroblastoma (p. 716.2). It is also under investigation in lung cancer, particularly non-small cell lung cancer (p. 710.2) and responses have been reported in advanced breast cancer (p. 702.1).

Adverse Effects, Treatment, and Precautions

As for Vinblastine Sulfate, p. 882.1.

The main dose-limiting effect of vindesine is granulocytopenia, with the nadir of the white cell count usually occurring 3 to 5 days after a dose and recovery after a further 4 to 5 days. Although neurotoxicity occurs it may be less severe than that seen with vincristine (see p. 883.1). Alopecia is the most common adverse effect.

Folinic acid has been suggested for the treatment of overdosage by analogy with vincristine.

Vindesine should not be given by the intrathecal route, as this may produce fatal toxicity. Care should be taken if acute abdominal pain occurs: further doses may result in paralytic ileus.

Administration error. *Inadvertent intrathecal doses of vinca alkaloids result in ascending paralysis and death.* In a 10-year-old child accidentally given an intrathecal injection of vindesine, treatment with folinic acid and dexamethasone produced transient recovery but symptoms subsequently recurred and the patient died of progressive ascending paralysis.[1] The CNS showed changes at necropsy similar to those seen after intrathecal vincristine. Other fatal cases[2,3] have subsequently been reported. For reference to the successful treatment of inadvertent intrathecal dosage of vincristine, and UK recommendations on dilution of vinca alkaloids to avoid intrathecal use, see p. 883.2.

3. Nisse P, *et al.* Administration accidentelle intrathécale de vindésine à propos de 2 cas mortels. *Therapie* 2007; **62**: 360–1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies vindesine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/09/11)

Interactions

As for Vinblastine Sulfate, p. 882.2.

Pharmacokinetics

The pharmacokinetics of vindesine are similar to those of the other vinca alkaloids. After intravenous doses elimination from the blood is triphasic; the drug is rapidly distributed to body tissues. The terminal half-life is reported to be about 20 hours. It is metabolised mainly in the liver and excreted in bile and urine.

Preparations

Proprietary Preparations (details are given in Volume B)

Vinflunine Tartrate *(rINNM)*

BMS-710485; F-12158; Tartrato de vinflunina; Vinflunine Ditartrate (BANM); Vinflunine Ditartrate (USAN); Vinflunine, Tartrate de; Vinflunini Tartras; Винфлунина Тартрат.
$C_{45}H_{54}F_2N_4O_8.2C_4H_6O_6$=1117.1
CAS — 194468-36-5.
ATC — L01CA05.
ATC Vet — QL01CA05.
UNII — 33MG53C7XW.

Uses and Administration

Vinflunine is a fluorinated vinca alkaloid derived from vinorelbine that has a similar antineoplastic action to vinblastine (p. 881.3). It is used in the treatment of advanced or metastatic bladder cancer (p. 700.2), as monotherapy after failure of a platinum-containing regimen. Vinflunine is given as the ditartrate but doses are expressed as the base; 1.37 mg of vinflunine ditartrate is equivalent to about 1 mg of vinflunine. It is given by intravenous infusion over 20 minutes, diluted in 100 mL sodium chloride 0.9% or glucose 5%, in a usual initial dose of vinflunine 320 mg/m² every 3 weeks. A lower initial dose of 280 mg/m² is given to patients with a performance status of 1 or less and prior pelvic irradiation; this can be increased thereafter to 320 mg/m² every 3 weeks in the absence of any toxicities.

Full blood counts should be monitored before each injection and the dose adjusted or delayed based on results; other toxicities may also affect the dose regimen (see Administration in Subsequent Cycles, below).

For dosage in patients with hepatic or renal impairment, see below.

Vinflunine is also being investigated in other neoplasms including non-small cell lung cancer and breast cancer.

Administration. Administration errors have occurred with the vinca alkaloids (see Administration Error, below). For UK guidelines on dilution of vinca alkaloids to avoid inadvertent intrathecal use, see p. 883.2.

Administration in hepatic impairment. The dose of vinflunine should be reduced in patients with hepatic impairment, according to Child Pugh class or based on prothrombin time, bilirubin, transaminase, and gamma glutamyl transferase (GGT) values.

The usual intravenous dose of vinflunine 320 mg/m² every 3 weeks is given to patients with the following hepatic parameters:

- prothrombin time > 70% of the normal value
  and
- bilirubin > the upper limit of normal (ULN) and ≤ 1.5 times the ULN
  and/or
- transaminases > 1.5 times the ULN and ≤ 2.5 times the ULN
  and/or
- GGT > the ULN and ≤ 5 times the ULN

A reduced intravenous dose of 250 mg/m² every 3 weeks is given to those with hepatic impairment defined as:

- Child Pugh class A
  or
- prothrombin time ≥ 60% of the normal value
  and
- bilirubin > 1.5 times the ULN and ≤ 3 times the ULN
  and
- transaminases > the ULN
  and/or
- GGT > 5 times the ULN

A reduced intravenous dose of 200 mg/m² every 3 weeks is given to those with hepatic impairment defined as:

- Child Pugh class B
  or
- prothrombin time ≥ 50% of the normal value
  and
- bilirubin > 3 times the ULN
  and
- transaminases > the ULN
  and
- GGT > the ULN

Vinflunine has not been studied in patients with Child Pugh class C, or in those with a prothrombin time < 50% of the normal value or with bilirubin > 5 times the ULN or with transaminases > 6 times the ULN or with GGT > 15 times the ULN.

Administration in renal impairment. The dose of vinflunine should be reduced in patients with renal impairment. UK licensed product information recommends the following based on creatinine clearance (CC):

- CC > 60 mL/min: usual intravenous dose of vinflunine 320 mg/m² every 3 weeks
- CC 40 to 60 mL/min: 280 mg/m² every 3 weeks
- CC 20 to 39 mL/min: 250 mg/m² every 3 weeks
- CC < 20 mL/min: not specified

Administration in subsequent cycles. Complete blood counts should be performed in all patients given vinflunine. Patients should not begin a new cycle if their absolute neutrophil count (ANC) is < 1000 cells/mm³ or if platelets are < 100 000 cells/mm³; treatment should be delayed until blood counts reach these levels or above. If recovery has not occurred within 2 weeks, treatment should be permanently stopped.

Dose adjustments are required for the following toxicities:

- grade 4 neutropenia (ANC < 500 cells/mm³) for > 7 days
- febrile neutropenia (ANC < 1000 cells/mm³ and fever ≥ 38.5 degrees)
- grade 2 mucositis or constipation for ≥ 5 days, or ≥ grade 3 for any duration
- any other toxicity that is ≥ grade 3, except grade 3 nausea or vomiting

If one of the above toxicities occurs in a patient whose initial intravenous dose of vinflunine was 320 mg/m² (the usual initial dose), a reduced dose of vinflunine 280 mg/m² is given. This is further reduced to 250 mg/m² if a toxicity occurs again in the next cycle; treatment should be permanently stopped for toxicities occurring in 3 consecutive cycles.

If one of the above toxicities occurs in a patient whose initial intravenous dose of vinflunine was 280 mg/m², a reduced dose of 250 mg/m² is given; treatment should be permanently stopped for toxicities occurring in 2 consecutive cycles.

For organ toxicity that is ≥ grade 2 on the day the next vinflunine dose is due, treatment should be delayed until recovery to ≤ grade 1.

Adverse Effects, Treatment, and Precautions

As for Vinblastine Sulfate, p. 882.1.

The main dose-limiting effect of vinflunine is neutropenia, and the dose should be adjusted according to regular blood counts. Use is contra-indicated in patients with a baseline absolute neutrophil count < 1500 cells/mm³ or a platelet count < 100 000 cells/mm³. Gastrointestinal adverse effects are also common; regular laxatives are recommended to prevent constipation. Other adverse effects include musculoskeletal adverse effects such as pain, myalgia, and arthralgia, and cardiovascular effects such as QT prolongation, tachycardia, ischaemia, and myocardial infarction; vinflunine should be used with caution in patients with pre-existing cardiac disease, or those with risk factors for QT prolongation. It should also not be given with other medicines that prolong the QT interval, or with potent inhibitors or inducers of the cytochrome P450 isoenzyme CYP3A4 (see under Interactions, below). Patients with hepatic or renal impairment may need a reduced dose of vinflunine (see under Uses, above and above).

Administration error. *Inadvertent intrathecal doses of vinca alkaloids result in ascending paralysis and death.* For reference to the successful treatment of inadvertent intrathecal dosage of vincristine, and UK recommendations on dilution of vinca alkaloids to avoid intrathecal use, see p. 883.2.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Vinflunine is metabolised by the cytochrome P450 isoenzyme CYP3A4; exposure to vinflunine or its active metabolite 4-*O*-deacetyl-vinflunine (DVFL) may be affected by inhibitors or inducers of this enzyme and their use with vinflunine is not recommended.

Caution is required when vinflunine is used with pegylated or liposomal doxorubicin, as exposure to vinflunine was increased and exposure to doxorubicin decreased with this combination. *In vitro* data have suggested that this could be due to adsorption of vinflunine on the liposomes and a change in the distribution of both drugs in the blood.

Vinflunine should not be given with other medicines that prolong the QT interval.

Pharmacokinetics

Vinflunine is moderately bound to plasma proteins, mainly high-density lipoproteins and serum albumin, and it is extensively distributed into the tissues. The main metabolite of vinflunine is 4-*O*-deacetyl-vinflunine (DVFL), which has some antineoplastic activity and is formed by multiple esterases. All other metabolites are inactive and are formed by the cytochrome P450 isoenzyme CYP3A4. Vinflunine has a terminal elimination half-life of about 40 hours, while DVFL is eliminated more slowly, with a half-life of about 120 hours. Excretion occurs via the faeces (about two-thirds) and the urine (about one-third).

Vinorelbine Tartrate *(BANM, USAN, rINNM)*

Tartrato de vinorelbina; Vinorelbiinitartraati; Vinorelbin Bitartrat; Vinorelbina, tartrato de; Vinorelbin-ditartarát; Vinorelbine Ditartrate; Vinorelbine, tartrate de; Vinorelbini Ditartras; Vinorelbini Tartras; Vinorelbino tartratas; Vinorelbintartrat; Винорелбина Тартрат; 5'-Nor-anhydrovinblastine Tartrate.

3',4'-Didehydro-4'-deoxy-8'-norvincaleukoblastine ditartrate.

$C_{45}H_{54}N_4O_8.2C_4H_6O_6$=1079.1
CAS — 71486-22-1 (vinorelbine); 125317-39-7 (vinorelbine tartrate).
ATC — L01CA04.
ATC Vet — QL01CA04.
UNII — 253GQW851Q.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US.*

Ph. Eur. 8: (Vinorelbine Tartrate). A white or almost white, hygroscopic powder. Freely soluble in water and in methyl alcohol; practically insoluble in hexane. A 1.4% solution in water has a pH of 3.3 to 3.8. Store under an inert gas at a temperature not exceeding -15 degrees. Protect from light.

USP 36: (Vinorelbine Tartrate). A white to yellow or light brown amorphous powder. Freely soluble in water. pH of a 1% solution in water is between 3.3 and 3.8. Store at a temperature between -25 degrees and -10 degrees in airtight containers. Protect from light.

Uses and Administration

Vinorelbine is a semisynthetic vinca alkaloid with antineoplastic activity similar to vinblastine (p. 881.3). It is used, alone or with other antineoplastics, in the first-line treatment of non-small cell lung cancer (p. 710.2) and in the treatment of advanced breast cancer (p. 702.1) that has relapsed or is refractory to an anthracycline-containing regimen.

Vinorelbine is given as the tartrate but doses are calculated in terms of vinorelbine: vinorelbine tartrate 1.385 mg is equivalent to about 1 mg of vinorelbine. Vinorelbine may be given orally or intravenously. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

It may be given by intravenous injection over 5 to 10 minutes, as a solution containing the equivalent of vinorelbine 1.5 to 3 mg/mL in glucose 5% or sodium chloride 0.9% injection, into a freely-running intravenous infusion. However, UK guidelines recommend that the required dose should be supplied in a 50 mL infusion bag of sodium chloride 0.9% or glucose 5% and infused intravenously over 5 to 10 minutes. It may also be given by intravenous infusion over 20 to 30 minutes after dilution in 125 mL of glucose 5% or sodium chloride 0.9%.

The usual initial intravenous dose in the treatment of breast cancer or non-small cell lung cancer is the equivalent of vinorelbine 25 to 30 mg/m² (maximum 60 mg) once weekly. Doses may be adjusted or delayed based on blood counts (see Administration in Subsequent Cycles, p. 886.1).

The drug is also given orally as a single agent in a dose of 60 mg/m² (maximum 120 mg) once weekly for 3 weeks. Subsequent doses may be increased to 80 mg/m² (maximum 160 mg), based on neutrophil counts (see Administration in Subsequent Cycles, p. 886.1). The dose and schedule may vary in combination regimens.

For dosage in patients with hepatic impairment or with massive liver metastases, see p. 886.1.

Administration. Administration errors have occurred with the vinca alkaloids (see Administration Error, below). For UK guidelines on dilution of vinca alkaloids to avoid inadvertent intrathecal use, see p. 883.2.

Administration in the elderly. UK licensed product information states that, while no relevant differences in response rates to vinorelbine have been seen in the elderly, greater sensitivity of some older patients cannot be ruled out; age is stated to not affect the pharmacokinetics of vinorelbine. A review[1] found conflicting data on the effect of age on pharmacokinetics of intravenous vinorelbine, yet concluded that no dose modification was required on the basis of age.

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; 25: 1832–43.

Administration in hepatic impairment. Clearance of intravenous vinorelbine was markedly reduced in patients with diffuse liver metastases and hence severely altered hepatic function: a 50% dose reduction was probably appropriate in such patients even if hyperbilirubinaemia was not marked.[1] However, reduced doses were not necessary in patients with moderate liver involvement in whom liver function, as measured by lidocaine metabolism, was not markedly reduced. Others have also confirmed that doses need not be reduced in mild to moderate hepatic impairment.[2]

Licensed product information in the UK suggests that the *intravenous* dose be reduced by one-third in patients with severe hepatic impairment (defined as bilirubin greater than twice the upper limit of normal (ULN) and/or transaminases greater than five times the ULN), or in those with massive liver metastases (more than 75% of liver volume replaced by tumour cells). In the USA, licensed product information recommends that the intravenous dose of vinorelbine be reduced by 50% in patients with total bilirubin values of 2.1 to 3 mg per 100 mL and by 75% in those with total bilirubin greater than 3 mg per 100 mL.

UK licensed product information recommends the following *oral* weekly doses of vinorelbine for patients with hepatic impairment:
- mild (bilirubin less than 1.5 times the ULN and transaminases from 1.5 to 2.5 times the ULN): 60 mg/m² (the standard dose)
- moderate (bilirubin 1.5 to 3 times the ULN): 50 mg/m²
- severe: use is contra-indicated

1. Robieux I, *et al.* Pharmacokinetics of vinorelbine in patients with liver metastases. *Clin Pharmacol Ther* 1996; 59: 32–40.
2. Kitzen JJ, *et al.* Mild to moderate liver dysfunction does not require dose reduction of oral or intravenous vinorelbine: results of a pharmacokinetic study. *Eur J Cancer* 2010; 46: 266–9.

Administration in subsequent cycles. Use of vinorelbine is contra-indicated if blood counts fall below acceptable levels.

In the UK, **intravenous** use is contra-indicated if platelet counts are less than 75 000 cells/mm³, or if neutrophils are less than 1500 to 2000 cells/mm³ (this varies slightly according to manufacturer), and treatment is delayed until recovery.

In the USA, dose adjustments (expressed as a percentage of the starting dose) are based on granulocyte counts as follows:
- ⩾ 1500 cells/mm³: 100%
- 1000 to 1499 cells/mm³: 50%
- < 1000 cells/mm³: dose should be omitted. Granulocyte counts are repeated in 1 week; if 3 consecutive counts are below this value, vinorelbine therapy should be stopped

For patients who, during treatment, had fever and/or sepsis while granulocytopenic, or had 2 consecutive weekly doses not given due to granulocytopenia, subsequent doses (expressed as a percentage of the starting dose) are:
- ⩾ 1500 cells/mm³: 75%
- 1000 to 1499 cells/mm³: 37.5%
- < 1000 cells/mm³: dose should be omitted. Granulocyte counts are repeated in 1 week, and if 3 consecutive weekly doses cannot be given, vinorelbine should be stopped altogether

For **oral** therapy, use is also contra-indicated if platelet counts are less than 75 000 cells/mm³ or if neutrophil counts are less than 1500 cells/mm³. For the recommended initial 3 doses, see Uses and Administration, p. 885.3. Subsequent doses are based on neutrophil counts. The recommended dose for the fourth week based on the neutrophil count during the first 3 doses (of 60 mg/m² weekly) is as follows:
- > 1000 cells/mm³: 80 mg/m²
- ⩾ 500 and < 1000 cells/mm³ (1 episode): 80 mg/m²
- ⩾ 500 and < 1000 cells/mm³ (2 episodes): 60 mg/m²
- < 500 cells/mm³: 60 mg/m²

Similarly, for any dose thereafter planned to be given as 80 mg/m², if the neutrophil count is below 1500 cells/mm³ and/or the platelet count is between 75 000 and 100 000 cells/mm³, then the treatment should be delayed until recovery. If the neutrophil count is below 500 cells/mm³ or more than once is between 500 and 1000 cells/mm³, the dose should be delayed until recovery and the dose reduced from 80 to 60 mg/m² weekly for the next 3 doses.

It is possible to re-escalate the weekly dose from 60 to 80 mg/m² if the neutrophil count did not drop below 500 cells/mm³, or to between 500 and 1000 cells/mm³ more than once, during 3 doses given at 60 mg/m².

Adverse Effects, Treatment, and Precautions

As for Vinblastine Sulfate, p. 882.1. The main dose-limiting effect of vinorelbine is neutropenia. The nadir of the neutrophil count occurs 5 to 10 days after a dose, with recovery usually after a further 7 to 14 days. The drug should be stopped if moderate or severe neurotoxicity develops. Other common adverse effects include taste disorders, dysphagia, insomnia, visual disorders, hypotension, cough, genito-urinary disorders such as dysuria, and chills. Severe hyponatraemia may occur. Local pain and thrombophlebitis may be seen with repeated injection of vinorelbine. Gastrointestinal effects such as nausea and vomiting are common with the oral formulation; giving capsules with food may reduce the incidence, and prophylaxis with antiemetics is recommended. Capsules should not be opened or chewed as the contents are irritant.

Care should be taken when using vinorelbine in patients with a history of ischaemic heart disease. Vinorelbine should not be given with radiotherapy if the treatment field includes the liver, and its use is contra-indicated in severe hepatic impairment, see Administration in Hepatic Impairment, above.

Administration error. *Inadvertent intrathecal doses of vinca alkaloids result in ascending paralysis and death.* For reference to the successful treatment of inadvertent intrathecal dosage of vincristine, and UK recommendations on dilution of vinca alkaloids to avoid intrathecal use, see p. 883.2.

Effects on the gastrointestinal tract. For reference to a report of vinorelbine possibly exacerbating ischaemic colitis in patients receiving docetaxel, see p. 781.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies vinorelbine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/09/11)

Interactions

As for Vinblastine Sulfate, p. 882.2. Vinorelbine is metabolised by the cytochrome P450 isoenzyme CYP3A4 and use with strong inhibitors or inducers of CYP3A4 may affect exposure to vinorelbine; caution is advised.

Antibacterials. A retrospective cohort study in Japan[1] found that patients given *clarithromycin* with vinorelbine were at greater risk for severe neutropenia than those given vinorelbine alone.

1. Yano R, *et al.* Evaluation of potential interaction between vinorelbine and clarithromycin. *Ann Pharmacother* 2009; 43: 453–8.

Pharmacokinetics

As with the other vinca alkaloids, vinorelbine exhibits triphasic pharmacokinetics after intravenous injection. Vinorelbine is rapidly absorbed from the gastrointestinal tract and peak plasma concentrations occur 1.5 to 3 hours after oral doses. The absolute bioavailability is about 40%; food does not alter exposure to vinorelbine. Comparable blood concentrations occur with oral vinorelbine doses of 60 and 80 mg/m² and intravenous doses of 25 and 30 mg/m², respectively. Vinorelbine is extensively distributed, especially into pulmonary tissues; however, it is not found in the CNS. Binding to plasma proteins is 13.5% but it is strongly bound to blood cells; binding to platelets is about 78%. Vinorelbine is metabolised via the cytochrome P450 isoenzyme CYP3A4. The metabolite 4-*O*-deacetylvinorelbine (deacetylvinorelbine), which has antineoplastic activity, is thought to be formed by carboxylesterases. The mean terminal half-life of vinorelbine is about 40 hours. Vinorelbine and its metabolites are excreted mainly in faeces via the bile but a small amount (less than 20% of a dose) is found in the urine, largely as unchanged drug.

Uses and Administration

Vismodegib is an orally active hedgehog pathway inhibitor that is used for the treatment of basal cell carcinoma (p. 714.2).

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

Vismodegib is used to treat patients with metastatic basal cell carcinoma, or with locally advanced disease that has recurred after surgery or who are not candidates for surgery, and who are not candidates for radiation. It is given in a dose of 150 mg once daily until there is disease progression or unacceptable toxicity. If a dose is missed it should be omitted and the next dose taken as scheduled. Capsules should be swallowed whole, and not opened or crushed.

Adverse Effects and Precautions

The most common adverse effects of vismodegib are muscle spasms, arthralgias, alopecia, fatigue, gastrointestinal disturbances, taste disturbances, reduced appetite, and weight loss. Amenorrhoea has been reported in some premenopausal women. Hyponatraemia, hypokalaemia, and azotaemia have also been found in some patients given vismodegib.

Vismodegib is expected to cause embryo-fetal death and severe birth defects, based on its mechanism of action and *animal* studies. Pregnancy should be excluded before starting vismodegib in female patients and highly effective contraception used during and for 7 months after therapy. The same potential risks apply to female partners of male patients, who can be exposed to vismodegib in semen; condoms with spermicide should be used, even after vasectomy, during and for 2 months after stopping vismodegib therapy.

Patients should also be advised not to donate blood or blood products during therapy and for 7 months after stopping vismodegib.

Interactions

The solubility of vismodegib is pH dependent and drugs that affect gastric pH, such as antacids, histamine H_2-antagonists, and proton pump inhibitors, may reduce its bioavailability. Drugs that inhibit P-glycoprotein might increase systemic exposure to vismodegib.

Pharmacokinetics

Vismodegib is absorbed from the gastrointestinal tract, but with an absolute bioavailability of only about 32% after a single dose. It is highly bound to plasma proteins. Vismodegib is excreted mainly as unchanged drug via the liver; about 82% of a dose is eliminated in the faeces and about 4.4% in the urine. The elimination half-life is about 12 days after a single dose, but 4 days after continuous once-daily dosing.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Israel*: Erivedge; *UK*: Erivedge; *USA*: Erivedge.

Vitespen *(USAN)*

gp-96; HSPPC-96.

Glucose regulated protein 94 (grp 94); Endoplasmin (human tumor rejection antigen 1).

CAS — 492448-75-6.

UNII — H3598Y1TLJ.

NOTE. The name Oncophage has been used as a trade mark for vitespen.

Profile

Vitespen is a personalised cancer vaccine (p. 757.3) prepared from heat shock glycoprotein 96 and associated peptides isolated from the patient's tumour, that stimulates an immune response to tumour cells. It is under investigation for the treatment of renal cell carcinoma, metastatic melanoma, and various other solid neoplasms.

Vorinostat *(USAN, rINN)*

SAHA; Suberoylanilide Hydroxamic Acid; Vorinostatum; Вориностат.

N-Hydroxy-*N*′-phenyl octanediamide.

$C_{14}H_{20}N_2O_3$=264.3

CAS — 149647-78-9.

ATC — L01XX38.

ATC Vet — QL01XX38.

UNII — 58IFB293JI.

Uses and Administration

Vorinostat is a histone deacetylase inhibitor used for the treatment of cutaneous T-cell lymphoma (see Non-Hodgkin's Lymphomas, p. 696.3). The recommended dose is 400 mg orally, given once daily with food. This may be reduced to 300 mg once daily, with a further reduction to 300 mg once daily for 5 consecutive days of each week, if needed. Treatment may be continued as long as there is no evidence of progressive disease or unacceptable toxicity. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Vorinostat is also under investigation for the treatment of multiple myeloma and mesothelioma.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The most common adverse effects of vorinostat are gastrointestinal disturbances, fatigue, chills, dry mouth and taste disorders. Thrombocytopenia and anaemia are also common, and are dose-related; dose reductions may be necessary and in some instances, therapy may need to be stopped. Pulmonary embolism and deep-vein thrombosis have occurred. Other adverse effects include muscle spasms, alopecia, dizziness, peripheral oedema, headache, pruritus, cough, upper respiratory-tract infection, and pyrexia. Increases in serum creatinine, hypokalaemia, and hyperglycaemia have been reported, as has prolongation of the QT interval. Blood cell counts, electrolytes, glucose, and serum creatinine should be monitored every 2 weeks during the first 2 months of therapy and monthly thereafter.

Interactions

Severe thrombocytopenia and gastrointestinal bleeding have been reported when vorinostat has been given with other histone deacetylase inhibitors such as valproic acid; platelet counts should be monitored every 2 weeks for the first 2 months of therapy. Vorinostat may prolong prothrombin time and affect the INR in patients receiving coumarin anticoagulants.

Pharmacokinetics

After an oral dose of vorinostat with a high-fat meal, mean time to peak plasma concentration was about 4 hours; this was reduced to 1.5 hours after fasting. Aside from this decrease in the rate of absorption, a high-fat meal also increased the extent of absorption. While these results were stated not to be clinically significant, licensed product information recommends that vorinostat be taken with food. Plasma protein binding is about 71%. Vorinostat is metabolised by glucuronidation and hydrolysis followed by oxidation; metabolites are pharmacologically inactive. Less than 1% of a dose is recovered in the urine as unchanged drug. The mean terminal half-life is about 2 hours for vorinostat.

Zalutumumab *(USAN, rINN)*

2F8; HuMax-EGFr; Zalutumumabum; Залутумаб.

Immunoglobulin G1, anti-(human epidermal growth factor receptor)(human monoclonal 2F8 heavy chain), disulfide with human monoclonal 2F8 κ-chain, dimer.

CAS — 667901-13-5.

Profile

Zalutumumab is a human monoclonal antibody targeted at the epidermal growth factor receptor (EGFR). EGFR is found on the surface of many cancer cells, and activation thereof promotes tumour cell growth. Zalutumumab is under investigation for the treatment of head and neck cancer.

References.
1. Rivera F, *et al.* Current situation of zalutumumab. *Expert Opin Biol Ther* 2009; 9: 667–74.

Zibotentan *(USAN, rINN)*

ZD-4054; Zibotentán; Zibotentanum; Зиботентан.

N-(3-Methoxy-5-methylpyrazin-2-yl)-2-[4-(1,3,4-oxadiazol-2-yl)phenyl]pyridine-3-sulfonamide.

$C_{19}H_{16}N_6O_4S$=424.4

CAS — 186497-07-4.

UNII — 8054MM4902.

Profile

Zibotentan is an endothelin-A receptor antagonist that is under investigation for the treatment of hormone-resistant prostate cancer and other solid tumours, although initial results have been disappointing.

References.

Zinostatin *(USAN, rINN)*

Neocarzinostatin; NSC-69856; NSC-157365; Zinostatina; Zinostatine; Zinostatinum; Зиностатин.

CAS — 9014-02-2.

UNII — PP082U6W1L.

Description. Zinostatin is an antineoplastic antibiotic obtained from *Streptomyces carzinostaticus*.

Pharmacopoeias. *Jpn* includes zinostatin stimalamer.

Profile

Zinostatin is an antibiotic with antineoplastic activity and has been used in the treatment of malignant neoplasms.

Zinostatin stimalamer, a conjugate of zinostatin with a styrene-maleic acid polymer, is given by hepatic intra-arterial injection for the treatment of liver cancer.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: SMANCS.

Zorubicin Hydrochloride *(USAN, rINNM)*

Hidrocloruro de zorubicina; NSC-164011; RP-22050 (zorubicin); Zorubicina, hidrocloruro de; Zorubicine, Chlorhydrate de; Zorubicini Hydrochloridum; Зорубицина Гидрохлорид.

Benzoic acid (2*S*-*cis*)-[1-[4-(3-amino-2,3,6-trideoxy-α-L-*lyxo*-hexopyranosyloxy)-1,2,3,4,6,11-hexahydro-2,5,12-trihydroxy-7-methoxy-6,11-dioxonaphthacen-2-yl]ethylidene]hydrazide hydrochloride.
$C_{34}H_{35}N_3O_{10}$,HCl=682.1
CAS — 54083-22-6 (zorubicin); 36508-71-1 (zorubicin hydrochloride).
ATC — L01DB05.
ATC Vet — QL01DB05.
UNII — WXM8D9M6DE.

Profile

Zorubicin is an anthracycline antibiotic with antineoplastic actions similar to those of doxorubicin (see p. 782.3). It has been used as the hydrochloride in the treatment of acute leukaemias.

Antiparkinsonian Drugs

The antiparkinsonian drugs described in this chapter can be broadly divided into 2 groups; the **dopaminergics**, drugs that are used to potentiate the actions of dopamine, and the **antimuscarinics**, drugs that are used to reduce excessive central cholinergic effects.

Dopamine is a key neurotransmitter in the CNS; in particular, striatal dopamine depletion is associated with the clinical condition of parkinsonism. Dopamine also inhibits prolactin release from the pituitary and is believed to be the prolactin-release inhibiting factor (PRIF or PIF); dopamine deficiency in the pituitary is associated with conditions characterised by hyperprolactinaemia. Accordingly, drugs that replenish central dopamine or that can act as stimulants of dopamine receptors (dopamine agonists), may alleviate the symptoms of parkinsonism (see below), hyperprolactinaemia (p. 2252.2), and related disorders.

At least 5 subtypes of dopamine receptor are thought to exist: D_1 receptors appear to stimulate adenylate cyclase activity; D_2 receptors activate various systems and inhibit adenylate cyclase activity. D_3, D_4, and D_5 receptors have been less well studied but D_3 and D_4 are similar to D_2, forming the D_2-like group, whereas D_1 and D_5 form the D_1-like group. D_2 receptors have been implicated in the pathophysiology of parkinsonism and schizophrenia.

Dopaminergics, or drugs that enhance their actions, described in this chapter include:

- levodopa, which is converted by decarboxylation into dopamine in the body, and which, unlike dopamine itself, can penetrate the blood-brain barrier and supply a source of dopamine to the brain
- the peripheral dopa-decarboxylase inhibitors, benserazide and carbidopa, which have no dopaminergic action of their own but increase the availability of levodopa
- apomorphine, which is structurally related to dopamine and acts as a dopamine agonist
- the adamantanamine, amantadine, which may augment dopaminergic activity
- the ergot derivatives, bromocriptine, cabergoline, lisuride, and pergolide, which act as dopamine agonists
- various other non-ergot dopamine agonists, such as piribedil, pramipexole, ropinirole, rotigotine, talipexole, and terguride
- the specific monoamine oxidase type B inhibitors, rasagiline and selegiline, which enhance the action of dopamine and levodopa
- the catechol-*O*-methyltransferase inhibitors (COMT-inhibitors), entacapone and tolcapone, which enhance the action of levodopa

Antimuscarinic drugs are used in Parkinson's disease (idiopathic or primary parkinsonism) and, particularly, drug-induced parkinsonism. They act by reducing the excessive central cholinergic effects of dopamine deficiency. Antimuscarinics described in this chapter include the tertiary amines, such as benzatropine, orphenadrine, procyclidine, and trihexyphenidyl, which are the most commonly used in the treatment of parkinsonism.

Drugs targeting non-dopaminergic pathways are being developed to reduce the impact of the motor complications associated with dopaminergic drugs. These include istradefylline, a selective adenosine A_{2A}-receptor antagonist that is given as an adjunct to levodopa therapy.

Parkinsonism

The syndrome of parkinsonism is characterised by tremor, rigidity, akinesia or bradykinesia, and loss of postural reflexes, associated with reduced dopamine activity in the brain. It may be classified as follows:

- primary (idiopathic) parkinsonism, usually referred to as Parkinson's disease (formerly paralysis agitans)
- secondary (acquired) parkinsonism, including postencephalitic parkinsonism, drug-induced parkinsonism, and symptoms associated with manganese poisoning
- 'parkinsonism-plus' syndromes where parkinsonism is a feature of other degenerative diseases of the CNS, such as progressive supranuclear palsy and multiple system atrophy

'Arteriosclerotic parkinsonism' has been used to describe parkinsonism associated with cerebrovascular disease, although this may be confusing since vascular brain damage is not a cause of Parkinson's disease.

The term parkinsonism is often used for the idiopathic form, that is, Parkinson's disease. Parkinson's disease and postencephalitic parkinsonism have been attributed mainly to depletion of striatal dopamine in the basal ganglia as a result of the loss of neurones in the substantia nigra. Striatal dopamine deficiency results in loss of the normal functional balance between dopaminergic and cholinergic activity and the aim of treatment is to increase the former and/or decrease the latter.

The **cause** of *Parkinson's disease* is not established, although environmental and genetic factors are probably superimposed on a background of neuronal loss related to ageing. MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), a contaminant of an illicitly produced pethidine analogue MPPP (1-methyl-4-phenyl-4-propionoxypiperidine), causes irreversible parkinsonism similar to Parkinson's disease. This effect appears to follow conversion by monoamine oxidase B to the neurotoxic methylphenylpyridinium ion, which is selectively concentrated in dopaminergic neurones in the substantia nigra. It has been proposed that free radicals produced during normal metabolism of dopamine in the brain by monoamine oxidase B might be similarly neurotoxic to dopaminergic neurones in the substantia nigra (the oxidant stress hypothesis). This has led to concern that use of levodopa, by increasing the supply of dopamine, might therefore exacerbate neurodegeneration and hasten the progression of Parkinson's disease but compelling evidence of such an effect is lacking.

Drug-induced parkinsonism (see Extrapyramidal Disorders, p. 1049.2) can arise from depletion of presynaptic dopamine, as with reserpine and tetrabenazine, or from blockade of postsynaptic dopamine receptors in the striatum, as by antipsychotics and some antiemetics such as metoclopramide. It is generally reversible on drug withdrawal or dose reduction and may sometimes disappear gradually despite continuous drug therapy. Although the use of levodopa to overcome antipsychotic-induced blockade of dopamine receptors might appear rational, it has generally been reported to be ineffective or to increase psychiatric symptoms. Antimuscarinics may provide relief from the extrapyramidal symptoms that occur as adverse effects of antipsychotic therapy; however, they do not relieve the symptoms of tardive dyskinesia and should be withdrawn if it develops.

There is no cure for Parkinson's disease. Although the possibility of using drug therapy to slow neurodegeneration is being investigated, no drug so far has a proven neuroprotective effect. **Treatment** is palliative and symptomatic and consists mainly of drug therapy supplemented when necessary with physical treatment such as physiotherapy and speech therapy. Surgery is occasionally used and there is growing interest in the use of transplantation and in electrical devices for the control of tremor.

Drugs used in Parkinson's disease. Drug therapy consists largely of the use of dopaminergics or antimuscarinics in an attempt to restore the normal balance between dopaminergic and cholinergic activity. Dopaminergics may act by direct replacement of dopamine, by delaying the metabolism of endogenous dopamine, by stimulation of dopamine receptors directly, or by enhancement of release of endogenous dopamine. Drugs with differing actions are often used together to achieve optimum control of symptoms.

- *Levodopa* is the most effective symptomatic treatment. It is converted by decarboxylation into dopamine and, unlike dopamine, can penetrate the blood-brain barrier and supply a source of dopamine to the brain. Levodopa is usually given with a peripheral dopa-decarboxylase inhibitor such as *benserazide* or *carbidopa*. These drugs are unable to penetrate the blood-brain barrier and therefore prevent only extracerebral conversion of levodopa to dopamine. This allows effective concentrations of dopamine to be achieved in the brain with lower doses of levodopa and also reduces nausea and vomiting and other adverse effects associated with peripheral formation of dopamine.

  The majority of patients respond initially to levodopa and its use has improved the quality and duration of life. However, after 2 years or more, benefit is reduced as the disease progresses and late complications emerge. Apart from dyskinesias and psychiatric effects, a major problem with long-term levodopa treatment is the appearance of fluctuations in mobility, the two predominant forms being 'end-of-dose' deterioration ('wearing-off' effect) and the 'on-off' phenomenon (see Complications of Treatment, below). Thus, views differ as to the best time to start treatment and the dosage to use in order to limit the long-term complications.

  Catechol-*O*-methyltransferase (COMT) inhibitors, such as *entacapone* and *tolcapone*, are selective and reversible inhibitors of COMT, with mainly peripheral actions. They are given as adjunctive therapy to patients with fluctuations in disability related to levodopa and dopa-decarboxylase inhibitor combinations; because of the risk of serious hepatotoxicity, tolcapone should be restricted to when other adjunctive therapy is ineffective or contra-indicated. When levodopa is used with a peripheral dopa-decarboxylase inhibitor, *O*-methylation becomes the predominant form of metabolism of levodopa; adding a peripheral COMT inhibitor can thus extend the duration and effect of levodopa in the brain, and allow lower and less frequent doses of levodopa. They therefore can help to stabilise patients, especially those with 'end-of-dose' deterioration.
- *Rasagiline* and *selegiline* are selective inhibitors of monoamine oxidase type B, an enzyme involved in the metabolism of dopamine in the brain. When used with levodopa in severe parkinsonism they have a dose-sparing effect and are of value in patients with fluctuations in mobility. Early treatment with selegiline may delay the need for levodopa and there has been much interest in the possibility that these drugs might have neuroprotective effects, but it is difficult to separate any putative effect on disease progression from symptomatic benefits, and at present there is insufficient evidence to show that any treatment can slow progression of the disease. Used alone, selegiline produces few adverse effects but when used with levodopa it can provoke or worsen dyskinesias or psychiatric symptoms and doubts have been expressed on the safety of long-term use.
- Dopamine agonists such as *bromocriptine, cabergoline, pergolide, pramipexole, ropinirole,* and *rotigotine* act by direct stimulation of remaining postsynaptic dopamine receptors. Dopamine agonists are increasingly used in the early treatment of younger patients with parkinsonism in an attempt to delay therapy with levodopa (younger patients are at an increased risk of motor complications with levodopa). However, their efficacy often decreases after a few years. In older patients they may be reserved for adjunctive use when levodopa is no longer effective alone or cannot be tolerated. They are sometimes useful in reducing 'off' periods with levodopa and in ameliorating fluctuations in mobility in the later stages of the disease. *Apomorphine* is a potent dopamine agonist, but must be given parenterally and with an antiemetic. Although this restricts its use, it has a role in stabilising patients who suffer unpredictable 'on-off' effects. It is also used in the differential diagnosis of parkinsonism.
- *Antimuscarinics* are considered to have a weak antiparkinsonian effect compared with levodopa. They may reduce tremor but have little effect on bradykinesia. They may be of use alone or with other drugs in the initial treatment of patients with mild symptoms, especially when tremor is pronounced, or later as an adjunct to levodopa, such as in patients with refractory tremor or dystonias. Antimuscarinic adverse effects, particularly cognitive impairment, occur frequently and can limit their use. However, some antimuscarinic effects can ameliorate complications associated with Parkinson's disease; dry mouth may be an advantage in patients with sialorrhoea. There appear to be no important differences in the efficacy of antimuscarinics for Parkinson's disease but some patients may tolerate one drug better than another. Those commonly used for Parkinson's disease include *benzatropine, orphenadrine, procyclidine,* and *trihexyphenidyl.*
- *Amantadine* is a weak dopamine agonist with some antimuscarinic activity although its activity as an antagonist of *N*-methyl-D-aspartate may also have a beneficial effect in Parkinson's disease. It has mild antiparkinsonian effects compared with levodopa but is relatively free from adverse effects. It can improve bradykinesia as well as tremor and rigidity but only a small proportion of patients derive much benefit. It is used similarly to antimuscarinics in early disease when symptoms are mild, but tolerance to its effects can occur rapidly.
- *Istradefylline* is a selective adenosine A_{2A}-receptor antagonist given as an adjunct to levodopa therapy. Drugs targeting non-dopaminergic pathways, such as the adenosine pathway, are being developed in order to reduce the impact of the motor complications associated with dopaminergic drugs.

Choice and implementation of drug treatment. If symptoms are mild, drug therapy may not be required in the early stages of the disease. When symptoms become troublesome but are still relatively mild *amantadine* or an *antimuscarinic* may be started; antimuscarinics are useful when tremor predominates but are generally more suitable for younger patients and in drug-induced rather than idiopathic parkinsonism. Some have begun treatment with

selegiline immediately, but there have been doubts over whether it has a neuroprotective effect, as postulated, and also over long-term safety. There is no consensus on when to start dopaminergic treatment or whether to begin with *levodopa* or a *dopamine agonist*. For most patients treatment with levodopa eventually becomes necessary, but many neurologists delay initial treatment with levodopa because of the increased risk of motor complications. New patients, especially younger patients, therefore often begin treatment with a dopamine agonist, with levodopa reserved for the elderly, the frail, or those with intercurrent illness or more severe symptoms.

When levodopa does become necessary, the usual practice is to start with small doses, given with a peripheral dopa-decarboxylase inhibitor, and increase slowly to a dose which reduces disability to an acceptable level. Variations in response and diminishing efficacy over the years necessitate careful adjustment of the size and form of the dose and the dosage schedule.

Complications of treatment. Fluctuations in mobility have been reported in more than half of patients on levodopa after 5 years of therapy. They generally proceed through predictable **'end-of-dose'** deterioration to the **'on-off'** phenomenon with marked very sudden swings from mobility to immobility. The cause of the fluctuations is not known, but multiple factors including desensitisation of dopamine receptors, interference with the response to dopamine by other levodopa metabolites such as 3-*O*-methyldopa, fluctuating plasma concentrations, and erratic transport of levodopa from blood to the brain have been suggested. It appears that as the disease progresses the capacity of the nigrostriatal dopaminergic system to synthesise and store dopamine, and to act as a buffer in maintaining dopamine brain concentrations, declines. Dopamine concentrations therefore become more dependent on levodopa dosage and the pattern of response will come to reflect more closely the rise and fall in levodopa concentrations. Eventually the effect of various factors that produce even small changes in plasma concentrations of levodopa will progressively become more pronounced.

Approaches to the management of 'end-of-dose' fluctuations include more frequent but smaller doses and the use of modified-release preparations. Addition of selegiline or partial replacement of levodopa by a dopamine agonist with a more prolonged action may also be tried.

Various attempts have been made to overcome the 'on-off' phenomenon. Those speculating that long-term treatment results in altered dopamine receptor sensitivity have used controlled withdrawal of levodopa for short periods ('drug holidays') but it is a dangerous procedure of doubtful value and no longer recommended.

Others have linked the 'on-off' phenomenon to variable plasma concentrations although, since transfer of levodopa into the brain involves active transport mechanisms, concentrations in plasma may not necessarily reflect those in the brain. Continuous intraduodenal or intravenous infusion of levodopa has been shown to reduce fluctuations in mobility, which suggests that dopamine receptors are still sensitive, although this is not practical for day-to-day management (but see below). However, there is evidence that some patients may benefit from modified-release formulations of levodopa with a peripheral dopa-decarboxylase or COMT inhibitor. As levodopa competes with amino acids for uptake into the brain, attempts to lessen fluctuations in dopamine brain concentrations have included taking levodopa on an empty stomach and also delaying most of a day's protein consumption until the evening. Addition of entacapone, rasagiline, selegiline, or a dopamine agonist may also help to reduce 'on-off' phenomena. If fluctuations remain a problem subcutaneous apomorphine is often effective. In some countries a gel formulation of levodopa with carbidopa is available for continuous infusion by an ambulatory pump into the duodenum when other available combination therapy has not been satisfactory.

Other complications of treatment with levodopa can include **dyskinesia**, which may respond to dosage adjustment or partial replacement of levodopa with a dopamine agonist. Amantadine may also be considered, although evidence is lacking. Some patients with Parkinson's disease may have **severe pain** and **dystonia**; measures to increase 'on' periods can help reduce or eliminate pain in most patients.

Patients with Parkinson's disease can suffer from a range of **psychiatric effects**, such as depression, dementia, sleep disturbances, and psychosis, due to the adverse effects of drug therapy and to disease progression. It has been recommended that if patients develop psychotic reactions, an attempt to adjust their antiparkinsonian drugs should be tried before resorting to the use of antipsychotics. Although classical antipsychotics are usually contra-indicated because they can exacerbate parkinsonism, atypical antipsychotics such as clozapine and quetiapine may be used in treatment-resistant psychosis—see Disturbed Behaviour, p. 1030.2. The cholinesterase inhibitor rivastigmine is licensed in some countries for the symptomatic treatment of mild to moderately severe dementia in Parkinson's disease. **Excessive daytime sleepiness** and **sudden onset of sleep** have been reported with dopamine agonists, as have **behavioural disturbances** including intense urges to gamble and increased sexual urges, and patients should be warned of the possible risks (see Effects on Mental Function, under Adverse Effects of Levodopa, p. 905.2). **Fibrotic reactions** resulting in cardiovascular and pulmonary adverse effects have been reported with ergot derivatives and patients should be monitored (see Fibrosis, under Adverse Effects of Bromocriptine, p. 897.3). **Nausea and vomiting** induced by dopaminergics may be minimised by introducing the drug gradually and giving the dose with food, but if this is ineffective or apomorphine is being used these effects can be controlled by the antiemetic domperidone. Domperidone does not readily cross the blood-brain barrier and therefore acts mainly as a peripheral dopamine antagonist. Tolerance to the nausea usually develops after a few weeks and domperidone may then be withdrawn.

CAS — 31377-23-8.

ATC — N04BB01.

ATC Vet — QN04BB01.

UNII — 992IT5P019.

Uses and Administration

Amantadine is a weak dopamine agonist with some antimuscarinic activity; it is also an antagonist at *N*-methyl-D-aspartate receptors. Amantadine has mild antiparkinsonian activity and is used in the management of parkinsonism (p. 891.2), mainly in early disease when symptoms are mild. It may improve bradykinesia, rigidity, and tremor but tolerance can develop.

Amantadine is also an antiviral that inhibits replication of influenza type A virus; it has very little or no activity against influenza type B virus. It is used prophylactically against infection with influenza type A virus and to ameliorate symptoms when given during the early stages of infection (but see p. 891.2).

Amantadine has also been used in the management of herpes zoster (see Varicella-zoster Infections, p. 956.2).

Amantadine is usually given orally as the hydrochloride and the doses below are expressed in terms of this salt.

In **parkinsonism**, treatment is usually started with 100 mg daily, increasing to 100 mg twice daily after a week or more. Doses up to a maximum of 400 mg daily have occasionally been used. The lowest effective dose should be used in patients over 65 years of age because of the potential for reduced renal clearance in this age group. Withdrawal of

amantadine treatment for parkinsonism should be gradual to avoid exacerbating the condition; UK licensed product information suggests decreasing the dose by half at weekly intervals.

The dose of amantadine in the UK for the treatment of **influenza A** is 100 mg daily, usually given for about 5 days. For the prophylaxis of influenza A the same dose is given for as long as protection from infection is required, which may be for about 6 weeks. If amantadine is being given with influenza vaccination then it is usually only given for up to 3 weeks after vaccination. Children aged 10 to 15 years may also be given 100 mg daily for the recommended period. A daily dose of less than 100 mg or 100 mg given at intervals greater than one day has been recommended for patients over 65 years of age.

Doses in the USA are higher than those in the UK: for the treatment of influenza A the daily dose is 200 mg daily as a single dose or in two divided doses, continued for 24 to 48 hours after the disappearance of symptoms. The same dose is given for the prophylaxis of influenza A for at least 10 days after exposure. If given with vaccination then amantadine should be taken for the next 2 to 4 weeks. The dose of amantadine should be reduced to 100 mg daily in patients aged 65 years and over, and in those who show intolerance to the higher dose. US licensed product information recommends that children aged 1 to 9 years may be given 4.4 to 8.8 mg/kg daily to a maximum of 150 mg daily, although the CDC suggests 5 mg/kg daily (maximum 150 mg daily) to reduce the risk of toxicity. Older children may be given 100 mg twice daily; CDC suggests that children weighing less than 40 kg should be given a dose of 5 mg/kg daily, regardless of their age.

In **herpes zoster**, treatment with 100 mg twice daily may be given for 14 days; if pain persists, treatment may be continued for a further 14 days.

The dosage of amantadine should be reduced in patients with renal impairment (see below).

Amantadine sulfate has been used similarly to the hydrochloride; it has been given orally or by intravenous infusion.

Administration. Amantadine sulfate has been used successfully in doses of up to 600 mg daily by intravenous infusion in the management of akinetic crisis in patients with Parkinson's disease.[1]

1. Gadoth N, *et al.* I.V. amantidine [sic] sulfate for extrapyramidal crisis. *Clin Pharm* 1985; 4: 146.

Administration in children. For doses of amantadine hydrochloride in the prophylaxis and treatment of influenza A in children, see p. 890.3.

Administration in renal impairment. The oral dose of amantadine hydrochloride should be reduced in patients with renal impairment by either reducing the total daily dose or by increasing the dosage interval in accordance with their creatinine clearance (CC).

In the UK the following doses are recommended:

- CC over 35 mL/min: 100 mg daily
- CC 15 to 35 mL/min: 100 mg every 2 to 3 days
- CC less than 15 mL/min: not recommended

In the USA the following doses are recommended:

- CC 30 to 50 mL/min: 200 mg on the first day followed by 100 mg daily thereafter
- CC 15 to 29 mL/min: 200 mg on the first day followed by 100 mg on alternate days
- CC less than 15 mL/min or those on haemodialysis: 200 mg every 7 days

See also under Precautions, p. 892.2.

Extrapyramidal disorders. Amantadine has been used as an alternative to antimuscarinics[1] in the short-term management of *drug-induced extrapyramidal symptoms* (p. 1049.2). US licensed product information has recommended a usual oral dose of 200 mg daily in 2 divided doses increased up to 300 mg daily if necessary. However, the development of tolerance has limited its usefulness. See also Parkinsonism, below.

Amantadine has been investigated in the management of *chorea* in patients with Huntington's disease.[2,3]

1. König P, *et al.* Amantadine versus biperiden: a double-blind study of treatment efficacy in neuroleptic extrapyramidal movement disorders. *Neuropsychobiology* 1996; 33: 80–4.
2. Magnet MK, *et al.* Amantadine in the akinetic-rigid variant of Huntington's disease. *Ann Pharmacother* 2004; 38: 1194–6.
3. Heckmann JM, *et al.* IV amantadine improves chorea in Huntington's disease: an acute randomized, controlled study. *Neurology* 2004; 63: 597–8.

Hepatitis C. Amantadine has been investigated[1-4] as an addition to interferon-based antiviral regimens in the treatment of chronic hepatitis C infection (p. 952.1). A meta-analysis[1] concluded that it was of no value in treatment-naive patients or relapsers, but that triple therapy with amantadine, ribavirin, and interferon improved sustained responses in patients previously unresponsive to therapy.

1. Delenne P, *et al.* Evaluation of amantadine in chronic hepatitis C: a meta-analysis. *J Hepatol* 2004; 41: 462–73.
2. Stauber RE, *et al.* Retreatment of patients with chronic hepatitis C not responding to interferon/ribavirin combination therapy with daily interferon plus ribavirin plus amantadine. *Wien Klin Wochenschr* 2004; 116: 530–5.
3. Herrine SK, *et al.* Peginterferon alpha-2a combination therapies in chronic hepatitis C patients who relapsed after or had a viral breakthrough on therapy with standard interferon alpha-2b plus ribavirin: a pilot study of efficacy and safety. *Dig Dis Sci* 2005; 50: 719–26.
4. Mangia A, *et al.* A randomized controlled trial of pegylated interferon alpha-2a (40 KD) or interferon alpha-2a plus ribavirin and amantadine vs interferon alpha-2a and ribavirin in treatment-naive patients with chronic hepatitis C. *J Viral Hepatitis* 2005; 12: 292–9.

Hiccup. Amantadine[1] has been reported to have produced beneficial results in patients with intractable hiccups. For the management of intractable hiccups see under Chlorpromazine, p. 1046.3.

1. Askenasy JJM, *et al.* Persistent hiccup cured by amantadine. *N Engl J Med* 1988; 318: 711.

Influenza. Amantadine has been used similarly to rimantadine (p. 1012.2) in the prophylaxis and treatment of influenza A (p. 960.2). In adults, the two drugs are equally effective, but amantadine is associated with more adverse effects;[1] further study on their safety and efficacy in children and the elderly is considered warranted.[2] Amantadine reduced the duration of influenza A symptoms when given in a dose of 200 mg daily within 48 hours of the onset of symptoms.[3] However, although amantadine is licensed in the UK and USA for the prophylaxis and treatment of influenza A, its use for such purposes is not recommended by authorities in these countries because of resistance in circulating influenza A virus strains.[4-6]

Resistance to amantadine may occur rapidly.[7] For further information see Resistance, under Rimantadine, p. 1013.1.

Multiple sclerosis. Amantadine has been used to alleviate fatigue associated with multiple sclerosis (p. 996.3). However, a systematic review[1] concluded that there was insufficient evidence to support its use in reducing fatigue in patients with multiple sclerosis; further large controlled studies are considered warranted.

1. Pucci E, *et al.* Amantadine for fatigue in multiple sclerosis. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2007 (accessed 29/05/08).

Neuroleptic malignant syndrome. Amantadine has been tried[1-3] in the treatment of the neuroleptic malignant syndrome (p. 1050.2).

3. Woo J, *et al.* Neuroleptic malignant syndrome successfully treated with amantadine. *Postgrad Med J* 1986; 62: 809–10.

Parkinsonism. Amantadine's mechanism of action in parkinsonism (p. 889.1) is unclear but may be due to its antimuscarinic activity and alterations in dopamine release and reuptake. It has also been suggested that its action as a non-competitive antagonist of *N*-methyl-D-aspartate may have a beneficial effect.[1,2] It has mild antiparkinsonian activity compared with levodopa but is relatively free from adverse effects. It can improve bradykinesia as well as tremor and rigidity and is used in a similar manner to antimuscarinics mainly in the treatment of patients with early Parkinson's disease when symptoms are mild. It may also be useful for dyskinesias in more advanced disease.[3] However, few patients obtain much benefit and tolerance to its effects can occur. Moreover, two systematic reviews[4,5] concluded that there was insufficient evidence from randomised controlled studies on the safety and efficacy of amantadine in the treatment of both Parkinson's disease and levodopa-induced dyskinesias in late disease.

Licensed product information suggests that the efficacy of amantadine may be prolonged by withdrawing it for 3 to 4 weeks, continuing with existing antiparkinsonian therapy or starting low-dose levodopa treatment if clinically necessary in the meantime.

5. Crosby NJ, *et al.* Amantadine for dyskinesia in Parkinson's disease. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2003 (accessed 16/02/06).

Withdrawal syndromes. *COCAINE.* Despite some early promising results a systematic review[1] considered that there was no evidence to support the use of dopamine agonists, including amantadine, in the treatment of cocaine dependence (p. 1990.1).

1. Soares B, *et al.* Dopamine agonists for cocaine dependence. [Withdrawn]. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2010 (accessed 23/08/10).

Adverse Effects

Most adverse effects associated with amantadine therapy appear to be dose-related and relatively mild; some resemble those of antimuscarinic drugs. They may be reversed by withdrawing therapy but many resolve despite continuation.

Livedo reticularis, sometimes associated with ankle oedema, is quite common in patients given very high doses of amantadine or with long-term therapy. CNS effects such as anxiety, inability to concentrate, dizziness, insomnia, nightmares, headache, and changes in mood may occur. Psychotic reactions, hallucinations, and confusion have been reported, especially in the elderly, patients with renal impairment or psychiatric disorders, and those also receiving antimuscarinics.

Other adverse effects reported have included orthostatic hypotension, palpitations, urinary retention, slurred speech, ataxia, lethargy, anorexia, nausea, vomiting, dry mouth, constipation, rash, diaphoresis, and blurred vision. There have been isolated reports of congestive heart failure, photosensitisation leucopenia, neutropenia, dyskinesias, oculogyric episodes, and convulsions.

Effects on the cardiovascular system. Congestive heart failure has been reported with amantadine;[1] the patient had been receiving combined treatment with amantadine, levodopa, and orphenadrine for 4 years. Others have considered that while amantadine sometimes causes ankle oedema, an association between amantadine and heart failure is not proven.[2] Livedo reticularis, a mottled blue discoloration of the skin due to prominence of the normal pattern of venous drainage, has been reported[2] to occur in about 50% of all elderly patients given amantadine 100 to 300 mg daily for 2 to 6 weeks and was associated with oedema in 5 to 10%. Both livedo and oedema have usually been confined to the legs and may result from the catecholamine-releasing action of amantadine in certain vascular beds; the oedema was unlikely to be due to heart failure. Angina, dyspnoea, pulmonary congestion, or distension of neck veins has also been reported[2] in 4 of 89 parkinsonian patients treated with amantadine; only 2 of these 4 had had ankle oedema before heart failure developed. No patient had been seen in whom heart failure seemed due directly to amantadine.

See also Overdosage, p. 892.1.

2. Parkes JD, *et al.* Amantadine-induced heart-failure. *Lancet* 1977; i: 904.

Effects on electrolytes. For a report of a patient who developed hyponatraemia when given amantadine or levodopa, see Effects on Kidney Function under Levodopa, p. 905.2.

Effects on the eyes. Superficial punctate keratitis and corneal abrasion with loss of visual acuity was seen in both eyes of a 64-year-old man about 3 weeks after starting treatment with amantadine 100 mg daily.[1] Symptoms resolved on stopping amantadine but recurred when retreatment with amantadine was attempted. In another report,[2] a 14-year-old boy developed bilateral corneal oedema with visual loss associated with amantadine treatment. He had been taking amantadine 300 mg daily for several months with many other drugs; symptoms resolved when amantadine was stopped.

1. Nogaki H, Morimatsu M. Superficial punctate keratitis and corneal abrasion due to amantadine hydrochloride. *J Neurol* 1993; 240: 388–9.
2. Hughes B, *et al.* Reversible amantadine-induced corneal edema in an adolescent. *Cornea* 2004; 23: 823–4.

Effects on mental function. It has been suggested[1] that the ability of amantadine and memantine to cause psychotic

disturbances in patients with Parkinson's disease might be related to their action as *N*-methyl-D-aspartate antagonists.

For reference to disturbed behaviour including excessive gambling, and to daytime somnolence reported in patients with Parkinson's disease receiving dopamine agonists, see under Levodopa, p. 905.2.

1. Riederer P, *et al.* Pharmacotoxic psychosis after memantine in Parkinson's disease. *Lancet* 1991; 338: 1022–3.

Effects on the nervous system. Peripheral sensory motor neuropathy secondary to long-term (8 years) use of amantadine has been reported[1] in a 48-year-old woman with parkinsonism. Trophic skin ulcers, paraesthesias, and distal weakness resolved on stopping amantadine.

1. Shulman LM, *et al.* Amantadine-induced peripheral neuropathy. *Neurology* 1999; 53: 1862–5.

Overdosage. A patient with postencephalitic parkinsonism who had taken an estimated 2.8 g of amantadine hydrochloride in a suicide attempt developed acute toxic psychosis with disorientation, visual hallucinations, and aggressive behaviour.[1] Convulsions did not occur, possibly because he had been receiving phenytoin, which was continued. The patient was treated with hydration and chlorpromazine and recovered in 4 days.

A 2-year-old child who had ingested 600 mg of amantadine hydrochloride developed symptoms of acute toxicity, including agitation and dystonic posturing, despite emesis with 'syrup of ipecac'.[2] She responded immediately to physostigmine 500 micrograms intravenously, repeated after 10 minutes. Her pupils remained moderately dilated until about 20 hours after the ingestion; thereafter she made a full recovery.

Cardiac arrest developed 4 hours after a 37-year-old woman ingested 2.5 g of amantadine hydrochloride and was treated successfully.[3] However, ventricular arrhythmias, including torsade de pointes, continued over the ensuing 48 hours and may have been exacerbated by use of isoprenaline and dopamine. The patient was subsequently stabilised with lidocaine by intravenous infusion, but died of respiratory failure 10 days after admission.

3. Sartori M, *et al.* Torsade de pointe: malignant cardiac arrhythmia induced by amantadine poisoning. *Am J Med* 1984; 77: 388–91.

Precautions

Amantadine is usually contra-indicated in severe renal disease and in patients with a history of epilepsy or other seizure disorders, or gastric ulceration. It should also not be given to patients with untreated angle-closure glaucoma. Amantadine should be used with caution in patients with cardiovascular or liver disease, renal impairment, recurrent eczema, or psychiatric disorders. Suicide attempts, in some cases fatal, and suicidal ideation have been reported in patients taking amantadine. Care should be taken in all elderly patients, who may be more sensitive to antimuscarinic effects, and in whom renal clearance is likely to be reduced.

In common with other drugs having antimuscarinic properties amantadine may cause blurred vision or impair alertness; patients so affected should not drive or operate machinery.

Treatment with amantadine should not be stopped abruptly in parkinsonian patients since a sudden marked clinical deterioration may occur. There have been isolated reports of a neuroleptic malignant-like syndrome associated with abrupt withdrawal of amantadine, especially in patients also receiving antipsychotics.

Antiviral resistance. See Influenza under Uses and Administration, p. 891.2.

Breast feeding. Amantadine is distributed into breast milk and licensed product information states that adverse effects have occurred in breast-fed infants of mothers taking amantadine.

Pregnancy. Amantadine should not be used during pregnancy; embryotoxicity and teratogenicity have been reported in *rats* given high doses.[1]

A complex cardiovascular lesion occurred in an infant whose mother had taken amantadine hydrochloride 100 mg daily during the first 3 months of pregnancy.[1] In another case, tetralogy of Fallot and limb deformities were seen in the neonate of a mother who was given amantadine hydrochloride 100 mg daily for 7 days during the 4th and 6th weeks of gestation.[2] However, a report of the use of amantadine during 2 separate pregnancies by a woman with multiple sclerosis noted no abnormalities in either infant.[3]

3. Levy M, *et al.* Fetal outcome following intrauterine amantadine exposure. *Reprod Toxicol* 1991; 5: 79–81.

Renal impairment. Evidence of extremely limited excretion of amantadine was found in 12 patients who were either anephric or had negligible renal function after a single 100-mg dose of amantadine hydrochloride.[1] Only small amounts were removed by dialysis. It was suggested that amantadine should be given with caution to patients requiring maintenance haemodialysis; a single dose may provide adequate plasma concentrations for many days.[1]

Dosage regimens based on creatinine clearance[2] or fixed doses at extended intervals[3] have been published. However, both regimens have been criticised and a conservative approach to amantadine dosage in these patients recommended[4] (for the regimens in licensed product information, see Administration in Renal Impairment, p. 891.1). The need for caution in using amantadine in patients with renal impairment is highlighted by a report of a patient with end-stage renal disease who progressed from delirium to coma after receiving amantadine 100 mg twice daily for 3 days.[5]

5. Macchio GJ, *et al.* Amantadine-induced coma. *Arch Phys Med Rehabil* 1993; 74: 1119–20.

Withdrawal. Neuroleptic malignant syndrome occurred in a patient being treated for heat stroke when all his medication, including antipsychotics and amantadine, was withdrawn.[1] It is suggested that dopamine agonists should not be stopped in patients with hyperpyrexia at risk from this syndrome. In another report,[2] a 14-year-old boy being treated with amantadine for influenza A encephalopathy developed neuroleptic malignant syndrome when the drug was stopped after 5 days; the patient improved when amantadine treatment was resumed. The authors recommended a gradual reduction in dosage when stopping amantadine therapy.

Acute delirium developed in 3 elderly patients with Parkinson's disease after gradual withdrawal of long-term amantadine therapy;[3] symptoms resolved when amantadine was restarted.

2. Ito T, *et al.* Neuroleptic malignant syndrome following withdrawal of amantadine in a patient with influenza A encephalopathy. *Eur J Pediatr* 2001; 160: 401.
3. Factor SA, *et al.* Acute delirium after withdrawal of amantadine in Parkinson's disease. *Neurology* 1998; 50: 1456–8.

Interactions

Amantadine may enhance the adverse effects of antimuscarinics and the dose of these drugs should be reduced when used with amantadine; adverse effects of levodopa may also be exacerbated.

Licensed product information states that amantadine should be used with caution in patients receiving drugs that affect the CNS. The rate of excretion of amantadine may be reduced by drugs that raise urinary pH.

Antiarrhythmics. *Quinine* and *quinidine* have been reported to reduce the renal clearance of amantadine in healthy male, but not female, subjects.[1] Patients taking these drugs together should be observed for signs of amantadine toxicity.

1. Gaudry SE, *et al.* Gender and age as factors in the inhibition of renal clearance of amantadine by quinine and quinidine. *Clin Pharmacol Ther* 1993; 54: 23–7.

Antimalarials. For the possible effects of the use of *quinine* and *quinidine* with amantadine, see Antiarrhythmics, above.

Diuretics. A patient with Parkinson's disease, previously stabilised on amantadine hydrochloride 300 mg daily, developed symptoms of amantadine toxicity, including ataxia, myoclonus, and confusion, 7 days after starting treatment with a preparation containing *triamterene* and *hydrochlorothiazide* (*Dyazide*).[1] It was postulated that the effect was due to reduction of the tubular secretion of amantadine.

1. Wilson TW, Rajput AH. Amantadine-Dyazide interaction. *Can Med Assoc J* 1983; 129: 974–5.

MAOIs. Hypertension occurred about 48 hours after starting treatment with *phenelzine sulfate* in a patient already receiving amantadine.[1]

1. Jack RA, Daniel DG. Possible interaction between phenelzine and amantadine. *Arch Gen Psychiatry* 1984; 41: 726.

Pharmacokinetics

Amantadine hydrochloride is well absorbed from the gastrointestinal tract; peak concentrations in the plasma appear within about 4 hours after oral doses. Plasma protein binding is reported to be about 67%, with a substantial amount bound to erythrocytes; the concentration is about 2.7 times higher in erythrocytes than in plasma. It is mainly excreted unchanged in the urine by glomerular filtration and tubular secretion although small amounts of an acetylated metabolite have also been detected in urine; the plasma elimination half-life is reported to be about 15 hours in patients with normal renal function but is significantly prolonged in the elderly and in patients with renal impairment. The rate of elimination may be increased by acidification of the urine. Amantadine crosses the placenta and the blood-brain barrier. It is also distributed into breast milk.

UNII — F39049Y068 (apomorphine hydrochloride hemihydrate); 9K13MD7A0D (anhydrous apomorphine hydrochloride).

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Br. also includes a form for homoeopathic preparations.

Ph. Eur. 8: (Apomorphine Hydrochloride Hemihydrate). White or slightly yellowish-brown or green-tinged greyish crystals or crystalline powder, the green tinge becoming more pronounced on exposure to air and light. Sparingly soluble in water and in alcohol; practically insoluble in toluene. A 1% solution in water has a pH of 4.0 to 5.0. Store in airtight containers. Protect from light.

USP 36: (Apomorphine Hydrochloride). Odourless, minute white or greyish-white, glistening crystals or white powder. It gradually acquires a green colour on exposure to light and air. Soluble 1 in 50 of water and 1 in 20 of water at 80 degrees; soluble 1 in 50 of alcohol; very slightly soluble in ether and in chloroform. Its solutions are neutral to litmus. Store in airtight containers. Protect from light.

BP 2014: (Apomorphine Hydrochloride for Homoeopathic Preparations; Apomorphinum Muriaticum for Homoeopathic Preparations).

Stability. Aqueous solutions of apomorphine hydrochloride decompose on storage and should not be used if they turn green or brown or contain a precipitate.

Uses and Administration

Apomorphine is a morphine derivative with structural similarities to dopamine. It is a potent dopamine D_1- and D_2-receptor agonist used in the management of parkinsonism (below), especially in the control of the 'on-off' effect. It has also been used in the management of erectile dysfunction. Apomorphine is given as the hydrochloride and doses are expressed in terms of this salt. The regimen for parkinsonism given below applies to the UK preparation and doses are given subcutaneously; a similar preparation is available in the USA although the licensed maximum single and daily doses are less than those in the UK.

The optimal dose of apomorphine in the management of 'off' periods in parkinsonism should be established individually under specialist care. At least 2 days of pretreatment with the antiemetic domperidone is advised before starting apomorphine. After withholding antiparkinsonian therapy overnight to provoke an 'off' period, a test dose of 1 mg is given initially, followed by a second dose of 2 mg after 30 minutes, if necessary. Subsequent incremental increases should then be given at intervals of at least 40 minutes, as necessary, to determine the lowest dose producing a satisfactory motor response. Once the patient's normal antiparkinsonian therapy is re-established, the effective dose of apomorphine hydrochloride is given at the first signs of an 'off' period.

The dose and frequency are further adjusted according to response; patients typically require 3 to 30 mg daily in divided doses but individual injections should not be greater than 10 mg. Patients who require more than 10 injections daily or those whose overall control of symptoms remains unsatisfactory with intermittent injections may benefit from continuous subcutaneous infusion. The infusion is started at a rate of 1 mg/hour and this may be increased in steps of up to 500 micrograms/hour at intervals of not less than 4 hours to a maximum rate of 4 mg/hour. It is advised that infusions should only be given during waking hours and that the infusion site should be changed every 12 hours; 24-hour infusions are not advised unless there are severe night-time symptoms. Patients usually need to supplement the infusion with intermittent bolus injections but the recommended maximum total daily dose given by infusion and/or injection is 100 mg.

Apomorphine stimulates the chemoreceptor trigger zone in the brain and can produce emesis within a few minutes of a dose. However, the use of apomorphine for the induction of emesis in poisoning is considered dangerous owing to the risk of inducing protracted vomiting and shock, and is not recommended.

Homoeopathy

Apomorphine has been used in homoeopathic medicines.

Erectile dysfunction. Apomorphine is among many drugs that have been used in the management of erectile dysfunction[1-5] (p. 2348.2) with some beneficial results. It is usually given sublingually although it has also been given subcutaneously.[1] Inhaled apomorphine is also under investigation.[6]

Parkinsonism. *DIAGNOSIS.* Test doses of subcutaneous apomorphine have been used in the differential diagnosis of parkinsonian syndromes,[1-4] to distinguish forms responsive to dopaminergics from other parkinsonian syndromes such as Wilson's disease, corticobasal degeneration, and diffuse Lewy-body dementia. Oral challenge with levodopa is still the best test of dopaminergic responsiveness[5,6] but apomorphine has proved of value in re-assessing patients who have become less responsive to levodopa.[1,4]

6. Müller T, *et al.* Repeated rating improves value of diagnostic dopaminergic challenge tests in Parkinson's disease. *J Neural Transm* 2003; 110: 603–9.

TREATMENT. Although apomorphine has produced benefit in Parkinson's disease (p. 889.1) when given orally, the high doses required to overcome extensive first-pass hepatic metabolism (up to 1.4 g daily in one study[1]), were associated with uraemia. The use of apomorphine in Parkinson's disease has therefore been limited by the need for parenteral dosage. The current main use of apomorphine in Parkinson's disease is for the stabilisation of patients with 'on-off' fluctuations unresponsive to other dopamine agonists. It is usually given subcutaneously either by injection or infusion but a review[2] of the use of apomorphine in Parkinson's disease also discussed studies of rectal, sublingual, and intranasal use. Inhaled apomorphine is also under investigation.

1. Cotzias GC, *et al.* Treatment of Parkinson's disease with apomorphines. *N Engl J Med* 1976; 294: 567–72.
2. Koller W, Stacy M. Other formulations and future considerations for apomorphine for subcutaneous injection therapy. *Neurology* 2004; 62 (suppl 4): S22–S26.

Adverse Effects

Treatment of parkinsonism. Apomorphine usually produces nausea and vomiting when given in therapeutic doses but these effects can be controlled by treatment with domperidone or trimethobenzamide. Transient sedation can be common during the first few weeks of treatment. Increased salivation and perspiration have also been reported. Apomorphine can produce neuropsychiatric disturbances including increasing cognitive impairment, personality changes, confusion, and hallucinations. Signs of CNS stimulation including euphoria, lightheadedness, restlessness, tremor, tachycardia, and tachypnoea occur less frequently. Apomorphine may induce dyskinesias during 'on' periods in patients with parkinsonism and these may be severe enough to require stopping therapy; postural instability and falls may also be a problem. Transient orthostatic hypotension may also occur infrequently. Eosinophilia has occurred rarely. The use of apomorphine with levodopa may cause haemolytic anaemia and treatment may need to be stopped if this cannot be satisfactorily controlled through dosage adjustment. Induration, nodule formation, and panniculitis, sometimes leading to ulceration, often develops at the site of subcutaneous injection.

Management of erectile dysfunction. The most common adverse effects have been nausea, headache, and dizziness. Other effects reported include yawning, rhinitis, pharyngitis, somnolence, infection, pain, increased cough, flushing, taste disturbances, and sweating. Fainting and syncope (vasovagal syndrome) have also occurred.

Overdosage with apomorphine can produce persistent vomiting, respiratory depression, bradycardia, hypotension, and coma; death may occur.

Akinesia. A 60-year-old man who was being investigated for parkinsonian symptoms became totally immobile and mute 15 minutes after receiving apomorphine 4 mg subcutaneously.[1] He remained conscious but was drowsy and sweating. Similar profound akinesia occurred on rechallenge with 2- and 6-mg doses. A diagnosis of probable nigrostriatal degeneration was made as the patient had previously shown no improvement with levodopa, but the mechanism of the idiosyncratic reaction to apomorphine was unclear.

1. Jenkins JR, Pearce JMS. Paradoxical akinetic response to apomorphine in parkinsonism. *J Neurol Neurosurg Psychiatry* 1992; 55: 414–15.

Effects on the heart. A 67-year-old man developed palpitations with cold perspiration and chest pain, in addition to asthenia, salivation, nausea and vomiting, 5 minutes after receiving 3 mg apomorphine subcutaneously. An ECG showed atrial fibrillation with a ventricular frequency of 140 beats/minute.[1]

1. Stocchi F, *et al.* Transient atrial fibrillation after subcutaneous apomorphine bolus. *Mov Disord* 1996; 11: 584–5.

Effects on mental function. Severe confusion, hallucinations, and acute psychosis were reported in 4 of 6 parkinsonian patients given subcutaneous apomorphine.[1] Three of the 4 had previously had mental disturbances while receiving lisuride. However, other studies failed to note effects on mental function in parkinsonian patients given apomorphine[2,3] and it has been suggested that the risk of psychosis in patients with no history of confusion or hallucinations is low.[3] UK licensed product information notes that apomorphine has been reported to exacerbate neuropsychiatric disturbances in patients with parkinsonism.

For reference to disturbed behaviour including excessive gambling, and to daytime somnolence reported in patients with Parkinson's disease receiving dopamine agonists, see under Levodopa, p. 905.2.

1. Ruggieri S, *et al.* Side-effects of subcutaneous apomorphine in Parkinson's disease. *Lancet* 1989; i: 566.
2. Stibe CMH, *et al.* Subcutaneous apomorphine in parkinsonian on-off oscillations. *Lancet* 1988; i: 403–6.
3. Poewe W, *et al.* Side-effects of subcutaneous apomorphine in Parkinson's disease. *Lancet* 1989; i: 1084–5.

Hypersensitivity. Allergic reactions including contact dermatitis, severe rhinitis, and respiratory distress have been reported in 2 workers who came into contact with apomorphine powder.[1] Contact allergy has also been reported in a patient who developed a swollen nose and lips after intranasal use of apomorphine.[2] Skin testing in all these cases[1,2] gave a positive reaction to apomorphine. Biopsy of subcutaneous nodules, which develop at the site of injection in most patients using apomorphine subcutaneously, has not been able to clarify what type of reaction was responsible for the development of panniculitis.[3] Although the nodules may slowly resolve the sites are often unsuitable for reuse as absorption from them is unpredictable; concern has been expressed that this may limit long-term use of apomorphine.[3]

1. Dahlquist I. Allergic reactions to apomorphine. *Contact Dermatitis* 1977; 3: 349–50.
2. van Laar T, *et al.* Nasolabiale allergische reactie op intranasale toediening van apomorfine bij de ziekte van Parkinson. *Ned Tijdschr Geneeskd* 1992; 136 (suppl 47): 26–7.
3. Acland KM, *et al.* Panniculitis in association with apomorphine infusion. *Br J Dermatol* 1998; 138: 480–2.

Oedema. Severe reversible oedema of the lower limbs developed in a patient receiving subcutaneous apomorphine.[1] Oedema recurred when apomorphine was reintroduced, but to a lesser extent.

1. Vermersch P. Severe oedema after subcutaneous apomorphine in Parkinson's disease. *Lancet* 1989; ii: 802.

Stomatitis. Stomatitis, severe enough to warrant stopping treatment, occurred in 4 of 8 patients after 2 to 6 months of therapy with sublingual apomorphine.[1]

1. Montastruc JL, *et al.* Sublingual apomorphine in Parkinson's disease: a clinical and pharmacokinetic study. *Clin Neuropharmacol* 1991; 14: 432–7.

Treatment of Adverse Effects

In the UK, domperidone is usually given to control nausea and vomiting when apomorphine is used in the management of Parkinson's disease; pretreatment with domperidone for at least 2 days is advised before starting treatment with apomorphine. Usually domperidone can be withdrawn gradually over several weeks or longer although some patients may need to continue treatment indefinitely. In the USA, trimethobenzamide hydrochloride is used similarly, beginning 3 days before starting apomorphine treatment.

In overdosage an opioid antagonist such as naloxone has been given to treat excessive vomiting, and CNS and respiratory depression.

References.

1. Bonuccelli U, *et al.* Naloxone partly counteracts apomorphine side effects. *Clin Neuropharmacol* 1991; 14: 442–9.

Precautions

Apomorphine should not be given to patients with respiratory or CNS depression, hypersensitivity to opioids, neuropsychiatric problems, or dementia. It should be used with caution in patients prone to nausea and vomiting or when vomiting is likely to pose a risk. Apomorphine should also be used with care in patients with pulmonary, cardiovascular, or endocrine disease or with renal or hepatic impairment. Extra care is needed when starting treatment in elderly or debilitated patients and in those with a history of orthostatic hypotension. Patients who suffer dizziness, lightheadedness, or syncope should not drive or operate machinery.

Treatment of parkinsonism. Apomorphine is not suitable for use in patients who have an 'on' response to levodopa marred by severe dyskinesia, hypotonia, or psychiatric effects; it should also not be used in those with hepatic impairment. Periodic monitoring of hepatic, renal, haematopoietic, and cardiovascular function has been advised and the *BNF* recommends that patients receiving apomorphine with levodopa should be screened for haemolytic anaemia and thrombocytopenia on starting treatment and then every 6 months. Patients who develop anaemia, or those who have continuing confusion or hallucinations during treatment with apomorphine require observation and dosage adjustment under specialist supervision; treatment may need to be stopped. Excessive daytime sleepiness and sudden onset of sleep may also occur with apomorphine and caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring.

Local subcutaneous reactions can sometimes be reduced by using sodium chloride 0.9% to dilute injection solutions, by rotating injection sites, and possibly by use of ultrasound in areas of nodularity and induration.

Management of erectile dysfunction. UK licensed product information has warned that drugs for erectile dysfunction should be used with caution in patients with anatomical penile deformity.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies apomorphine as probably not porphyrinogenic when given sublingually; it may be used as a drug of first choice and no precautions are needed.[1] No classification is offered when used in injectable form.

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Interactions

Apomorphine should be used with caution in patients receiving antihypertensives or organic nitrates as it may potentiate their hypotensive effects. Enhanced hypotensive effects may also occur when alcohol is given with apomorphine. The therapeutic effects of apomorphine may be antagonised by antipsychotics and other drugs that act as CNS dopamine inhibitors. The effect of apomorphine is possibly enhanced by entacapone and memantine.

Antiemetics. *Domperidone* (in the UK) and *trimethobenzamide* (in the USA) are used with apomorphine to control nausea and vomiting when it is prescribed for the management of parkinsonism. However, whether other antiemetics may safely be used is less clear. US licensed product information contra-indicates the use of *ondansetron* and related 5-HT_3 antagonists with apomorphine, on the grounds that profound hypotension and loss of consciousness have been reported in patients given this combination. However, UK licensed product information makes no mention of such a contra-indication, and licensed information for lower-dose products used in the management of erectile dysfunction notes that on the basis of interaction studies, ondansetron hydrochloride or *prochlorperazine maleate* may safely be given to patients receiving apomorphine for this indication.

Pharmacokinetics

Apomorphine is well absorbed after subcutaneous injection but undergoes extensive first-pass hepatic metabolism when given by mouth and oral bioavailability is low. However, it is readily absorbed after sublingual doses and peak plasma concentrations occur in about 40 to 60 minutes; bioavailability is reported to be about 17 to 18% compared with subcutaneous injection. Apomorphine is about 90% bound to plasma proteins, mainly to albumin.

Apomorphine is extensively metabolised in the liver, mainly by conjugation with glucuronic acid or sulfate; the major metabolite is apomorphine sulfate. It is also demethylated to produce norapomorphine. Most of a dose is excreted in urine, mainly as metabolites.

NOTE. Compounded preparations of benserazide hydrochloride may be represented by the following names:

- Co-beneldopa *(BAN)*—benserazide 1 part and levodopa 4 parts (w/w).

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *Jpn*.

Ph. Eur. 8: (Benserazide Hydrochloride). A white or yellowish-white or orange-white crystalline powder. It shows polymorphism. Freely soluble in water; very slightly soluble in dehydrated alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 4.0 to 5.0. Protect from light.

Solubility. Benserazide is unstable in a neutral, alkaline, or strongly acidic medium.[1]

1. Schwartz DE, Brandt R. Pharmacokinetic and metabolic studies of the decarboxylase inhibitor benserazide in animals and man. *Arzneimittelforschung* 1978; 28: 302–7.

Uses and Administration

Benserazide hydrochloride is a peripheral dopa-decarboxylase inhibitor with actions similar to those of carbidopa (p. 900.3) and is used similarly as an adjunct to levodopa in the treatment of parkinsonism (p. 889.1). For details of dosage, see Levodopa, p. 902.3.

References.

1. Dingemanse J, *et al.* Pharmacodynamics of benserazide assessed by its effects on endogenous and exogenous levodopa pharmacokinetics. *Br J Clin Pharmacol* 1997; 44: 41–8.

Adverse Effects and Precautions

Early reports[1] noted developmental abnormalities of the *rat* skeleton, but others found no evidence of any disorder involving bone metabolism in man.[2] Nevertheless, licensed product information recommends that benserazide should not be given to patients under 25 years of age, nor to pregnant women or to women of child-bearing potential in the absence of adequate contraception.

1. Theiss E, Schärer K. Toxicity of L-dopa and a decarboxylase inhibitor in animal experiments. In: de Ajuriaguerra J, Gauthier G, eds. *Monoamines Noyaux Gris Centraux et Syndrome de Parkinson*. Geneva: Georg, 1971: 497–504.
2. Ziegler WH, *et al.* Toxicity of L-dopa and a dopa decarboxylase inhibitor in humans. In: de Ajuriaguerra J, Gauthier G, eds. *Monoamines Noyaux Gris Centraux et Syndrome de Parkinson*. Geneva: Georg, 1971: 505–16.

Pharmacokinetics

Pharmacokinetic and metabolic studies[1,2] in *animals* and man have shown that, after oral doses in parkinsonian patients, benserazide was rapidly absorbed to the extent of about 58%; giving it with levodopa tended to increase this slightly. Benserazide was rapidly excreted in the urine in the form of metabolites, mostly within the first 6 hours; 85% of urinary excretion had occurred within 12 hours. It is mainly metabolised in the gut and appears to protect levodopa against decarboxylation primarily in the gut, but also in the rest of the organism, mainly by way of its metabolite trihydroxybenzylhydrazine. Benserazide did not cross the blood-brain barrier in *rats*.

CAS — 86-13-5 (benzatropine); 132-17-2 (benzatropine mesilate).

ATC — N04AC01.

ATC Vet — QN04AC01.

UNII — WMJ8TL7510.

Pharmacopoeias. In *Br.* and *US*.

BP 2014: (Benzatropine Mesilate). A white, odourless o almost odourless, crystalline powder. Very soluble in water freely soluble in alcohol; practically insoluble in ether.

USP 36: (Benztropine Mesylate). A white, slightly hygroscopic, crystalline powder. Very soluble in water freely soluble in alcohol; very slightly soluble in ether. Store in airtight containers.

Uses and Administration

Benzatropine mesilate is a tertiary amine antimuscarinic with actions and uses similar to those of trihexyphenidyl (p. 917.3); it also has antihistaminic properties.

Benzatropine is used for the symptomatic treatment o parkinsonism (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. It has been used in the treatment of dystonias.

Benzatropine mesilate is given orally or, if necessary, by intramuscular or intravenous injection.

The usual oral daily dose of benzatropine mesilate in **parkinsonism** is 1 to 2 mg, with a range of 0.5 to 6 mg. In arteriosclerotic and idiopathic parkinsonism the usual initial daily dose is 0.5 to 1 mg at bedtime, although some patients may require an initial daily dose of 4 to 6 mg. Patients with post-encephalitic parkinsonism often tolerate an initial daily dose of 2 mg, given in one or more doses, although highly sensitive patients may initially be given 500 micrograms at bedtime. The actions of benzatropine are cumulative, and may not be evident for several days after beginning therapy. Doses may be gradually increased by 500 micrograms every 5 to 6 days to a maximum of 6 mg daily if necessary. Maintenance therapy may be given as a single daily dose at bedtime or in divided doses 2 to 4 times daily. Similar doses may also be given intramuscularly, if appropriate.

In the management of **drug-induced extrapyramidal symptoms** doses of 1 to 4 mg once or twice daily have been given orally or parenterally. Therapy should be stopped after 1 to 2 weeks to assess whether it is still necessary.

In an emergency such as **acute dystonia**, benzatropine mesilate may be injected intramuscularly or intravenously in a dose of 1 to 2 mg; intramuscular injection is reported to produce an effect as quickly as intravenous dosage so the latter is rarely necessary.

Benzatropine has also been given as the hydrochloride.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p. 1312.1. Drowsiness may be severe in some patients and patients so affected should not drive or operate machinery. Mental disturbances and excitement may occur with large doses or in susceptible patients.

Abuse. For mention of abuse of benzatropine see under Trihexyphenidyl Hydrochloride, p. 918.1.

Effects on the heart. Paradoxical sinus bradycardia in a patient with depression and psychotic symptoms was attributed to benzatropine since it persisted despite modification to other treatment and resolved only when benzatropine was withdrawn.[1]

1. Voinov H, *et al.* Sinus bradycardia related to the use of benztropine mesylate. *Am J Psychiatry* 1992; 149: 711.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies benztropine as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

Antidepressants. A report[1] of 5 patients who developed delirium while taking an antipsychotic, an *SSRI*, and benzatropine suggested that there might be an interaction between SSRIs and benzatropine.

1. Roth A, *et al.* Delirium associated with the combination of a neuroleptic, an SSRI, and benztropine. *J Clin Psychiatry* 1994; 55: 492–5.

Antipsychotics. Fatal heat stroke after exposure to an ambient temperature of over 29 degrees has been reported[1,2] in patients receiving benzatropine with antipsychotics. Paralytic ileus, sometimes fatal, has also been seen in patients taking benzatropine with antipsychotics.[3]

Biperiden Lactate *(BANM, rINNM)*

Biperiden Laktat; Bipéridène, Lactate de; Biperideni Lactas; Biperideno, lactato de; Lactato de biperideno; Бипериден Лактат.

$C_{21}H_{29}NO,C_3H_6O_3$=401.5

CAS — 7085-45-2.
ATC — N04AA02.
ATC Vet — QN04AA02.
UNII — 09TD6C5147.

Pharmacopoeias. *US* includes Biperiden Lactate Injection.

Uses and Administration

Biperiden is a tertiary amine antimuscarinic with actions and uses similar to those of trihexyphenidyl (p. 917.3) but with more potent antinicotinic properties.

Biperiden is used in the symptomatic treatment of parkinsonism (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias.

Biperiden is given orally as the hydrochloride and by injection as the lactate; doses are expressed in terms of the relevant salt.

US licensed product information gives the initial oral dose for **Parkinson's disease** as 2 mg of the hydrochloride 3 or 4 times daily which can then be increased according to response to a maximum of 16 mg daily. In some countries a much lower initial oral dose of 1 mg twice daily is recommended. In the USA the recommended oral dose for **drug-induced extrapyramidal symptoms** is 2 mg of the hydrochloride 1 to 3 times daily. In other countries a wider dose range of 1 to 4 mg 1 to 4 times daily is used. Modified-release tablets with different dose schedules are available in some countries.

In severe cases, or when biperiden cannot be given orally, the lactate can be given by intramuscular or slow intravenous injection; total daily doses of up to 10 to 20 mg daily have been used.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p. 1312.1.

Parenteral use may be followed by slight transient hypotension.

Abuse. Abuse of biperiden has been reported in psychiatric patients.[1,2]

1. Pullen GP, *et al.* Anticholinergic drug abuse: a common problem? *BMJ* 1984; 289: 612–13.
2. Ozucelik DN, *et al.* Gluteal abscess following intramuscular injection of dissolved biperiden tablets. *Int J Clin Pract* 2007; 61: 1417–18.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies biperiden as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

Pharmacokinetics

Biperiden is readily absorbed from the gastrointestinal tract, but bioavailability is only about 30% suggesting that it undergoes extensive first-pass metabolism. Biperiden has an elimination half-life of about 20 hours.

CAS — 20448-86-6 (bornaprine); 26908-91-8 (bornaprine hydrochloride).
ATC — N04AA11.
ATC Vet — QN04AA11.
UNII — R99RGW1B2Q.

Profile

Bornaprine hydrochloride is a quaternary ammonium antimuscarinic with actions and uses similar to those of trihexyphenidyl (p. 917.3). It is used in the symptomatic treatment of **parkinsonism** (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias; it is claimed to be mainly effective against tremor. Bornaprine hydrochloride is given orally in initial doses of 2 mg daily gradually increased to 6 to 12 mg daily according to response. It is also used in the treatment of **hyperhidrosis** (p. 1685.1) in a dose of 4 to 8 mg daily.

UNII — FFP983J3OD.

Pharmacopoeias. In *Eur.* (see p. vii), *Jpn*, and *US.*

Ph. Eur. 8: (Bromocriptine Mesilate). A white or slightly coloured fine crystalline powder. Practically insoluble in water; soluble in alcohol; sparingly soluble in dichloromethane; freely soluble in methyl alcohol. A 1% solution in a mixture of 2 parts methyl alcohol to 8 of water has a pH of 3.1 to 3.8. Store in airtight containers at a temperature not exceeding -15 degrees. Protect from light.

USP 36: (Bromocriptine Mesylate). A white or slightly coloured fine crystalline powder; odourless or having a weak characteristic odour. Store in airtight containers at a temperature not exceeding 8 degrees. Protect from light.

Uses and Administration

Bromocriptine, an ergot derivative (p. 2137.1), is a dopamine D_2-agonist. It inhibits the secretion of prolactin (p. 2145.1) from the anterior pituitary and is used in the treatment of prolactinoma and endocrinological disorders associated with hyperprolactinaemia (p. 896.2), including amenorrhoea, galactorrhoea, hypogonadism, and infertility in both men and women. Bromocriptine is also used to suppress puerperal lactation for medical reasons (p. 896.2); it is not recommended for the routine suppression of physiological lactation or for the treatment of postpartum breast pain and engorgement that may be adequately relieved with simple analgesics and breast support. Growth hormone secretion may be suppressed by bromocriptine in some patients with acromegaly (p. 896.1). Because of its dopaminergic activity bromocriptine is also used in the management of Parkinson's disease (p. 896.3). It is used in some countries as an adjunct to diet and exercise to improve glycaemic control in type 2 diabetes mellitus (p. 459.1) but its exact mode of action is unknown.

Bromocriptine is usually given orally as the mesilate; doses are expressed in terms of the base. Bromocriptine mesilate 2.87 mg is equivalent to about 2.5 mg of bromocriptine. Oral doses should be taken with food. Bromocriptine mesilate has also been given intramuscularly as a depot injection for disorders associated with hyperprolactinaemia.

For the **prevention of puerperal lactation** bromocriptine 2.5 mg is given on the day of delivery followed by 2.5 mg twice daily for 14 days. The risk of hypotension and, more rarely, hypertension must be borne in mind and it has been recommended that bromocriptine should not be given until at least 4 hours after delivery. For the **suppression of established lactation** it is given in a dose of 2.5 mg daily for 2 to 3 days subsequently increased to 2.5 mg twice daily for 14 days.

For the treatment of other conditions (see below) the dose of bromocriptine is usually increased gradually. In the UK, typically, an initial dose of 1 to 1.25 mg at night is given,

increased to 2 to 2.5 mg at night after 2 to 3 days, and subsequently increased by 1 to 2.5 mg every 2 to 3 days to a dose of 2.5 mg twice daily, or more if necessary. In the USA, a usual starting dose is 1.25 to 2.5 mg daily increased by 2.5 mg every 2 to 7 days.

In the **treatment of hypogonadism and galactorrhoea syndromes and infertility** bromocriptine is introduced gradually as described above. Most patients with hyperprolactinaemia respond to 7.5 mg daily but up to 30 mg daily may be required. Infertile patients without raised serum concentrations of prolactin are usually given 2.5 mg twice daily. In patients known to have **prolactinomas** the dose is also introduced gradually as described above and may then be increased further by 2.5 mg every 2 to 3 days to a dose of 5 mg every 6 hours but occasionally patients may require up to 30 mg daily. Although unlicensed in the UK and USA, bromocriptine is used in some countries for **cyclical benign breast and menstrual disorders**. In benign breast disease bromocriptine is introduced gradually up to a daily dosage of 5 to 7.5 mg if necessary. In the treatment of premenstrual symptoms therapy should begin on day 14 of the cycle and introduced gradually up to a usual dosage of 2.5 mg twice daily until menstruation begins.

Bromocriptine may be used as an adjunct to surgery and radiotherapy to reduce plasma-growth hormone concentrations in **acromegalic patients**. In the UK, it is introduced gradually as described above and may then be increased further by 2.5 mg every 2 to 3 days if necessary up to 5 mg every 6 hours, according to response. In the USA, the usual starting dose (see above) may be increased by 1.25 to 2.5 mg every 3 to 7 days to a maximum daily dose of 100 mg if necessary; the usual dosage range is 20 to 30 mg daily.

In **Parkinson's disease** bromocriptine has been used alone, although it is usually given as an adjunct to levodopa treatment. It should be introduced even more gradually than the regimen above, and during this period patients already receiving levodopa can have their levodopa dosage decreased gradually until an optimal response is achieved. In the UK, a suggested initial dose is the equivalent of 1 to 1.25 mg of bromocriptine at night during week 1, increased to 2 to 2.5 mg at night for week 2, 2.5 mg twice daily for week 3, and for week 4, 2.5 mg three times daily; the dose may be increased thereafter by 2.5 mg every 3 to 14 days according to response. The EMEA has recommended a maximum dose of 30 mg daily. In the USA, a usual starting dose is 1.25 mg twice daily increased by 2.5 mg every 14 to 28 days to a maximum dose of 100 mg daily if necessary.

In the USA, bromocriptine is used as an adjunct in **type 2 diabetes mellitus**. An initial oral dose of 800 micrograms daily is increased in weekly steps of 800 micrograms, according to tolerance, to a daily dose of between 1.6 to 4.8 mg; doses are given once daily within 2 hours of waking in the morning.

For details of uses and associated doses in children and adolescents, see below.

Administration in children. In the UK, bromocriptine is licensed for the treatment of prolactinomas and gigantism (acromegaly), under specialist supervision, in children and adolescents aged 7 to 17 years. For prolactinomas, an initial oral dose of 1 mg is given 2 or 3 times daily. A higher starting dose of 1.25 mg given 2 or 3 times daily is suggested for gigantism. Thereafter, the dose may be gradually increased according to response; a maximum of 20 mg daily is recommended in those aged 13 years or older, regardless of indication, while younger children may be given a maximum dose of 5 mg daily for prolactinomas and 10 mg daily for gigantism.

In the USA, bromocriptine is licensed for the treatment of prolactinomas in children and adolescents aged 11 to 15 years. An initial oral dose of 1.25 to 2.5 mg daily may be gradually increased, according to response, to a usual range of 2.5 to 10 mg daily.

Acromegaly. Dopaminergics can produce a paradoxical reduction in growth hormone secretion and bromocriptine has been used in acromegaly (p. 1921.1) as adjunctive therapy to surgery, radiotherapy, or somatostatin analogues to reduce circulating growth hormone levels. While it is less effective than somatostatin analogues, it can be given orally and is therefore more convenient to administer.

Cushing's syndrome. There have been occasional reports of benefit with the use of bromocriptine in the treatment of Cushing's syndrome (p. 2559.1). Remission of ACTH-dependent Cushing's syndrome was maintained for 6 years by bromocriptine 2.5 mg twice daily in a patient who had initially received pituitary irradiation.[1] However, the same group subsequently reported that they had found that bromocriptine did not effectively reduce ACTH secretion following bilateral adrenalectomy.[2]

1. Atkinson AB, *et al.* Six year remission of ACTH-dependent Cushing's syndrome using bromocriptine. *Postgrad Med J* 1985; 61: 239–42.
2. Atkinson AB. The treatment of Cushing's syndrome. *Clin Endocrinol (Oxf)* 1991; 34: 507–13.

Hepatic encephalopathy. For the view that the evidence does not support the use of dopaminergics such as bromocriptine in the management of hepatic encephalopathy see p. 1811.2.

Hyperprolactinaemia and prolactinomas. Prolactinomas (prolactin-secreting pituitary adenomas) are among the commonest causes of hyperprolactinaemia. Raised serum-prolactin concentrations can result in reduced gonadotrophin production, which in turn may suppress gonadal function. Consequences may include oligomenorrhoea or amenorrhoea, and infertility in either sex. Galactorrhoea may also result from high prolactin levels and can occur in men as well as women.

Dopamine is the major inhibitory factor in the hypothalamus and directly inhibits the secretion of prolactin. Bromocriptine, a dopamine agonist, has been the first choice of treatment in many centres for the treatment of hyperprolactinaemia secondary to a prolactinoma although cabergoline is now preferred by some. Bromocriptine is extremely effective in controlling elevated circulating prolactin concentrations and restoring gonadal function; although it is rarely curative, it may produce considerable shrinkage of the adenoma.[1]

The sensitivity of hyperprolactinaemia to bromocriptine therapy can vary considerably between patients and this is reflected in the wide range of oral doses required to reduce prolactin concentrations to normal levels. Although beginning therapy with gradually increasing doses can minimise adverse effects it has been reported that about 5 to 10% of patients are unable to tolerate oral bromocriptine;[2] other dosage routes have therefore been investigated. Bromocriptine is well absorbed from standard oral tablets placed in the vagina and appears to be both effective in lowering prolactin concentrations and well tolerated when given by this route.[3] However, limitations are considered to be the relatively short duration of action and the relatively low dose that can be given.[2] A depot preparation given intramuscularly in a dose of 50 to 250 mg monthly has been found to be effective and well tolerated in long-term studies;[4,5] it is reported to be used in some centres to begin treatment for macroprolactinomas.[2]

For discussions of the management of hyperprolactinaemia and associated disorders see p. 2252.2 (hyperprolactinaemia), p. 2251.3 (amenorrhoea), p. 2252.3 (hypogonadism), p. 2348.2 (erectile dysfunction), and p. 2253.1 (infertility).

PREGNANCY. References to the management of prolactinoma during pregnancy.[1-3] Bromocriptine has been successfully used for management in pregnant women, particularly if there is symptomatic enlargement of the tumour, although there continues to be debate on the appropriateness of continuous therapy in less high-risk individuals.

Lactation inhibition. Because of its effects on prolactin, bromocriptine is a potent suppressor of lactation and has been widely used for the prevention of lactation in women who choose not to breast feed post partum. However, bromocriptine has been associated with severe adverse effects in some women, and its use to suppress a physiological state has been criticised (see p. 2130.1). Consequently, licensed product information from some countries recommends that bromocriptine should only be used to suppress puerperal lactation for medical reasons; it is also not recommended for the treatment of postpartum breast pain and engorgement that may be adequately relieved with simple analgesics and breast support.

Mastalgia. Since mastalgia (p. 2265.1) can improve spontaneously, treatment should rarely be considered unless pain has been present for about 6 months. Bromocriptine is one of the drugs that may be used to treat mastalgia.[1,2] It may improve symptoms in up to about 50% of patients with cyclical mastalgia, but is less effective in the non-cyclical form.[3,4] Adverse effects can be severe in some patients.

Neuroleptic malignant syndrome. Bromocriptine has been used in doses of up to 30 mg daily,[1-6] usually alone or with dantrolene, in the treatment of neuroleptic malignant syndrome (p. 1050.2) although some workers have not found it to be of use.[7]

Parkinsonism. Dopamine agonists such as bromocriptine are often used to begin treatment of parkinsonism (p. 889.1), particularly in younger patients, in an attempt to delay therapy with levodopa. They also have an adjunctive use when levodopa is no longer effective alone or cannot be tolerated and may sometimes be useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations of mobility in the later stage of the disease. However, in early disease, there is no evidence that adjunctive bromocriptine prevents or delays the onset of motor complications associated with levodopa monotherapy.

Polycystic ovary syndrome. Bromocriptine has been tried in women with the polycystic ovary syndrome (p. 2253.3) who have mild basal hyperprolactinaemia without evidence of a pituitary tumour.

Restless legs syndrome. The aetiology of restless legs syndrome (see Sleep-associated Movement Disorders, p. 1034.2) is obscure and treatment has largely been empirical but dopaminergic therapy has emerged as a common first-line choice. Bromocriptine showed some benefit in a small study.[1]

1. Walters AS, *et al.* A double-blind randomized crossover trial of bromocriptine and placebo in restless legs syndrome. *Ann Neurol* 1988:24: 455–8.

Withdrawal syndromes. *ALCOHOL* Studies of the efficacy of bromocriptine as an aid in the maintenance of abstinence from alcohol (p. 1735.1) have yielded conflicting results.[1-4] However, it has been suggested[3] that response to bromocriptine might be linked to a specific genotype of the D_2 dopamine receptor.

Adverse Effects

Nausea is the most common adverse effect at the beginning of treatment with bromocriptine, but vomiting, dizziness, and orthostatic hypotension may also occur. Syncope has followed initial doses.

Adverse effects are generally dose-related and may therefore be more frequent with the higher doses that have been used in the treatment of parkinsonism and acromegaly. Reduction of the dosage, followed in a few days by a more gradual increase, may alleviate many adverse effects. Nausea may be reduced by taking bromocriptine with food; domperidone may also be given at least 1 hour before bromocriptine, for the first few days of therapy.

Bromocriptine and similar drugs are vasoconstrictors; Raynaud's syndrome or digital vasospasm, induced by cold, and leg cramps have been reported. Other cardiovascular effects have included erythromelalgia, prolonged severe hypotension, arrhythmias, and exacerbation of angina. Very rarely hypertension, myocardial infarction, seizures or stroke (both sometimes preceded by severe headache or visual disturbances), and psychiatric disorders have been reported in postpartum women given bromocriptine.

The use of ergot derivatives such as bromocriptine has been associated with retroperitoneal fibrosis, pleural thickening and effusions, and pericarditis and pericardial effusions.

Other adverse effects reported include headache, nasal congestion, drowsiness, dry mouth, constipation, diarrhoea, and altered liver-function tests. Dyskinesias and psychomotor excitation have occurred in patients suffering from parkinsonism. Gastrointestinal bleeding has been reported in acromegalic patients. Psychosis, with hallucinations, delusions, and confusion, occurs particularly when high doses are used to treat parkinsonism, but has also been reported with low doses. A neuroleptic malignant-like syndrome associated with abrupt withdrawal of bromocriptine has been reported very rarely.

Incidence of adverse effects. In 27 published studies of the treatment of Parkinson's disease, 217 of the 790 patients given bromocriptine had adverse effects.[1] Mental changes were noted in 90 patients, dyskinesia in 20, orthostatic hypotension in 40, and gastrointestinal effects in 40. The fewest adverse effects (9%) occurred with low-dose bromocriptine, more occurred with high-dose bromocriptine (27%) or with low-dose bromocriptine with levodopa (26%), and the most occurred with high-dose bromocriptine and levodopa (32%). However, those on high doses had more advanced disease and might have been more susceptible to mental changes and dyskinesias.

An analysis by the manufacturer of published reports on patients treated with bromocriptine for 1 to 10 years concluded that in general, adverse effects noted were no different from those associated with short-term treatment.[2]

2. Weil C. The safety of bromocriptine in long-term use: a review of the literature. *Curr Med Res Opin* 1986; 10: 25–51.

Effects on the blood. Severe leucopenia and mild thrombocytopenia developed in a 23-year-old woman after treatment with bromocriptine 7.5 to 10 mg daily for about 3 months.[1]

1. Giampietro O, *et al.* Severe leukopenia and mild thrombocytopenia after chronic bromocriptine (CB-154) administration. *Am J Med Sci* 1981; 281: 169–72.

Effects on the cardiovascular system. An early review noted that asymptomatic **hypotension** occurred in many subjects given bromocriptine.[1] However, faintness and dizziness, sometimes accompanied by *nausea* and *vomiting*, were common at the start of treatment with bromocriptine and these symptoms rather than an anaphylactic type of reaction were likely to account for the collapse that occurred in a few sensitive patients. Two of 53 patients with Parkinson's disease fainted after an initial dose of 1.25 or 2.5 mg, but the exact incidence of shock-like syndromes was difficult to assess; the manufacturers had stated that 22 of over 10 000 subjects given bromocriptine had had hypotension and collapse, mainly at the start of treatment.

- All patients starting treatment should be warned of the possibility of fainting. The initial dose should not exceed 1.25 to 2.5 mg and should be taken with food and in bed.

If fainting does occur recovery is usually rapid and spontaneous. Tolerance to adverse effects such as hypotension and nausea may develop rapidly.

Hypertension, seizures, stroke, and *myocardial infarction* have been associated with bromocriptine therapy, notably in postpartum women.[2-4] A study involving 1813 women suggested that the risk of **postpartum hypertension** was increased in women who had pregnancy-induced hypertension and that this risk was further increased in those who took bromocriptine for suppression of lactation.[5] A case-controlled study[6] involving 43 of the women who had had postpartum seizures while taking bromocriptine found that while the initial risk of seizures appeared to be lower in patients taking bromocriptine there was a small positive association with seizures occurring more than 72 hours after delivery.

- Although a causal relationship between the use of bromocriptine and these adverse effects in postpartum women has not been established, licensed product information recommends that bromocriptine should not be used post partum or in the puerperium in women with high blood pressure, coronary artery disease or other severe cardiovascular disorders, or symptoms or history of serious psychiatric disorders.
- It is also recommended that when bromocriptine is used in postpartum women blood pressure should be carefully monitored, especially during the first few days and if hypertension, unremitting headache, or signs of CNS toxicity develop, treatment should be discontinued immediately.

Severe dilated **cardiomyopathy** has been reported in a patient being treated with bromocriptine for microprolactinoma.[7]

For details of **fibrotic reactions** resulting in cardiovascular adverse effects, see Fibrosis, below.

2. Damase-Michel C, *et al.* Hyponatraemia in a patient treated with bromocriptine. *Drug Invest* 1993; 5: 285–7.

Effects on the eyes. Blurred vision and diplopia have been reported in several patients receiving bromocriptine.[1] Reversible myopia also developed in a patient with hyperprolactinaemia given bromocriptine.[2]

Licensed product information states that visual field impairment associated with macroprolactinoma usually resolves with bromocriptine treatment. However, in a patient with progressive visual loss due to compression of the optic chiasm by a large pituitary tumour, bromocriptine caused total visual loss within hours.[3] Vision slowly returned to normal when the patient was placed in the supine position; the most likely cause of the visual loss was thought to be orthostatic hypotension with resultant decrease in perfusion pressure to the visual system. Monitoring of visual fields is recommended in patients with macroprolactinoma.

Bromocriptine has been reported to cause visual cortical disturbances.[4] In some cases blurred vision and transient cortical blindness have preceded seizures and strokes.

Effects on mental function. High doses of bromocriptine are well known to cause **psychotic reactions** in patients with parkinsonism.[1] However, mania has also been associated with the use of bromocriptine post partum[2,3] and it has been stated that psychological symptoms can occur with doses of only 2.5 to 5 mg daily.[4] It was also noted that, unlike the relatively mild and transient symptoms associated with levodopa, bromocriptine produces a severe psychosis in which the patient is violent and aggressive, suffering from intense delusions which are often hostile and violent; complete withdrawal of bromocriptine may still leave a residue of severe psychotic illness persisting for 1 to 3 weeks. Psychosis associated with low doses of bromocriptine has often occurred in patients with a history of psychotic illness or disturbances in behaviour and mood.[5-7] Drug-related psychotic reactions have also been reported in patients with no psychiatric history;[8,9] of 600 patients given bromocriptine or lisuride for the treatment of acromegaly or prolactinoma, 8 developed symptoms including anxiety, depression, auditory hallucinations, delusions, hyperactivity, disinhibition, euphoria, and insomnia and 4 had received doses only previously associated with psychosis in susceptible patients.[9]

Effects on the nervous system. CSF rhinorrhoea has been associated with bromocriptine therapy in patients with invasive prolactinomas. A report of 3 cases found 13 further cases on reviewing the literature;[1] of these, 7 patients had developed rhinorrhoea within 1 month of starting bromocriptine and 2 cases developed after 12 months.

For reference to seizures associated with the use of bromocriptine in postpartum women, see Effects on the Cardiovascular System, above.

Effects on the respiratory system. For reports of fibrotic reactions occurring in patients with Parkinson's disease receiving ergot derivative dopamine agonists including bromocriptine, see Fibrosis, below.

Effects on sexual function. For reports of the effects of dopamine agonists on sexual function, see under Levodopa, p. 906.1.

Effects on the urinary tract. Constant dribbling urinary incontinence developed in a woman receiving bromocriptine 2.5 mg daily for a recurrent pituitary growth; symptoms resolved on stopping the drug and recurred on rechallenge.[1] Bromocriptine has been shown to have two effects, one on the bladder outflow tract and one on the detrusor muscle, that could predispose to urinary incontinence.[2]

1. Sandyk R, Gillman MA. Urinary incontinence in patient on long-term bromocriptine. *Lancet* 1983; ii: 1260–1.
2. Caine M. Bromocriptine and urinary incontinence. *Lancet* 1984; i: 228.

Fibrosis. Fibrosis has been associated with the long-term use of ergot derivatives (see under Methysergide, p. 677.2). Fibrotic reactions such as cardiac valvulopathy and pleuropulmonary effusion have been reported with bromocriptine, cabergoline, lisuride, and pergolide therapy in patients with Parkinson's disease.

Constrictive pericarditis[1] was reported in 2 patients who had received *bromocriptine* for 2 and 4 years, respectively; the latter still had slight pleural effusion 13 months after the drug was stopped. Valvular heart disease[2] developed in another patient who had received bromocriptine for 5 years; symptoms resolved 6 months after stopping the drug. Interstitial lung disease, with dyspnoea, chest pain, cough, and pulmonary fibrosis was reported[3] in a patient after use of relatively high doses of bromocriptine (62 mg daily). Respiratory symptoms largely resolved on withdrawal of the drug, although functional respiratory changes and moderate dyspnoea persisted after 6 months. A review of the literature revealed several other reports of pleuropulmonary fibrosis associated with relatively high doses of bromocriptine which occurred after between 15 days and up to 3 years of treatment. Although the incidence of this effect did not seem to be high, similar cases have continued to be reported.[4-6] In June 2008 the EMEA recommended that for long-term use in conditions such as Parkinson's disease, the maximum dose should be 30 mg daily.[7]

A patient developed pleuropulmonary disease 16 months after starting treatment with *cabergoline*;[8] he had previously received bromocriptine for 10 years and had had a normal chest X-ray at the time of transfer to cabergoline treatment. In another report, 2 cases of pleural effusion/pulmonary fibrosis, occurring after 10 to 11 months of treatment, were described.[9] One patient had modest pretreatment lung alterations attributed to previous bromocriptine therapy. Withdrawal was associated with improvement in both cases. Congestive heart failure secondary to constrictive pericarditis, and severe pleuropulmonary fibrosis that resulted in

dyspnoea, persistent in one case,[10] have also been reported in 2 patients receiving long-term cabergoline.[10,11] Another patient developed cardiac valvulopathy after taking cabergoline for a total of 20 months;[12] her dosage was 4 mg daily for the last 7 months. Cardiac symptoms slowly improved on withdrawal of the drug, although some evidence of valvular defects was still present 23 months later. Valvular heart disease has also been reported in a 74-year-old man after 4 months of therapy with cabergoline [dosage not stated].[13] By December 2005, 86 cases of suspected adverse reactions to cabergoline had been reported to the Australian Drug Reactions Advisory Committee (ADRAC),[14] of which 15 described pleural or pulmonary fibrosis/effusion, or pneumonitis; time to onset ranged from a few days to over 3 years with a median of 4 months. There had been no reports of fibrotic complications associated with low-dose cabergoline in the treatment of lactation suppression and hyperprolactinaemia. The UK MHRA considers the risk of cardiac valvulopathy to be high and UK labelling for cabergoline has been amended accordingly (see p. 900.2) with the EMEA in June 2008 recommending a maximum dose of 3 mg daily.[7]

A woman developed bilateral pleural effusions after taking *lisuride* 4 mg daily for about 17 months.[8] Her condition improved on stopping lisuride.

The UK CSM[15] reported in 2003 that *pergolide* had been associated with cases of cardiac valvulopathy; since 1989, valvulopathy had been reported in fewer than 5 in 100 000 patients. The CSM also referred to a published case series[16] which reported on 3 patients with severe tricuspid regurgitation after long-term pergolide treatment. The authors of this case series and the CSM both considered that, based on the available evidence, there was a potential association between pergolide and cardiac valvulopathy. Subsequently, the FDA[17] stated that, up to the end of 2002, it was aware of 15 cases of valvular heart disease with pergolide treatment; this figure included the 3 cases reported in the above series and 4 cases from the UK. A later study[18] that examined 78 patients taking pergolide for Parkinson's disease found evidence of restrictive valvular heart disease in 15 of 52 (29%) patients taking doses less than 5 mg daily and in 11 of 26 (42%) receiving doses of 5 mg or more daily. Pulmonary fibrosis and retroperitoneal fibrosis have also been associated with pergolide treatment;[19-21] in most cases, symptoms improved when the drug was stopped. Duration of exposure to pergolide ranged from 6 months[20] to 11 years.[21]

In April 2002 the CSM[22] calculated crude reporting rates of fibrotic reactions associated with the ergot derivative dopamine agonists (bromocriptine, cabergoline, lisuride, and pergolide), based on data submitted to its Yellow Card scheme and estimated drug exposure. Pergolide was found to be associated with a higher reporting rate of fibrotic reactions compared with the other ergot derivatives; however, this result needed further investigation to see if it reflected a true increase in risk or was due to factors such as reporting biases. There is some evidence that the incidence of reactions to pergolide are dose-related; doses are restricted in many countries (see p. 910.3) and in June 2008 the EMEA recommended a maximum dose of 3 mg daily.[7] Pergolide was withdrawn from the market in the USA and Canada. It is recommended that baseline investigations such as erythrocyte sedimentation rate, urea and electrolyte concentrations, and a chest x-ray should be performed before starting treatment with this class of drugs.

Hypersensitivity. An allergic reaction developed in a 26-year-old woman being treated with bromocriptine for a prolactin-secreting microadenoma.[1] The patient reacted similarly to lisuride and treatment was continued with quinagolide.

1. Merola B, *et al.* Allergy to ergot-derived dopamine agonists. *Lancet* 1992; 339: 620.

Oedema. Oedema poorly responsive to diuretics has been reported[1] in a patient given bromocriptine as part of treatment for prolactinoma. The oedema improved on substitution of pergolide but worsened with higher doses. Oedema resolved when treatment was changed to quinagolide. The reaction was considered to be idiosyncratic since enquiries by the author of the report had revealed only one similar case. In a subsequent report[2] a patient with Parkinson's disease who had been receiving bromocriptine for 5 years developed marked lower leg oedema, and subsequently cough, dyspnoea, and chest pain associated with an exudative pleural effusion; there was no evidence of fibrosis. Both oedema and effusion had largely resolved within 4 weeks of stopping bromocriptine.

2. Messiaen T, *et al.* Épanchement pleural et importants œdèmes des membres inférieurs induits par la bromocriptine. *Rev Med Interne* 1996; 17: 680–3.

Overdosage. The most striking symptom in two children aged 2 and 2½ years who accidentally ingested an estimated 25 and 7.5 mg of bromocriptine, respectively, was lethargy with altered mental status.[1] The first child vomited and became sleepy. On admission he was markedly lethargic, but combative when disturbed, and also had hypotension, shallow breathing, dilated pupils, and hyperreflexic lower extremities. Nasogastric lavage was promptly performed, and activated charcoal and then magnesium citrate given. Blood pressure and ECG were monitored, and glucose and sodium chloride solution infused. The other child vomited, became lethargic, and had dilated pupils. Ipecacuanha was given, and activated charcoal followed by magnesium citrate given by nasogastric tube. Both children recovered completely.

1. Vermund SH, *et al.* Accidental bromocriptine ingestion in childhood. *J Pediatr* 1984; 105: 838–40.

Withdrawal syndromes. Transient galactorrhoea and hyperprolactinaemia occurred in a young woman after withdrawal of bromocriptine therapy for Parkinson's disease.[1] It was suggested the effects were due to a rebound phenomenon. For discussion of a syndrome resembling neuroleptic malignant syndrome that has developed on withdrawal of bromocriptine and other antiparkinsonian drugs, see under Levodopa, p. 906.2.

1. Pentland B, Sawers JSA. Galactorrhoea after withdrawal of bromocriptine. *BMJ* 1980; 281: 716.

Precautions

Patients with hyperprolactinaemia should be investigated for the possibility of a pituitary tumour before treatment with bromocriptine. Malignancy must be excluded in patients with cyclical benign breast disorders such as mastalgia. Annual gynaecological examinations (or every 6 months for postmenopausal women) are recommended. Treatment of women with hyperprolactinaemic amenorrhoea results in ovulation; patients not wishing to conceive should be advised to use contraceptive measures although oral contraceptives should be avoided because they may increase prolactin levels. Acromegalic patients should be checked for symptoms of peptic ulceration before therapy and should immediately report symptoms of gastrointestinal discomfort during therapy.

In general, bromocriptine should be given with caution to patients with cardiovascular disease, Raynaud's syndrome, or a history of psychosis. It is contra-indicated in patients with hypersensitivity to bromocriptine or other ergot alkaloids, and in those with uncontrolled hypertension.

Bromocriptine is contra-indicated in the toxaemia of pregnancy. It should also not be used postpartum or in the puerperium in women with hypertension, coronary artery disease, or symptoms or a history of serious psychiatric disorders. When used, blood pressure should be monitored carefully, especially during the first few days in postpartum women. Particular caution is necessary in patients who are receiving or who have recently received drugs that can alter blood pressure; use with ergot alkaloids during the puerperium is not recommended. Treatment in postpartum women should be stopped immediately if hypertension, unremitting headache, or signs of CNS toxicity develop.

Hypotensive reactions may be disturbing in some patients during the first few days of treatment and those who drive or operate machinery should be warned of the possibility of dizziness and fainting during this period. Excessive daytime sleepiness and sudden onset of sleep may also occur with bromocriptine and other dopaminergic agonists, and caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring. A reduction in dosage or withdrawal of the drug may be appropriate. Because of the risk of fibrosis bromocriptine is contra-indicated in patients with pre-existing valve problems.

Patients on long-term, high-dose therapy should be monitored for signs of progressive fibrotic disorders such as retroperitoneal fibrosis and bromocriptine withdrawn if fibrotic changes are diagnosed or suspected. It is recommended that baseline investigations such as erythrocyte sedimentation rate, urea and electrolyte concentrations, and a chest x-ray should be performed before starting treatment with bromocriptine. Periodic monitoring of cardiovascular, haematopoietic, hepatic, and renal function is also recommended. Monitoring of visual fields is recommended in patients with macroprolactinoma.

Breast feeding. The American Academy of Pediatrics[1] considers that bromocriptine should be given with caution to breast-feeding mothers, since it suppresses lactation and may be hazardous to the mother.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://appolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 16/02/06)

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies bromocriptine as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Pregnancy. Details of various surveys of the effect of the use of bromocriptine during pregnancy have been published by the manufacturer.[1,2] The first survey was based on spontaneous reporting of all pregnancies between 1977 and 1980 in women who had taken bromocriptine after conception.[1] Information was obtained on 1410 pregnancies in 1335 women, the majority of whom had been treated for hyperprolactinaemic conditions, while in 256 pregnancies pituitary tumours and acromegaly were the primary diagnosis. Bromocriptine was generally taken at some time in the first 8 weeks after conception, the mean duration of treatment being 21 days. In 4 patients bromocriptine was not prescribed until late in pregnancy and in 9 with acromegaly and pituitary microadenoma it was taken continuously throughout gestation. There were 157 (11.1%) spontaneous abortions, 12 (0.9%) extrauterine pregnancies, 2 patients with 3 hydatidiform moles (0.2%) and an incidence of twin pregnancies of 1.8%. Major congenital abnormalities were detected in 12 (1%) infants at birth and minor abnormalities in 31 (2.5%). A second survey,[2] which consisted of formal monitoring of the use of bromocriptine at 33 clinics between 1979 and 1980, collected data on a further 743 pregnancies in 668 women and had similar findings. The incidence rates reported in these surveys were comparable with those quoted for normal populations and the data indicate that the use of bromocriptine in the treatment of women with infertility is not associated with an increased risk of abortion, multiple pregnancy, or congenital abnormalities. Furthermore follow-up, for up to 9 years, of 546 children exposed to bromocriptine *in utero* found no evidence that bromocriptine had any adverse effect on postnatal development.[2] Nevertheless, since the risk of abortion is not increased by interruption of treatment, licensed product information recommends that bromocriptine therapy be stopped as soon as pregnancy is confirmed unless there is a definite indication for its continuation.

Interactions

Dopamine antagonists such as the phenothiazines, butyrophenones, thioxanthenes, and metoclopramide (but see below) might be expected to reduce the prolactin-lowering and the antiparkinsonian effects of bromocriptine and domperidone might reduce its prolactin-lowering effect. Memantine may enhance the effects of bromocriptine. Stimulants of gastrointestinal motility such as macrolide antibacterials or octreotide can increase the bioavailability of bromocriptine.

Alcohol. Alcohol intolerance was noted in 5 of 73 patients receiving bromocriptine 10 to 60 mg daily for the treatment of acromegaly.[1] Two patients who had gastrointestinal adverse effects while taking low doses of bromocriptine had a marked reduction in their symptoms and were able to tolerate higher doses when they refrained completely from alcohol.[2]

2. Ayres J, Maisey MN. Alcohol increases bromocriptine's side effects. *N Engl J Med* 1980; 302: 806.

Antibacterials. Drowsiness, dystonia, choreoathetoid dyskinesias, and visual hallucinations occurred when *josamycin* was given to a patient receiving bromocriptine.[1]

The systemic bioavailability of a single oral dose of bromocriptine 5 mg was markedly increased in 5 healthy subjects after treatment with *erythromycin estolate* 250 mg four times daily for 4 days;[2] clearance of bromocriptine was decreased and peak plasma concentrations of bromocriptine were more than 4 times higher than when given alone.

2. Nelson MV, *et al.* Pharmacokinetic evaluation of erythromycin and caffeine administered with bromocriptine. *Clin Pharmacol Ther* 1990; 47: 694–7.

Antifungals. The response to bromocriptine was blocked in a patient who was also receiving *griseofulvin*.[1]

1. Schwinn G, *et al.* Metabolic and clinical studies on patients with acromegaly treated with bromocriptine over 22 months. *Eur J Clin Invest* 1977; 7: 101–7.

Antineoplastics. *Tamoxifen* may increase the dopaminergic effect of bromocriptine; for the effect of bromocriptine on tamoxifen, see Interactions, under Tamoxifen, p. 863.2.

Antipsychotics. Serum concentrations of prolactin rose and visual fields deteriorated when *thioridazine* was given to a 40-year-old man receiving bromocriptine therapy for a large prolactinoma.[1]

For a discussion of the effect of bromocriptine on patients receiving antipsychotics, see Antiparkinsonian Drugs under Chlorpromazine on p. 1052.3.

1. Robbins RJ, *et al.* Interactions between thioridazine and bromocriptine in a patient with a prolactin-secreting pituitary adenoma. *Am J Med* 1984; 76: 921–3.

Metoclopramide. As noted in Interactions, above, there are theoretical reasons to suppose that dopamine antagonists such as metoclopramide might reduce the effects of bromocriptine. However, an early study[1] in 10 patients with Parkinson's disease given single doses of bromocriptine 12.5 to 100 mg found that pretreatment with metoclopramide 60 mg had no consistent effect upon plasma concentrations of bromocriptine or growth hormone and no consistent effect upon clinical response.

1. Price P, *et al.* Plasma bromocriptine levels, clinical and growth hormone responses in parkinsonism. *Br J Clin Pharmacol* 1978; 6: 303–9.

Sympathomimetics. There have been isolated reports[1,2] of severe hypertension, with headache and life-threatening complications, in patients taking bromocriptine with *isometheptene mucate* or *phenylpropanolamine*.

1. Kulig K, *et al.* Bromocriptine-associated headache: possible life-threatening sympathomimetic interaction. *Obstet Gynecol* 1991; 78: 941–3.
2. Chan JCN, *et al.* Postpartum hypertension, bromocriptine and phenylpropanolamine. *Drug Invest* 1994; 8: 254–6.

Pharmacokinetics

Bromocriptine is rapidly absorbed from the gastrointestinal tract and peak plasma concentrations occur within 1 to 3 hours after oral doses. However, only about 30% of an oral dose is absorbed and, owing to extensive first-pass metabolism, the bioavailability is only about 6%. It has been reported to be 90 to 96% bound to serum albumin *in vitro*. It is metabolised in the liver, mainly by hydrolysis to lysergic acid and peptides. The elimination of bromocriptine is biphasic; half-lives of about 4 to 4.5 hours and 15 hours, respectively have been reported for the 2 phases. It is excreted mainly in faeces via the bile, with small amounts in urine.

In a study involving 10 patients with Parkinson's disease, single oral doses of bromocriptine 12.5, 25, 50, and 100 mg resulted in very variable peak plasma concentrations ranging from 1.3 to 5.3, 1.4 to 3.5, 2.6 to 19.7, and 6.5 to 24.6 nanograms/mL, respectively, 30 to 210 minutes (mean 102 minutes) after dosage.[1] After 4 hours plasma concentrations were about 75% of the peak values. Clinical improvement was evident within 30 to 90 minutes of a dose with peak effect at about 130 minutes and in most patients improvement persisted throughout the 4-hour study period. Peak clinical response, peak fall in blood pressure, and peak rise in plasma concentrations of growth hormone occurred about 30, 60, and 70 minutes, respectively after peak plasma-bromocriptine concentrations but there was no significant relationship between them. However, there was a significant relationship between plasma concentrations and concurrent changes in clinical response compared with pretreatment scores. Dyskinesias occurred within 90 to 180 minutes of dosage in 5 of 10 patients.

Bromocriptine is well absorbed from standard oral tablets placed in the vagina and plasma concentrations sufficient to lower plasma prolactin concentrations have been achieved using this route.[2,3]

Budipine *(rINN)*

Budipino; Budipinum; Будипин.
1-*tert*-Butyl-4,4-diphenylpiperidine.
$C_{21}H_{27}N$=293.5
CAS — 57982-78-2.
ATC — N04BX03.
ATC Vet — QN04BX03.
UNII — L9026OPI2Z.

Profile

Budipine is a phenylpiperidine derivative used as an adjunct in the treatment of parkinsonism (p. 889.1). It is given orally as the hydrochloride in daily doses of up to 60 mg. Budipine has been reported to prolong the QT interval.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Cabergoline). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; freely soluble in alcohol; very slightly soluble in *n*-hexane. It is slightly soluble in 0.1M hydrochloric acid. Protect from light.

USP 36: (Cabergoline). A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in alcohol; slightly soluble in 0.1M hydrochloric acid; very slightly soluble in hexane. Store in airtight containers. Protect from light.

Uses and Administration

Cabergoline, an ergot derivative, is a dopamine D_2-agonist with actions and uses similar to those of bromocriptine (p. 895.3). It is a potent and long-lasting inhibitor of prolactin secretion used in the management of disorders associated with hyperprolactinaemia (p. 900.1). It is also used to suppress puerperal lactation for medical reasons (p. 900.1); it is not recommended for the routine suppression of physiological lactation or for the treatment of postpartum breast pain and engorgement that may be adequately relieved with simple analgesics and breast support. Cabergoline is also used in the management of Parkinson's disease (p. 900.1) as monotherapy, or as an adjunct to levodopa therapy to reduce 'end-of-dose' or 'on-off' fluctuations in response; in the UK cabergoline is restricted to patients who are intolerant of, or who do not respond to, non-ergot drug treatment.

Cabergoline is given orally and should be taken with food.

To **inhibit physiological lactation**, cabergoline is given as a single 1-mg dose on the first day post partum. For **suppression of established lactation**, the dose is 250 micrograms every 12 hours for 2 days.

In the treatment of **disorders associated with hyperprolactinaemia**, the initial dose of cabergoline is 500 micrograms weekly. The dose is then increased at monthly intervals in increments of 500 micrograms weekly according to response. The weekly dose may be given on a single occasion or divided into 2 or more doses on separate days according to tolerance; doses over 1 mg should be given as divided doses although the maximum single daily dose should not exceed 3 mg. The usual dose is 1 mg weekly but up to 4.5 mg weekly has been used.

In **Parkinson's disease**, cabergoline should be introduced gradually and during this period the dose of levodopa may be reduced gradually until an optimal response is achieved. A suggested initial dose of cabergoline given as a single daily dose is 500 micrograms in monotherapy or 1 mg in adjunctive therapy. The dose may be increased in increments of 0.5 or 1 mg, at intervals of 7 or 14 days, to 2 to 3 mg daily. The EMEA has recommended a maximum dose of 3 mg daily.

Doses of cabergoline may need to be reduced in patients with severe hepatic impairment (see below).

Administration in hepatic impairment. Licensed product information recommends caution in patients with severe hepatic impairment (Child-Pugh category C), and doses of cabergoline should be adjusted accordingly.

Acromegaly. Dopaminergics can produce a paradoxical reduction in growth hormone secretion and may be used in the treatment of acromegaly as adjunctive therapy to surgery, radiotherapy, or somatostatin analogues to reduce circulating growth hormone concentrations, although they are less effective than somatostatin analogues (p. 1921.1).

A small study comparing cabergoline with depot bromocriptine and quinagolide failed to find evidence of its efficacy.[1] However, in a later open study[2] there was a good response in about 40% of patients treated with cabergoline, which is better than the response usually reported for bromocriptine. The addition of cabergoline has

also been beneficial in acromegaly that is resistant to somatostatin analogue therapy.[3]

Hyperprolactinaemia and prolactinomas. Dopamine agonists are widely used for the treatment of hyperprolactinaemia secondary to a prolactinoma (see p. 2252.2). Although bromocriptine has been the first choice for this indication, some now prefer cabergoline,[1] which appears to be more effective and better tolerated.[2,3]

Lactation inhibition. A single 1-mg dose of cabergoline was found to be as effective as bromocriptine 2.5 mg given twice daily for 14 days for preventing puerperal lactation in a double-blind multicentre study involving 272 women.[1] It has been suggested that cabergoline would be a better choice than bromocriptine for lactation inhibition.[2] However, as discussed on p. 2130.1, the routine use of dopaminergics such as bromocriptine or cabergoline is not recommended for the suppression of physiological lactation.

Parkinsonism. Cabergoline is used as a long-acting dopamine agonist in Parkinson's disease (p. 889.1). Dopamine agonists are often used to begin treatment in an attempt to delay therapy with levodopa, particularly in younger patients. They also have an adjunctive use when levodopa is no longer effective alone or cannot be tolerated, and may sometimes be useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations of mobility in the later stages of the disease.

Restless legs syndrome. The aetiology of restless legs syndrome (RLS—see Sleep-associated Movement Disorders, p. 1034.2) is obscure and treatment has been largely empirical but dopaminergic therapy has emerged as a common first-line choice. Long-acting drugs such as cabergoline may be preferred in order to avoid the complications associated with levodopa therapy. Randomised multicentre studies[1,2] in patients with idiopathic RLS concluded that a single evening dose of cabergoline for 5 weeks markedly reduced symptoms during the night and the next day compared with placebo. Results from follow-up analysis of one study[1] after 1 year of treatment suggested that cabergoline at a median dose of 2 mg daily has a high rate of remission and is well tolerated; the authors recommended an initial dose of cabergoline 500 micrograms in the evening increased in increments of 500 micrograms weekly according to response.

Adverse Effects and Precautions

As for Bromocriptine, p. 896.3, although patients unable to tolerate bromocriptine may tolerate cabergoline (and vice versa).

Licensed product information states that conception should be avoided for at least one month after treatment.

Effects on mental function. For reports of **daytime somnolence** occurring in patients receiving dopamine agonists including cabergoline, see under Levodopa, p. 905.2.

For reference to **pathological gambling** reported in patients with Parkinson's disease receiving dopamine agonists including cabergoline, see under Levodopa, p. 905.2.

Fibrosis. For reports of fibrotic reactions occurring in patients with Parkinson's disease receiving ergot derivative dopamine agonists including cabergoline, see under Bromocriptine, p. 897.3.

In 2007, based on further evidence from 3 studies,[1-3] the UK MHRA[4] considered the risk of cardiac valvulopathy to be high and clinically significant with cabergoline and pergolide, and the risks of treatment with these 2 drugs to be similar. This resulted in the following changes to UK labelling for cabergoline products in Parkinson's disease:

- restricted to second-line treatment in patients intolerant of, or who do not respond to, non-ergot drug treatment
- contra-indicated in patients with a history of pulmonary, pericardial, and retroperitoneal fibrotic disorders, or in those with anatomical evidence of cardiac valvulopathy
- monitoring for development of valvular disease or fibrosis recommended: echocardiography should be performed within 3 to 6 months of starting treatment and every 6 to 12 months thereafter

In June 2008 the EMEA further recommended that the maximum dose should be 3 mg daily.[5]

5. EMEA. EMEA recommends new warnings and contraindications for ergot-derived dopamine agonists (issued 26th June, 2008). Available at: http://www.emea.europa.eu/pdfs/human/press/pr/32239508en.pdf (accessed 08/08/08)

Oedema. Three cases of lower limb oedema after chronic treatment with cabergoline have been reported.[1] In one case the oedema was severe enough to necessitate withdrawal of therapy.

1. Geminiani G, *et al.* Cabergoline in Parkinson's disease complicated by motor fluctuations. *Mov Disord* 1996; **11**: 495–500.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies cabergoline as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Interactions

As for Bromocriptine, p. 899.1.

Pharmacokinetics

Cabergoline is absorbed from the gastrointestinal tract and mean peak plasma concentrations occur within 2 to 3 hours. It is subject to first-pass metabolism and is extensively metabolised to several metabolites that do not appear to contribute to its pharmacological activity. Plasma protein binding has been estimated to be about 40%. Cabergoline is mainly eliminated via the faeces; a small proportion is excreted in the urine. In *rats*, cabergoline has been reported to cross the placenta and to be distributed into breast milk.

General references.

Half-life. Pharmacokinetic studies of cabergoline have been hampered by lack of an assay method sensitive enough to detect plasma concentrations of cabergoline after therapeutic doses. However, the plasma elimination half-life of cabergoline has been estimated indirectly to be 63 to 68 hours in healthy subjects and 79 to 115 hours in patients with hyperprolactinaemia.[1]

Carbidopa *(BAN, USAN, rINN)*

Carbidopa-Monohydrat; Carbidopum; Carbidopum Monohydricum; Karbidopa; Karbidopa monohydrát; α-Methyldopa Hydrazine; MK-486; Карбидопа.

(+)-2-(3,4-Dihydroxybenzyl)-2-hydrazinopropionic acid monohydrate; (-)-L-α-Hydrazino-3,4-dihydroxy-α-methylhydrocinnamic acid monohydrate.

$C_{10}H_{14}N_2O_4.H_2O$=244.2

CAS — 28860-95-9 (anhydrous); 38821-49-7 (monohydrate).

UNII — MNX7R8C5VO (carbidopa monohydrate); KR87B45RGH (anhydrous carbidopa).

NOTE. The synonym MK-485 has been used for the racemic mixture.

Compounded preparations of carbidopa and levodopa may be represented by the following names:

- Co-careldopa *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of carbidopa and levodopa respectively
- Co-careldopa (*PEN*)—carbidopa and levodopa

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*

Ph. Eur. 8: (Carbidopa). A white or yellowish-white powder. Slightly soluble in water; very slightly soluble in alcohol; practically insoluble in dichloromethane; dissolves in dilute solutions of mineral acids. Protect from light.

USP 36: (Carbidopa). A white to creamy-white, odourless or practically odourless powder. Slightly soluble in water and in methyl alcohol; practically insoluble in alcohol, in acetone, in chloroform, and in ether; freely soluble in 3N hydrochloric acid. Protect from light.

Uses and Administration

Carbidopa is a peripheral dopa-decarboxylase inhibitor with little or no pharmacological activity when given alone in usual doses. It inhibits the peripheral decarboxylation of levodopa to dopamine and as, unlike levodopa, it does not cross the blood-brain barrier, effective brain concentrations of dopamine are produced with lower doses of levodopa. At the same time reduced peripheral formation of dopamine reduces peripheral adverse effects, notably nausea and vomiting, and cardiac arrhythmias, although the dyskinesias and adverse mental effects associated with levodopa therapy tend to develop earlier. Contrary to its effect in patients on levodopa alone, pyridoxine does not inhibit the response to levodopa in patients also receiving a peripheral dopa-decarboxylase inhibitor.

In the treatment of parkinsonism (p. 889.1) carbidopa is given with levodopa to enable a lower dosage of the latter to be used, a more rapid response to be obtained, and to decrease adverse effects. For details of administration and dosage, see Levodopa, p. 902.3.

Carbidopa also inhibits the peripheral decarboxylation of the serotonin precursor oxitriptan (p. 440.3).

General references.

2. Boshes B. Sinemet and the treatment of parkinsonism. *Ann Intern Med* 1981; 94: 364–70.

Adverse Effects

Hypersensitivity. Henoch-Schönlein purpura that developed in a 68-year-old patient being treated for Parkinson's disease appeared to be due to either carbidopa or an excipient of the carbidopa preparation (*Sinemet*).[1]

1. Niedermaier G, Briner V. Henoch-Schönlein syndrome induced by carbidopa/levodopa. *Lancet* 1997; 349: 1071–2.

Pharmacokinetics

Carbidopa is rapidly but incompletely absorbed from the gastrointestinal tract. It is rapidly excreted in the urine both unchanged and in the form of metabolites. It does not cross the blood-brain barrier. In *rats*, carbidopa has been reported to cross the placenta and to be distributed into breast milk.

UNII — 43477QYX3D.

Dexetimide Hydrochloride *(BANM, rINNM)*

Dexbenzetimide Hydrochloride; Dexetimida, hidrocloruro de; Dexétimide, Chlorhydrate de; Dexetimidi Hydrochloridum; Hidrocloruro de dexetimida; R-16470; Дексэтимида Гидрохлорид.

$C_{23}H_{26}N_2O_2$,HCl=398.9

CAS — 21888-96-0.

ATC — N04AA08.

ATC Vet — QN04AA08.

UNII — B987A3XX7D.

Profile

Dexetimide is a tertiary antimuscarinic with actions similar to those of trihexyphenidyl (p. 917.3). It has been used to alleviate drug-induced extrapyramidal symptoms (see under Chlorpromazine, p. 1049.2), but, like other antimuscarinics, is of no value against tardive dyskinesias. Dexetimide hydrochloride has been given orally and by intramuscular injection.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Neth.*: Tremblex†.

Diethazine Hydrochloride *(BANM, rINNM)*

Diaethazinium Chloratum; Dietazina, hidrocloruro de; Diéthazine, Chlorhydrate de; Diethazini Hydrochloridum; Eazamine Hydrochloride; Hidrocloruro de dietazina; RP-2987; Диэтазина Гидрохлорид.

10-(2-Diethylaminoethyl)phenothiazine hydrochloride.

$C_{18}H_{22}N_2S$,HCl=334.9

CAS — 60-91-3 (diethazine); 341-70-8 (diethazine hydrochloride).

UNII — S88072126Q.

Profile

Diethazine hydrochloride is an antimuscarinic with actions similar to those of profenamine hydrochloride (p. 912.3), but it is more toxic and bone-marrow depression may occur. It has been used in the treatment of parkinsonism.

Droxidopa *(USAN, rINN)*

DOPS; Droxidopum; L-DOPS; L-*threo*-DOPS; L-*threo*-3,4-Dihydroxyphenylserine; Дроксидопа.

(-)-*threo*-3-(3,4-Dihydroxyphenyl)-L-serine.

$C_9H_{11}NO_5$=213.2

CAS — 23651-95-8.

UNII — J7A92W69L7.

Profile

Droxidopa is a precursor of noradrenaline that is used in the treatment of parkinsonism (p. 889.1) and some forms of orthostatic hypotension (p. 1634.3). The usual oral maintenance dose is 600 mg daily for the treatment of parkinsonism and 300 to 600 mg daily in orthostatic hypotension; daily doses should be divided.

The racemic form (DL-*threo*-3,4-dihydroxyphenylserine) has also been studied for orthostatic hypotension.

CAS — 130929-57-6.

ATC — N04BX02.

ATC Vet — QN04BX02.

UNII — 4975G9NM6T.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Entacapone). A greenish-yellow or yellow powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in anhydrous ethanol; soluble or sparingly soluble in acetone. Protect from light.

USP 36: (Entacapone). A greenish yellow to yellow powder. Practically insoluble in water; slightly soluble in alcohol; in chloroform, in ether, and in isopropyl alcohol; sparingly soluble in acetone and in methyl alcohol; very slightly soluble in toluene. Store in airtight containers.

Uses and Administration

Entacapone is a selective, reversible, peripheral inhibitor of catechol-*O*-methyltransferase (COMT), an enzyme involved in the metabolism of dopamine and levodopa. It is used as an adjunct to combination preparations of levodopa and dopa-decarboxylase inhibitors, in patients with Parkinson's disease (below) and 'end-of-dose' motor fluctuations who cannot be stabilised on levodopa combinations alone. Entacapone is given orally in a dosage of 200 mg at the same time as each dose of levodopa with dopa-decarboxylase inhibitor, up to a maximum of 200 mg ten times daily. It is often necessary to gradually reduce the dosage of levodopa by about 10 to 30% within the first few weeks after starting treatment with entacapone; this effect may be more marked in the presence of benserazide than of carbidopa.

Entacapone may also be given as a combination preparation with carbidopa and levodopa; for dosage details, see Levodopa, p. 902.3.

Parkinsonism. Entacapone is a selective and reversible inhibitor of catechol-*O*-methyltransferase (COMT), with mainly peripheral actions. It is given as adjunctive therapy to patients with Parkinson's disease (p. 889.1) having fluctuations in disability related to levodopa and dopa-decarboxylase inhibitor combinations. When levodopa is given with a peripheral dopa-decarboxylase inhibitor, *O*-methylation then becomes the predominant form of metabolism of levodopa; therefore adding a peripheral COMT inhibitor such as entacapone potentially extends the duration and effect of levodopa in the brain, and thus allows levodopa to be given less often and in lower doses.

Adverse Effects

The most frequent adverse effects produced by entacapone relate to increased dopaminergic activity and occur most commonly at the start of treatment: reduction of the levodopa dosage may reduce the severity and frequency of such effects. Adverse effects may include nausea, vomiting, abdominal pain, constipation, diarrhoea, colitis, dry mouth, and dyskinesias. Other commonly reported adverse effects include dizziness, insomnia, nightmares, hallucinations, confusion, fatigue, and increased sweating. Behavioural disturbances including intense urges to gamble and increased sexual urges have also been reported (see Effects on Mental Function, in Levodopa, p. 905.2). There have been rare reports of agitation, urticaria, erythematous or maculopapular rash, anorexia, and weight decrease. Increases in liver enzyme values have been reported rarely; there have also been isolated cases of cholestatic hepatitis. Isolated cases of neuroleptic malignant syndrome have been reported after abrupt reduction or withdrawal of entacapone; there have also been isolated cases of rhabdomyolysis. It may produce a harmless reddish-brown discoloration of the urine. Skin, hair, beard, and nail discolorations have been reported.

Carcinogenicity. The FDA[1] reported that it is continuing to review data from the STRIDE-PD study, which suggested that parkinsonian patients who were taking the combination preparation containing entacapone, carbidopa, and levodopa (*Stalevo; Novartis, USA*) had an increased risk of prostate cancer when compared with those who were taking carbidopa with levodopa. The FDA commented that previous studies of shorter duration did not find such an association with entacapone, and that prostate cancer is most commonly diagnosed in men of the same age as those in the STRIDE-PD study.

Available at: http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm206363.htm (accessed 14/05/10)

Effects on the cardiovascular system. The FDA[1] is continuing to evaluate data from clinical studies that initially suggest that patients taking a combination preparation containing entacapone, carbidopa, and levodopa (*Stalevo; Novartis, USA*) are at an increased risk of cardiovascular events compared with those taking carbidopa with levodopa. The FDA commented that most patients had pre-existing risk factors for cardiovascular disease.

Precautions

Entacapone is contra-indicated in patients with phaeochromocytoma and in patients with a history of neuroleptic malignant syndrome or nontraumatic rhabdomyolysis. It should be avoided in patients with hepatic impairment, and given with caution to patients with biliary obstruction. A general medical evaluation, including liver function, should be considered in those who develop progressive anorexia, asthenia, and weight decrease within a relatively short period of time. Use with levodopa may cause dizziness and orthostatic hypotension; if affected patients should not drive or operate machinery. Excessive daytime sleepiness and sudden onset of sleep may also occur with combination use (see Effects on Mental Function, under Adverse Effects of Levodopa, p. 905.2) and again, caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring.

Treatment with entacapone should not be stopped abruptly; when necessary withdrawal should be made gradually, increasing the dose of levodopa as required.

Genetic polymorphism. For reference to slow metabolisers being more susceptible to COMT-inhibitor induced hepatotoxicity, see under Tolcapone, p. 917.2.

Interactions

Use of entacapone with a non-selective MAOI is contra-indicated. Entacapone should be used with caution in patients receiving drugs metabolised by catechol-*O*-methyltransferase (COMT) including adrenaline, apomorphine, dobutamine, dopamine, isoprenaline, methyldopa, noradrenaline, paroxetine, and rimiterol. Caution is also advised when used with certain antidepressants including the tricyclics, reversible inhibitors of monoamine oxidase type A, and noradrenaline reuptake inhibitors such as venlafaxine.

Entacapone may aggravate levodopa-induced orthostatic hypotension and should be used cautiously in patients who are taking other drugs that may cause orthostatic hypotension.

Entacapone may form chelates with iron preparations in the gastrointestinal tract; the two drugs should be taken at least 2 to 3 hours apart.

Pharmacokinetics

There are large intra- and interindividual variations in the absorption of entacapone. Peak plasma concentrations occur about one hour after oral doses. Entacapone undergoes extensive first-pass metabolism and oral bioavailability is about 35%. Absorption is not affected significantly by food. Entacapone is about 98% bound to plasma proteins. It is eliminated mainly in the faeces with about 10 to 20% being excreted in the urine, mainly as glucuronide conjugates. Entacapone is thought to be distributed into breast milk on the basis of studies in *rats*.

Entacapone is rapidly absorbed from the gastrointestinal tract and bioavailability after oral doses has been reported to range from 29 to 46%. It does not cross the blood-brain barrier. Over half of a dose appears in the faeces with smaller amounts being excreted in the urine as glucuronides of entacapone and its (*Z*)-isomer. Elimination half-lives of about 1.6 to 3.4 hours have been reported for entacapone.

Pharmacopoeial Preparations
USP 36: Entacapone Tablets.

Istradefylline *(USAN, rINN)*

Istradefilina; Istradéfylline; Istradefyllinum; KW-6002; Истрадефиллин.

8-[(1*E*)-2-(3,4-Dimethoxyphenyl)ethenyl]-1,3-diethyl-7-methyl-3,7-dihydro-1*H*-purine-2,6-dione.

$C_{20}H_{24}N_4O_4$=384.4

CAS — 155270-99-8.

UNII — 2GZ0UK7T4.

Profile

Istradefylline is a selective adenosine A_{2A}-receptor antagonist given to reduce 'end-of-dose' deterioration with levodopa therapy in the treatment of Parkinson's disease (p. 889.1). Istradefylline is given orally in a usual dose of 20 mg once daily, which can be increased to 40 mg daily if necessary.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Nouriast.

Levodopa *(BAN, USAN, rINN)*

Dihydroxyphenylalanine; L-Dopa; 3-Hydroxy-L-tyrosine; Laevo-dopa; Lévodopa; Levodopum; Леводопа.

(-)-3-(3,4-Dihydroxyphenyl)-L-alanine.

$C_9H_{11}NO_4$=197.2

CAS — 59-92-7.

ATC — N04BA01.

ATC Vet — QN04BA01.

UNII — 46627O600J.

NOTE. Compounded preparations of levodopa may be represented by the following names:
- Co-beneldopa (*BAN*)—benserazide 1 part and levodopa 4 parts (w/w)
- Co-careldopa *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of carbidopa and levodopa, respectively
- Co-careldopa (*PEN*)—carbidopa and levodopa

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Levodopa). A white or slightly cream-coloured, crystalline powder. Slightly soluble in water; freely soluble in 1M hydrochloric acid but sparingly soluble in 0.1M hydrochloric acid; practically insoluble in alcohol. A 1% suspension in water has a pH of 4.5 to 7.0. Protect from light.

USP 36: (Levodopa). A white to off-white, odourless, crystalline powder. In the presence of moisture, it is rapidly oxidised by atmospheric oxygen and darkens. Slightly soluble in water; freely soluble in 3N hydrochloric acid; insoluble in alcohol. Store in a dry place in airtight containers at a temperature not exceeding 40 degrees. Protect from light.

Stability. Extemporaneously prepared oral liquid dosage forms may be unstable and manufacturers' formulations should be used where possible.[1] Water dispersible formulations of levodopa with benserazide are available in some countries but a method that can be used by patients to prepare daily solutions of levodopa with carbidopa has been suggested:[2] one litre of a solution in potable water may be prepared with ten crushed standard tablets of levodopa 100 mg with carbidopa 25 mg and 2 g of ascorbic acid added to stabilise the levodopa.

Uses and Administration

Levodopa, a naturally occurring amino acid, is the immediate precursor of the neurotransmitter dopamine. The actions of levodopa are mainly those of dopamine (p. 1367.2).

Unlike dopamine, levodopa readily enters the CNS and is used in the treatment of conditions, such as Parkinson's disease (p. 904.1), that are associated with depletion of dopamine in the brain. Levodopa is rapidly decarboxylated by peripheral enzymes so that very little unchanged drug is available to cross the blood-brain barrier for central conversion into dopamine. Consequently, levodopa is usually given with a peripheral dopa-decarboxylase inhibitor such as benserazide (p. 894.1) or carbidopa (p. 900.3) to increase the proportion of levodopa that can enter the brain. This enables the dosage of levodopa to be reduced and may diminish peripheral adverse effects, such as nausea and vomiting and cardiac arrhythmias, by blocking the peripheral production of dopamine. It may also provide a more rapid response at the start of therapy.

The majority of patients with Parkinson's disease benefit from levodopa therapy, but after 2 years or more, improvement in disability is gradually lost as the disease progresses and fluctuations in mobility emerge. Postencephalitic parkinsonism responds to levodopa, but a higher incidence of adverse effects has been reported than in the idiopathic form so smaller doses are generally used. Levodopa has also been used to control the neurological symptoms of chronic manganese poisoning, which resemble those of parkinsonism. It should not be used in antipsychotic-induced parkinsonism.

Levodopa has an effect on pituitary function as a result of its conversion to dopamine. It may enhance growth hormone secretion and has been used diagnostically as a provocative test for growth hormone deficiency. Levodopa also inhibits prolactin secretion.

Response to levodopa varies considerably between patients. **Treatment of parkinsonism** should begin with small doses increased gradually, ideally to a dose that improves mobility without producing adverse effects. Levodopa should be taken with or after meals, although in later disease, it may be preferable to take it on an empty stomach (see Precautions, p. 906.3). Once established, maintenance doses may need to be reduced as the patient ages. When given **without a peripheral dopa-decarboxylase inhibitor** (which is rare) a suggested initial oral dose is 125 mg twice daily increased gradually every 3 to 7 days, according to response, to up to 8 g daily in divided doses. The intervals between doses should be adjusted to meet individual needs; many patients find 4 or 5 divided doses daily to be satisfactory although some may require smaller, more frequent doses in order to control fluctuations in mobility. Maximum improvement may take up to 6 months or longer to occur.

When given **with a peripheral dopa-decarboxylase inhibitor** lower doses of levodopa are used. As high central dopamine concentrations can be achieved more quickly, both beneficial and adverse effects tend to occur more rapidly than with levodopa alone and patients should be monitored carefully. In those already receiving levodopa the drug should be stopped and benserazide or carbidopa with levodopa started on the next day or after 24 hours if the patient was receiving a modified-release preparation of levodopa.

Benserazide is given as the hydrochloride but doses are expressed in terms of the base. Benserazide hydrochloride 28.5 mg is equivalent to about 25 mg of benserazide. Benserazide is usually given with levodopa in the ratio of 1 part of benserazide base to 4 parts of levodopa (co-beneldopa) and the doses for co-beneldopa that follow are expressed in terms of the levodopa component.

- An initial oral dose for *patients not previously treated with levodopa* is levodopa 50 mg three or four times daily increased gradually in increments of levodopa 100 mg once or twice weekly, according to response. If the disease is at an advanced stage, the initial starting dose may be increased to levodopa 100 mg three times daily. For some elderly patients, an initial dose of levodopa 50 mg once or twice daily, increased by 50 mg every third or fourth day, may be suitable. Maintenance doses usually lie within the range of levodopa 400 to 800 mg daily in divided doses, although most patients require no more than 600 mg daily. If optimal improvement has not been achieved after several weeks at the average dose, further increases may be made with caution; it is rarely necessary to give more than 1 g of levodopa daily.
- The initial dose of levodopa given with benserazide in *patients previously treated with levodopa alone* should be about 10 to 15% of the dose previously being taken, thus levodopa 300 mg would be appropriate for a patient previously taking levodopa 2 g daily. For *patients previously treated with other levodopa/dopa-decarboxylase inhibitor combinations* an initial dose is levodopa 50 mg given three or four times daily. In either situation, the dose may then be adjusted in a similar manner as described for previously untreated patients.
- Modified-release capsules containing the equivalent of benserazide 25 mg with levodopa 100 mg are available to reduce fluctuations in response to immediate-release preparations. For *patients not already receiving levodopa* the initial dose is one capsule three times daily adjusted every 2 to 3 days according to response; it is recommended that initial dosages should not exceed 600 mg of levodopa daily. For *patients already receiving an immediate-release preparation* of levodopa with benserazide, initially one capsule should be substituted for every 100 mg of levodopa and should be given at the same dosage frequency as before; increases in dosage can then be made every 2 to 3 days according to response. An average of 50% more levodopa may be required compared with previous therapy and titration may take up to 4 weeks. *Supplementary doses* of an immediate-release preparation of benserazide with levodopa may also be required with the first morning dose.

Carbidopa is usually given with levodopa (co-careldopa) as tablets in the ratio of 1 to 4 or 1 to 10, which allows dosage adjustments of either drug for individual patients. Carbidopa is given as the hydrous base although doses are expressed in terms of the anhydrous base; hydrous carbidopa 10.8 mg is equivalent to about 10 mg of anhydrous carbidopa. Full inhibition of peripheral dopa-decarboxylase is reported to be achieved with 70 to 100 mg of carbidopa daily.

- A suggested initial oral dose for *patients not previously treated with levodopa* is carbidopa 25 mg with levodopa 100 mg three times daily, increased gradually, in increments of carbidopa 12.5 mg with levodopa 50 mg or carbidopa 25 mg with levodopa 100 mg every day or on alternate days, as necessary, until a total daily dose of carbidopa 200 mg with levodopa 800 mg is reached. Maintenance therapy should be individualised and adjusted gradually according to response. Carbidopa doses greater than 200 mg daily are not generally exceeded.
- The initial dose of levodopa with carbidopa in *patients previously treated with levodopa alone* should be about 20 to 25% of the dose previously being taken, thus for patients taking less than 1.5 g of levodopa daily a suggested initial dose is carbidopa 25 mg with levodopa 100 mg given three or four times daily; a suggested initial dose for patients taking more than 1.5 g of levodopa daily is carbidopa 25 mg with levodopa 250 mg given three or four times daily. For *patients previously treated with other levodopa/dopa-decarboxylase inhibitor combinations* an initial dose should provide a similar daily amount of levodopa.
- Modified-release tablets containing carbidopa with levodopa in the ratio of 1 to 4 are available to reduce fluctuations in response to immediate-release preparations. For *patients not already receiving levodopa* therapy, or for *those currently receiving levodopa alone*, the initial dose is carbidopa 50 mg with levodopa 200 mg twice daily, adjusted according to response, at intervals of not less than 3 days. It is recommended that for patients who are not already receiving levodopa initial dosages should not exceed 600 mg of levodopa daily. For *patients already receiving an immediate-release preparation* of carbidopa with levodopa, the initial dose of the modified-release preparation should provide a similar daily amount of levodopa, but the dosing intervals should be prolonged and are normally between 4 to 12 hours. The initial substitution dose of the modified-release preparation should provide no greater than 10% more levodopa than was previously given for doses of levodopa exceeding 900 mg daily. Doses and intervals may then be altered according to clinical response, allowing at least 3 days between adjustments. Up to 30% more levodopa may be required in the modified-release preparation than was previously given in the immediate-release preparation. Average maintenance doses of modified-release preparations lie within the range of carbidopa 100 mg with levodopa 400 mg to carbidopa 400 mg with levodopa 1.6 g daily in divided doses. *Supplementary doses* of an immediate-release preparation of carbidopa with levodopa may be required in some patients.

Combination preparations of levodopa with carbidopa and the catechol-*O*-methyltransferase (COMT) inhibitor **entacapone** are also available; each tablet contains levodopa and carbidopa in a ratio of 4 to 1 with entacapone 200 mg. Such preparations are indicated for patients with end-of-dose motor fluctuations not stabilised on levodopa/peripheral dopa-decarboxylase inhibitor treatment. Patients should only take one combination tablet for each dose.

- *Patients previously treated with an immediate-release preparation of levodopa with a peripheral dopa-decarboxylase inhibitor and separate entacapone* should be transferred to the combination preparation at a dose that provides similar or slightly higher amounts of levodopa.
- For *patients not currently taking entacapone*, the dose of the combination preparation should normally provide a similar or slightly lower dose of levodopa to that previously taken. However, patients with *dyskinesia* or taking *levodopa in doses above 800 mg daily* should start entacapone as a separate medication before being transferred to the combination preparation, as a 10 to 30% reduction in their levodopa dose may be needed when starting combination therapy, especially if levodopa is being given with benserazide.

In some countries a gel formulation of levodopa 20 mg/mL with carbidopa 5 mg/mL is available for *continuous infusion* by an ambulatory pump into the duodenum. It is indicated for the treatment of advanced levodopa-responsive Parkinson's disease with severe motor fluctuations when other available combination therapy has not been satisfactory. A positive test of the clinical response via a temporary nasoduodenal tube is required before a permanent tube is inserted into the duodenum or upper jejunum. The total daily dose comprises of 3 individually-adjusted doses, which are expressed in terms of the levodopa component as follows:

- the *morning bolus dose*, based on the patient's previous morning intake of levodopa, is usually 100 to 200 mg and should not exceed 300 mg in total; the therapeutic dose level is achieved within 10 to 30 minutes
- the *continuous maintenance dose*, based on the patient's previous daily intake of levodopa, is usually 40 to 120 mg/hour infused over 16 hours, adjustable in steps of 2 mg/hour to within a range of 20 to 200 mg/hour; higher doses may be needed in exceptional cases
- *extra bolus doses*, given when required, are usually between 10 to 40 mg although higher doses may be needed in exceptional cases; the maintenance dose should be increased if more than 5 bolus doses are needed daily

After the initial dose setting, further dose adjustments should be made over a few weeks. If medically justified, it may be administered during the night.

Melevodopa, the methyl ester of levodopa, has been used orally as the hydrochloride with carbidopa in some countries for parkinsonism. The ethyl ester of levodopa, etilevodopa, has also been studied.

Administration. A small crossover study involving 24 patients with severe Parkinson's disease found that daytime intraduodenal infusion of a levodopa and carbidopa gel preparation for 3 weeks was clinically superior to individually optimised conventional regimens.[1] Another small case series of 5 patients found that continuous 24-hour intraduodenal infusion was also generally well-tolerated and improved motor fluctuations without the development of clinically significant tolerance to its effects.[2] Long-term experience (up to 7 years) in a limited number of patients has suggested that intraduodenal infusion is a good alternative for those with advanced disease and disabling motor fluctuations.[3] A gel formulation of levodopa 20 mg/mL with carbidopa 5 mg/mL is available in some countries for intraduodenal infusion.

Administration in children. Although unlicensed, levodopa has been tried for various conditions in neonates, children, and adolescents. For further details and suggested doses, see Amino Acid Metabolic Disorders (below), Dystonias (below), and Pituitary and Hypothalamic Disorders (p. 904.2).

Amino acid metabolic disorders. Although not licensed for the treatment of defects in tetrahydrobiopterin synthesis and dihydrobiopterin reductase deficiency, the *BNFC* suggests that neonates, children, and adolescents up to the age of 18 years may be given initial oral doses of 250 to 500 micrograms/kg of levodopa (with carbidopa in the ratio of 4 to 1) four times daily increased according to response every 4 to 5 days to a maintenance dose of 2.5 to 3 mg/kg four times daily. Preparations containing levodopa with carbidopa in the ratio of 10 to 1 should be considered at higher doses. Treatment should be reviewed regularly every 3 to 6 months during early childhood.

Drug-induced extrapyramidal disorders. The management of drug-induced extrapyramidal disorders is discussed under the Adverse Effects of Chlorpromazine on p. 1049.2. Although the use of dopamine agonists, especially levodopa, to overcome antipsychotic-induced blockade of dopamine receptors might appear rational, levodopa has generally been reported to be ineffective or to increase psychiatric symptoms.

Dysphagia. Results of a small study[1] have suggested that levodopa may improve the impaired swallowing reflex in patients with basal ganglia infarctions and thereby help to prevent aspiration pneumonia.

1. Kobayashi R, *et al.* Levodopa and swallowing reflex. *Lancet* 1996; **348**: 1320–1.

Dystonias. A dystonia is a syndrome of sustained muscle contractions, frequently causing twisting and repetitive movements or abnormal postures; it may also have additional myoclonic or tremulous components. Typically it starts as a focal dystonia localised in one part of the body and to begin with may appear only during a specific motor act (action dystonia). If the syndrome is progressive the dystonias may become apparent at rest and spread first to more than one part of the body (segmental dystonia) and may eventually affect most or all of the body (generalised dystonia). Progression of the dystonia appears to be related to age of onset. Dystonia beginning in childhood usually starts in the legs and progresses to become segmental or generalised, whereas in adults the dystonia usually starts in other parts of the body and rarely becomes generalised. Examples of focal dystonias are blepharospasm (affecting the eye and surrounding facial muscles), writer's cramp (hand and arm), spasmodic torticollis (neck), spasmodic dysphonia, or dystonic dysphagia (larynx or pharynx), and leg dystonias. Some dystonias may be associated with metabolic disorders such as Wilson's disease or Lesch-Nyhan syndrome; with neurological disorders such as Huntington's disease; or with other causes including head trauma, manganese or carbon disulfide toxicity, or the adverse effects of antipsychotics or antiparkinsonian drugs. However, in the majority of cases the disease is idiopathic.

There are no cures for most types of dystonia, but with appropriate **management** symptomatic relief is possible in many patients.[1-5]

- It has been suggested that all children and adolescents presenting with dystonia, particularly starting in the legs, should first be given a trial with *levodopa*.[1,3,5] Although not licensed for children in the UK, the *BNFC* states that children aged 3 months and older with dopamine-sensitive dystonias, including dystonic cerebral palsy, may be given 250 micrograms/kg of levodopa (with carbidopa in the ratio of 4 to 1) orally two or three times daily increased according to response every 2 to 3 days to a maximum of 1 mg/kg of levodopa three times daily. Another suggested regimen is to gradually build up to a dose of levodopa 200 mg with carbidopa 50 mg given three times daily and to maintain this dose for 3 months; if there is no useful response in this period the drug is withdrawn.[1] Where there is benefit it is usually dramatic and is sustained as long as the drug is taken, which may be more than 10 years in some cases, in general without the long-term problems associated with levodopa for parkinsonism (see p. 889.1).
- In children and adolescents who fail to respond to levodopa an *antimuscarinic* such as trihexyphenidyl is second choice; the *BNFC* also suggests using procyclidine. Adverse effects are minimised by starting with a low dose which is then gradually increased. General experience indicates that about half of all children and adolescents benefit from antimuscarinics; adults tolerate the drug less well and only about a fifth of adult patients with focal dystonia benefit.
- In patients who do not respond to levodopa or high-dose antimuscarinics other drugs may be used. Many benefit from *benzodiazepines* such as diazepam; a few have responded to *baclofen* or *carbamazepine*. *Antipsychotics* are sometimes useful but carry the risk of inducing tardive dyskinesia. *Tetrabenazine* carries less risk of tardive dyskinesia but may induce depression. In very severe dystonia combination therapy may be required: tetrabenazine with pimozide and trihexyphenidyl is sometimes effective.

- In patients refractory to oral therapy *intrathecal* baclofen, or surgery may be tried.
- The response in patients with adult onset focal dystonia is usually poor. However, the use of *botulinum A toxin* can produce relief in blepharospasm, spasmodic torticollis, and spasmodic dysphonia, and is under investigation for writer's cramp and other occupational dystonias. In some patients with generalised and segmental dystonia, botulinum A toxin injected into the most disabling or painful muscles has been used as adjunctive therapy. Local injections into the affected muscles produce weakness over the next week or so, thereby reducing or abolishing dystonic spasms. The effect lasts some 2 to 4 months. *Botulinum B toxin* has also been used in the management of spasmodic torticollis.

Further details of the management of blepharospasm and spasmodic torticollis can be found under Botulinum Toxins on p. 2018.1 and p. 2019.2, respectively. For a discussion of the management of antipsychotic-induced dystonic reactions, see Extrapyramidal Disorders, under Adverse Effects of Chlorpromazine, p. 1049.2.

Hepatic encephalopathy. For the view that the evidence does not support the use of dopaminergics such as levodopa in the management of hepatic encephalopathy see p. 1811.2.

Neuroleptic malignant syndrome. There have been isolated reports[1-4] that levodopa used alone or with bromocriptine has been successful in the treatment of patients with neuroleptic malignant syndrome (p. 1050.2). However, bromocriptine is usually preferred when a dopaminergic is required for the treatment of this condition.

Parkinsonism. Levodopa is the mainstay in the treatment of Parkinson's disease (p. 889.1) but opinion varies on when it should be used in the course of the disease. Most patients respond to levodopa initially but after a few years benefit may be reduced. There may be problems with dyskinesias and psychiatric effects and fluctuations in mobility necessitating careful dosage adjustment or the use of adjunctive drugs. For most patients treatment with levodopa eventually becomes necessary, but many neurologists delay initial treatment with levodopa because of the increased risk of motor complications. New patients, especially younger patients, therefore often begin treatment with a dopamine agonist, with levodopa reserved for the elderly, the frail, or those with intercurrent illness or more severe symptoms. Levodopa should be given with a peripheral dopa-decarboxylase inhibitor; a peripheral catechol-*O*-methyltransferase (COMT) inhibitor may also be necessary for patients with fluctuations in disability related to levodopa and dopa-decarboxylase inhibitor combinations. The various methods used for the pharmacokinetic optimisation of levodopa therapy as Parkinson's disease progresses include timing of doses, the use of modified-release formulations, oral solutions (but see Stability, p. 902.3) and dispersible formulations for immediate absorption, the timing of food intake, and the use of other drugs to increase the absorption of levodopa. In some countries a gel formulation of levodopa with carbidopa is available for intraduodenal infusion.

Pituitary and hypothalamic disorders. *DIAGNOSIS AND TESTING.* Diminished growth hormone reserve is one of the earliest functional abnormalities in anterior pituitary failure and, since dopamine is believed to stimulate growth hormone secretion, levodopa has been used as a provocative test for the diagnosis of growth hormone deficiency.[1,2] Levodopa 500 mg has been given orally after an overnight fast and serum concentrations of growth hormone measured hourly at 0 to 3 hours; children may be given 10 mg/kg to a maximum of 500 mg. Transient nausea, vomiting, vertigo, and hypotension may occur and the patient should be kept recumbent during the test. A normal response is an increase in serum concentration of growth hormone of more than 5 nanograms/mL or to a level of more than 10 nanograms/mL, although 10 to 15% of normal subjects may not respond. However, there is some dispute as to whether stimulated growth hormone secretion tests are superior to measurements of circulating somatomedins in detecting growth hormone deficiency.[3-5] For a discussion of the management of growth retardation, including the problems of accurate diagnosis, see p. 1921.3.

Sleep-associated movement disorders. The aetiology of *restless legs syndrome* and *periodic limb movements in sleep* is obscure and treatment has been largely empirical (p. 1034.2). Few of the treatments tried in these often co-existent disorders have been studied in a controlled manner but small controlled studies[1-6] have reported beneficial effects such as improved sleep quality and reduced leg movements from levodopa used with a peripheral dopa-decarboxylase inhibitor. Most patients received a bedtime dose of 50 to 200 mg of levodopa with possible additional doses during the night. A 1-year open-label extension study[7] confirmed the continued efficacy and safety of levodopa in patients with restless legs syndrome; the authors recommended a maximum daily dose of 400 mg levodopa to decrease the risk of exacerbation or rebound symptoms during the day. However, long-acting dopaminergic agonists are preferred in order to avoid the complications associated with levodopa.

Levodopa has also been reported to have been of benefit in a study of 10 patients with *sleep bruxism*.[8]

Adverse Effects

Gastrointestinal effects, notably nausea, vomiting, and anorexia are common early in treatment with levodopa, particularly if the dosage is increased too rapidly. Gastrointestinal bleeding has been reported in patients with a history of peptic ulcer disease.

The commonest cardiovascular effect is orthostatic hypotension, which is usually asymptomatic, but may be associated with faintness and dizziness. Cardiac arrhythmias have been reported and hypertension has occasionally occurred.

Psychiatric symptoms occur in a high proportion of patients, especially the elderly, and include agitation, anxiety, euphoria, nightmares, insomnia or sometimes drowsiness, and depression. More serious effects, usually requiring a reduction in dosage or withdrawal of levodopa, include aggression, paranoid delusions, hallucinations, delirium, severe depression, with or without suicidal behaviour, and unmasking of psychoses. Psychotic reactions are more likely in patients with postencephalitic parkinsonism or a history of mental disorders. Excessive daytime sleepiness and sudden onset of sleep have been reported very rarely, as have pathological gambling, increased libido, and hypersexuality.

Abnormal involuntary movements or dyskinesias are the most serious dose-limiting adverse effects of levodopa and are very common at the optimum dose required to control parkinsonism; their frequency increases with duration of treatment. Involuntary movements of the face, tongue, lips, and jaw often appear first and those of the trunk and extremities later. Severe generalised choreoathetoid and dystonic movements may occur after prolonged use. Muscle twitching and blepharospasm may be early signs of excessive dosage. Exaggerated respiratory movements and exacerbated oculogyric crises have been reported in patients with postencephalitic parkinsonism. Bradykinesia and akinesia, in the form of 'end-of-dose' deterioration and the 'on-off' phenomenon, may re-emerge in patients with parkinsonism as a complication of long-term treatment, but may be due to progression of the disease rather than to levodopa (see also Parkinsonism, p. 889.1).

A positive response to the direct Coombs' test may occur, usually without evidence of haemolysis although autoimmune haemolytic anaemia has occasionally been reported. Transient leucopenia and thrombocytopenia have occurred rarely. The effects of levodopa on liver and kidney function are generally slight; transient increases in liver enzymes, and in blood-urea nitrogen and serum-uric acid concentrations, have been reported. Levodopa may cause discoloration of the urine; reddish at first then darkening on standing. Other body fluids may also be discoloured.

Some of the adverse effects reported may not be attributable directly to levodopa, but rather to the use of antimuscarinics, to increased mobility, or to the unmasking of underlying conditions as parkinsonism improves. Use with a peripheral dopa-decarboxylase inhibitor may reduce the severity of peripheral symptoms such as gastrointestinal and cardiovascular effects, but central effects such as dyskinesias and mental disturbances may occur earlier in treatment.

Incidence of adverse effects. The major adverse effects of levodopa are dyskinesia in 75% of patients and psychiatric disturbances in 25%.[1] Nausea and vomiting in 40 to 50% gradually regress and hypotension in 25 to 30% is generally asymptomatic. Less common adverse effects include cardiac arrhythmias, particularly atrial and ventricular ectopic beats and less commonly atrial flutter and fibrillation; palpitations and flushing often accompanied by excessive sweating; hypertension; polyuria, incontinence and urinary retention, although antimuscarinic drugs often contribute to problems with micturition; and dark coloration of the urine and saliva. Rare adverse effects include abdominal pain, constipation, and diarrhoea, mydriasis, blurred vision, diplopia, and precipitation of glaucoma; headache; stridor; tachypnoea; and paraesthesias.

Abnormal coloration. Black pigmentation of rib cartilage has been noted at necropsy in patients treated with levodopa.[1,2] Abnormal pigmentation is generally not seen at other sites[2] but there have been isolated reports[2,3] of patients who also had pigmentation of the intervertebral discs. Although the pigmentation appears to be irreversible it was considered to be probably harmless.[2] It has been suggested that the pigmentation was due to deposition of dihydroxyphenylalanine (DOPA) in the cartilage.[1] It is known that DOPA will readily auto-oxidise *in vitro* in the presence of oxygen to a black pigment and this can also happen *in vivo* since black urine is a well known adverse effect of levodopa. Dark sweat and pigmentation of the skin and teeth are also known adverse effects.

Dysgeusia. A change in taste sensation was reported[1] in 23 of 514 patients treated with levodopa and a peripheral dopa-decarboxylase inhibitor; 2 of the 23 had total loss of taste initially. The altered taste, often described as insipid, metallic, or plastic, was first noted 3 to 32 weeks after

beginning treatment, and lasted for 2 to 40 weeks. In an earlier report, 22 of 100 patients receiving levodopa alone had had changes in taste.[2]

Effects on the blood. Reports of effects of levodopa on the blood are mostly confined to individual case reports. A study in 365 patients, receiving levodopa in a mean daily dosage of 4.04 g, found that 32 developed a positive direct Coombs' test, the majority after between 3 and 12 months of therapy, but none developed haemolytic anaemia.[1] However, occasional cases of auto-immune haemolytic anaemia have been reported;[2-4] in one case, dosage reduction and addition of a peripheral dopa-decarboxylase inhibitor largely abolished haemolysis,[3] but in another, haemolysis recurred on re-institution of levodopa with carbidopa and required corticosteroid treatment.[4] A case of severe acute non-haemolytic anaemia related to levodopa therapy has also been reported.[5]

Levodopa is widely stated to produce leucopenia in some patients; however, there are few published reports. Transient minor decreases in total leucocyte counts were reported in 3 of a group of 80 patients receiving levodopa.[6]

Severe thrombocytopenia has been reported in 2 patients who had received levodopa for 3 and 2 years respectively;[7,8] the condition was apparently an auto-immune response and responded to prednisone therapy and withdrawal of levodopa.

Effects on the cardiovascular system. There have been conflicting reports on the effects of peripheral dopa-decarboxylase inhibitors on orthostatic hypotension attributed to levodopa therapy. In a study,[1] supine and erect systolic blood pressure was found to be significantly higher in parkinsonian patients given levodopa with carbidopa than in those receiving levodopa alone, suggesting that the peripheral actions of dopamine contribute to levodopa-induced hypotension. However, another study[2] found no change in the incidence and degree of orthostatic hypotension after giving levodopa with carbidopa and, similarly, no difference in the frequency of ventricular arrhythmias.

Effects on electrolytes. See Effects on Kidney Function, below.

Effects on the endocrine system. Single doses of levodopa given to healthy subjects cause an increase in plasma concentrations of glucose, insulin, and glucagon, as well as of growth hormone[1] and there has been concern over the potential endocrine effects of levodopa therapy in patients with Parkinson's disease.[2] A study of carbohydrate metabolism in 24 patients with Parkinson's disease indicated that these patients had abnormally low rates of **glucose utilisation** when untreated, apparently due to impaired insulin release, and this was not altered when levodopa therapy was given.[3] However, a similar study completed by 19 patients[2] noted increased impairment of glucose utilisation after levodopa therapy for 1 year with a delayed hypersecretion of insulin in response to a glucose load similar to the metabolic changes of acromegaly. It was considered that patients given levodopa for parkinsonism should be monitored for evidence of diabetes mellitus or frank acromegaly.[2]

Postmenopausal bleeding occurred in varying degrees in 12 of 47 women treated with levodopa.[4] In one case bleeding was severe enough to warrant interrupting treatment and subsequent dosage reduction.

2. Weintraub ML, *et al.* Pupillary effects of levodopa therapy: development of anisocoria in latent Horner's syndrome. *N Engl J Med* 1970; **283**: 120–3.

Effects on the gastrointestinal tract. Although gastrointestinal bleeding has more commonly been reported in patients with a history of peptic ulceration, there is a rare report[1] of acute melaena and non-specific gastritis associated with levodopa therapy in a 56-year-old man without any previous evidence of a gastric disorder.

See also Dysgeusia, p. 904.3.

1. Riddoch D. Gastritis and L-dopa. *BMJ* 1972; **1**: 53–4.

Effects on kidney function. Levodopa 1 to 2 g given to 7 patients with idiopathic or postencephalitic Parkinson's disease produced significant increases in renal plasma flow, glomerular filtration rate, and sodium and potassium excretion.[1] It was considered that the natriuretic effects could contribute to the orthostatic hypotension commonly seen in patients receiving levodopa. There is a report of a patient who developed hyponatraemia when given levodopa with carbidopa.[2] The patient had previously had a similar reaction with amantadine. On each occasion symptoms disappeared when dopaminergic medication was withdrawn and recurred on rechallenge. Inappropriate secretion of antidiuretic hormone was suggested as a possible mechanism.

Levodopa has also been reported to have a kaliuretic effect, resulting in hypokalaemia, in some parkinsonian patients;[3] the effect could be prevented by also giving a peripheral dopa-decarboxylase inhibitor.

3. Granérus A-K, *et al.* Kaliuretic effect of L-dopa treatment in parkinsonian patients. *Acta Med Scand* 1977; **201**: 291–7.

Effects on mental function. Psychiatric complications were the single commonest reason for stopping levodopa treatment in a follow-up study of 178 patients with idiopathic Parkinson's disease, 81 of whom were still taking levodopa after 6 years.[1] Within 2 years, levodopa was withdrawn because of toxic confusional states (21 patients), paranoid psychosis (6 patients), unipolar depression (2 patients), and mania (1 patient). The incidence of visual hallucinations increased as treatment continued but, as with toxic confusional states, patients generally improved when levodopa was withdrawn. Before treatment, 40 patients had suffered severe depression and levodopa produced sustained improvement in only 2. After 6 years, 20 of the 81 patients remaining were moderately or severely depressed and were rarely improved by withdrawal or reduction in dosage of levodopa. Increasing dementia affected 26 of the 81 patients after 6 years; withdrawal of levodopa in 5 failed to improve cognitive disabilities, but increased parkinsonism.

Another study[2] reported that 141 of 400 patients being treated for Parkinson's disease developed mental disorders. In this study certain acute states, particularly anxiety, on-off hallucinations, and fits of delirium were linked to treatment with levodopa, whereas dementia and depression were not.

Long-term use of levodopa and dopamine agonists has been associated with various **behavioural disturbances**, including hypersexuality (see Effects on Sexual Function, p. 906.1), punding (purposeless repetitive acts), excessive gambling or shopping (see below), and other obsessive behaviour such as compulsive eating.[3-5] Risk factors include male gender, young age at onset of Parkinson's disease, underlying personality traits, and a personal or family history of addictive disorders.[4] Reduction in dopaminergic therapy can lead to cessation or improvement in symptoms. Some patients may develop dopamine dysregulation syndrome (see Abuse, under Precautions, p. 906.3).

A 12-month study of 1281 patients in the USA treated with dopamine agonists for Parkinson's disease found that 9 were suffering from **excessive gambling.**[6] All patients had received levodopa, 8 pramipexole, and the remaining patient pergolide. The rate of pathological gambling was 1.5% in the 529 patients taking pramipexole. The authors considered that this was not unexpected given the general availability of casinos in the local area and an incidence in the general US population of 0.3 to 1.3%. An analysis[7] of 11 patients who began pathological gambling after starting therapy with pramipexole (9 cases) or ropinirole (2 cases) found that in 8 patients such behaviour resolved when the drug was tapered or stopped; follow-up was not available in the other 3. In 7 patients the symptoms had developed within 1 to 3 months of achieving maintenance dose or after dose increases of dopamine agonist therapy. Of the 11 patients, 3 had not received levodopa. Cabergoline therapy has also been associated with pathological gambling.[8] Similar behaviour described as being markedly increased in "on" periods has been reported in other patients treated with levodopa.[9] Pathological gambling has also been associated with misuse of dopaminergics.[10]

Sleep-related complaints have occurred and were reported by 74 of 100 patients with Parkinson's disease.[11] All 74 were on levodopa and the prevalence of symptoms increased with the duration of treatment. Symptoms included insomnia, excessive daytime somnolence, altered dream phenomena, nocturnal vocalisation, involuntary myoclonic movements, and rarely, sleepwalking. Sleep fragmentation, which includes insomnia and somnolence, was the most common symptom overall. It has been suggested[12] that in patients with mild to moderate disease levodopa and dopamine agonists could cause sleep disruption. However, these drugs produce beneficial effects on nocturnal disabilities in patients with more severe disease. Reports[13-19] of daytime somnolence or sudden onset of sleep with various other dopamine agonists, including apomorphine, bromocriptine, cabergoline, lisuride, pergolide, piribedil, pramipexole, quinagolide, and ropinirole, suggest that this is a class effect of dopaminergic antiparkinsonian therapy, and patients should be warned of the possible risks (see Precautions, p. 906.3). The risk of somnolence may be increased in those patients taking combinations of dopaminergics.[18,20]

Effects on respiration. Respiratory crises, including attacks of gasping, panting, sniffing, puffing, and breath-holding, occurred in 12 of 25 patients with postencephalitic parkinsonism during treatment with levodopa.[1] A further 8 developed respiratory and phonatory tics, including sudden deep breaths, yawns, coughs, giggles, sighing, grunting, and moaning. All 20 patients also suffered tachypnoea, bradypnoea, and asymmetrical movement of both sides of the chest, paradoxical diaphragmatic movements, and reversal of inspiratory and expiratory phases. The induction of respiratory crises may be prompt or greatly delayed; 3 patients only developed crises after more than 9 months of treatment with levodopa. Crises were readily precipitated by psychophysiological arousals such as rage and exertion. Most of the patients who developed marked respiratory disorders had shown slight irregularities of respiratory rhythm, rate, and force before receiving levodopa.

In another report a distressing dose-related irregularity in the rate and depth of breathing occurred when a patient with Parkinson's disease was given levodopa with benserazide.[2] The respiratory abnormality was completely suppressed by use of tiapride, with no reduction in the efficacy of levodopa.

2. De Keyser J, Vincken W. L-Dopa-induced respiratory disturbance in Parkinson's disease suppressed by tiapride. *Neurology* 1985; 35: 235–7.

Effects on sexual function. An increase in libido, over and above the effects of improved mobility and well-being, has been reported in parkinsonian patients receiving levodopa or dopamine agonists. One report noted increased libido but no improvement in sexual performance in 4 of 80 patients receiving levodopa[1] while another reported a moderate increase in sexual interest in 4 of 7 male patients.[2] There have also been reports of hypersexuality and deviant sexual behaviour in patients with Parkinson's disease receiving levodopa or dopamine agonists.[3-6] In some cases this was associated with increased dosage and possibly abuse of the drugs. Symptoms often improved on dosage reduction or withdrawal. Hypersexual behaviour and hypergenitalism have also been reported in a pre-pubertal boy given levodopa for behavioural disturbances.[7]

Some workers[8] have commented that dopaminergics such as cabergoline are being promoted illegally on the Internet for male sexual enhancement and warn of the potential for abuse and serious adverse effects.

Clitoral tumescence and increased libido has been noted in a woman receiving bromocriptine to suppress lactation[9] but there has been a report of sexual dissatisfaction and decreased libido in 3 women receiving bromocriptine for hyperprolactinaemia.[10]

Effects on the skin and hair. Two women who were given levodopa, up to 3 g daily, developed diffuse alopecia in addition to other adverse effects.[1] Repigmentation of hair has occurred in a white-bearded man after being treated with levodopa 1.5 g daily for 8 months.[2] Vitiligo has been reported[3] in a patient with Parkinson's disease following addition of tolcapone to his levodopa/carbidopa regimen. The development of vitiligo was attributed to the increase in plasma-levodopa concentrations brought about by concomitant use of tolcapone.

3. Sabaté M, *et al.* Vitiligo associated with tolcapone and levodopa in a patient with Parkinson's disease. *Ann Pharmacother* 1999; 33: 1228–9.

Extrapyramidal effects. Choreiform movements were the major dose-limiting complication of long-term treatment with levodopa in a follow-up study of 178 patients with idiopathic Parkinson's disease, 81 of whom were still taking levodopa after 6 years.[1] Dyskinesias usually appeared in the first year and became more severe and generalised with time. Certain distinctive patterns of involuntary movements occurred as follows:

- peak-dose movements affected 65 of the 81 patients and were dose-related. Movements were usually choreic, affecting the face and limbs, but dystonic and ballistic movements were also seen; characteristically they began 20 to 90 minutes after an oral dose and lasted from 10 minutes to 4 hours with a tendency to be more severe mid-way through the interdose period
- biphasic movements presenting as 2 distinct episodes of chorea or dystonia within each interdose period occurred in only 3 patients
- early morning and 'end-of-dose' dystonia was present in 15 patients after 6 years of treatment with levodopa, but rarely developed during the first 3 years
- nocturnal myoclonus occurred in 12 patients

The frequency, intensity, and complexity of spontaneous fluctuations in performance were greatly enhanced by long-term levodopa therapy. Two clinically distinct types of fluctuation, 'end-of-dose' deterioration and the 'on-off' phenomenon, were related to treatment. 'End-of-dose' deterioration or the 'wearing-off' effect affected 52 patients after 6 years of treatment and was characterised by progressive reduction in the duration of benefit from each dose with a gradual return of nocturnal and early morning disability in some patients. The 'on-off' phenomenon affected 14 patients who had completely unpredictable swings from relative mobility, usually accompanied by involuntary movements, to periods of profound bradykinesia and hypotonia. In addition, 'freezing episodes' and abrupt falls became increasingly common and affected 50 patients after 6 years compared with 33 before therapy.

1. Shaw KM, *et al.* The impact of treatment with levodopa on Parkinson's disease. *Q J Med* 1980; 49: 283–93.

OCULOGYRIC CRISIS. After initial remission, oculogyric crises in 5 of 25 patients with postencephalitic parkinsonism recurred and were subsequently severely exacerbated during treatment with levodopa.[1] One patient, who previously had not had oculogyric crises, developed severe crises in the fourth month of therapy with levodopa. During these crises forced gaze deviation was always accompanied by severe neurological and mental symptoms, some of which were scarcely tolerable.

1. Sacks OW, Kohl M. L-Dopa and oculogyric crises. *Lancet* 1970; II: 215–16.

Gout. There have been reports of elevated serum uric acid concentrations in patients receiving levodopa, but some of these are of doubtful significance since levodopa has been shown to give falsely-elevated uric acid concentrations by colorimetric methods.[1] However, hyperuricaemia as measured by more specific methods,[2,3] with a few cases of overt gout,[2,3] has also been reported.

1. Cawein MJ, Hewins J. False rise in serum uric acid after L-dopa. *N Engl J Med* 1969; 281: 1489–90.

3. Calne DB, Fermaglich J. Gout induced by L-dopa and decarboxylase inhibitors. *Postgrad Med J* 1976; 52: 232–3.

Hypersensitivity. Reports of hypersensitivity reactions to levodopa have included a vasculitis characterised by neuromyopathy, periarteriolitis with eosinophilia,[1] and a lupus-like auto-immune syndrome.[2]

1. Wolf S, *et al.* Neuromyopathy and periarteriolitis in a patient receiving levodopa. *Arch Intern Med* 1976; 136: 1055–7.
2. Massarotti G, *et al.* Lupus-like autoimmune syndrome after levodopa and benserazide. *BMJ* 1979; 2: 553.

Overdosage. Adverse effects after ingestion of 80 to 100 g of levodopa over a 12-hour period by a parkinsonian patient included hypertension initially, followed by hypotension of a few hours' duration, sinus tachycardia, and symptomatic orthostatic hypotension for more than a week.[1] Marked confusion, agitation, insomnia, and restlessness were the most prominent clinical symptoms and did not disappear completely for over a week; severe anorexia and insomnia persisted for 2 to 3 weeks. After the overdose the patient had virtually no signs of parkinsonism and received no levodopa or antimuscarinic medication for 6 days; rigidity and akinesia began to recur on the fourth day.

1. Hoehn MM, Rutledge CO. Acute overdose with levodopa: clinical and biochemical consequences. *Neurology* 1975; 25: 792–4.

Withdrawal syndromes. Withdrawal of antiparkinsonian drugs, particularly levodopa, has been implicated in the development of a syndrome resembling the neuroleptic malignant syndrome,[1-6] characterised by fever, muscle rigidity, profuse sweating, tachycardia, tachypnoea, and elevated muscle enzyme values.[2] Several fatalities have occurred.[1,2] It has been suggested that the neuroleptic malignant syndrome is associated with blockade of dopamine receptors in the striatum, leading to increased rigidity and heat production, and in the hypothalamus, resulting in impaired thermoregulation[7] and it seems reasonable that withdrawal of levodopa might have a similar effect in patients with depleted central dopamine concentrations. Thus, the use of a 'drug holiday' to manage fluctuations in response to levodopa (see Parkinsonism, p. 889.1) is no longer recommended.

Fever, extrapyramidal symptoms and raised creatine kinase concentrations, resembling a very mild form of the neuroleptic malignant syndrome, have also been reported in parkinsonian patients exposed to stress such as dehydration or infection but without any change in medication.[8]

Treatment of Adverse Effects

Reduction in dosage reverses most of the adverse effects of levodopa. Nausea and vomiting may be diminished by increasing the dose of levodopa gradually, and/or by taking with or after meals, although taking levodopa on a full stomach may lead to lower plasma concentrations. Gastrointestinal effects may also be reduced by giving an antiemetic such as cyclizine or domperidone but not a phenothiazine (see Antipsychotics, under Interactions, p. 907.3). Use with a peripheral dopa-decarboxylase inhibitor reduces peripheral but not central adverse effects. Orthostatic hypotension may respond to the use of elastic stockings.

The benefits of gastric decontamination after an overdose of levodopa are uncertain. However, activated charcoal should be considered in adults who have ingested more than 2 g (or more than the total daily dose, whichever is greater), and in children who have taken more than 200 mg, if they present within 1 hour of ingestion. Supportive measures should also be instituted. Pyridoxine may increase the metabolism of levodopa (see Nutritional Agents, under Interactions, p. 908.1) but its value in overdosage has not been established; it does not reduce the effects of levodopa given with a peripheral dopa-decarboxylase inhibitor.

Nausea and vomiting. For reference to the use of domperidone in the management of nausea and vomiting associated with levodopa in patients with Parkinson's disease, see under Uses and Administration of Domperidone, p. 1841.2.

Psychosis. Atypical antipsychotics such as clozapine (p. 1058.1) have been tried in the management of psychosis occurring as a complication of parkinsonism and of drugs such as levodopa used in its treatment.

Precautions

Levodopa is contra-indicated in patients with angle-closure glaucoma and should be used with caution in open-angle glaucoma. Caution is also required in patients with cardiovascular disease, pulmonary disease, endocrine disorders, psychiatric disturbances, osteomalacia, hepatic or renal disease, or a history of peptic ulceration. Periodic evaluations of hepatic, psychiatric, haematological, renal and cardiovascular functions have been advised.

Since an association between levodopa and activation of malignant melanoma has been suspected (although not confirmed), it is generally recommended that levodopa should not be given to patients with (or with a history of) the disease or with skin disorders suggestive of it.

Parkinsonian patients who benefit from levodopa therapy should be warned to resume normal activities gradually to avoid the risk of injury. Treatment with levodopa should not be stopped abruptly.

Excessive daytime sleepiness and sudden onset of sleep may occur with levodopa and caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring.

Levodopa inhibits prolactin secretion and may therefore interfere with lactation.

Food interferes with the absorption of levodopa, though levodopa is usually given with or immediately after meals to reduce nausea and vomiting. However, patients with the 'on-off' phenomenon may benefit from dosage on an empty stomach (see Parkinsonism, p. 889.1).

Abuse. Abuse of levodopa and dopamine agonists in patients with Parkinson's disease has been reported.[1-6] The term dopamine dysregulation syndrome, has been used to describe a condition where there is a compulsive and dysregulated use of dopaminergic drugs beyond that needed to achieve relief of motor symptoms and which is harmful to the patient.[7] Patients have progressively increased the dosage of levodopa to obtain psychotropic effects such as euphoria despite accompanying dystonia and other extrapyramidal adverse effects. Withdrawal often led to craving, drug-seeking behaviour, and mood disturbances such as depression, features resembling a psychological dependence syndrome. Abuse in patients without parkinsonism has also occurred.[8]

8. Steiner I, Wirguin I. Levodopa addiction in non-parkinsonian patients. *Neurology* 2003; **61**: 1451.

Cardiovascular disorders. A high incidence of cardiovascular adverse effects was reported in early studies of levodopa, but both Parkinson's disease and heart disease are common in the elderly and adverse cardiac effects of levodopa may be less prevalent than was first thought. A study in 40 patients[1] concluded that, apart from those with severe orthostatic hypotension or unstable coronary disease, levodopa may be used safely in parkinsonian patients with heart disease. Others[2] noted that levodopa and bromocriptine cause cardiac arrhythmias in less than 1% of all patients, the incidence for levodopa with a peripheral dopa-decarboxylase inhibitor being lower still. Nevertheless, caution is advised in patients with cardiovascular disease.

1. Jenkins RB, *et al.* Levodopa therapy of patients with parkinsonism and heart disease. *BMJ* 1972; **3**: 512–14.
2. Parkes JD, *et al.* Amantadine-induced heart failure. *Lancet* 1977; **i**: 904.

Diabetes mellitus. For reference to concern over the potential of levodopa to impair glucose utilisation, see Effects on the Endocrine System under Adverse Effects, p. 905.1.

Melanoma. There has been concern over the effects of levodopa on melanoma in view of the ability of malignant melanoma cells to convert levodopa to melanin and isolated reports of melanoma developing or being exacerbated during levodopa therapy continue to appear. However, in a survey of 1099 patients with primary cutaneous malignant melanoma only one had taken levodopa.[1] It was concluded that levodopa therapy is not an important factor in the induction of malignant melanoma. Furthermore, use of levodopa in daily doses of up to 4 g with carbidopa in 17 patients with metastatic melanoma failed to provide any evidence that levodopa accelerated the progression of the disease.[2] Reviews[3,4] of these and later reports concluded that the purported link between levodopa and malignant melanoma was tenuous.

For a report of antineoplastic chemotherapy used for the treatment of melanoma reducing the efficacy of levodopa, see under Interactions, below.

1. Sober AJ, Wick MM. Levodopa therapy and malignant melanoma. *JAMA* 1978; **240**: 534–5.
2. Gurney H, *et al.* The use of L-dopa and carbidopa in metastatic malignant melanoma. *J Invest Dermatol* 1991; **96**: 85–7.
3. Siple JF, *et al.* Levodopa therapy and the risk of malignant melanoma. *Ann Pharmacother* 2000; **34**: 382–5.
4. Fiala KH, *et al.* Malignant melanoma and levodopa in Parkinson's disease: causality or coincidence? *Parkinsonism Relat Disord* 2003; **9**: 321–7.

Pregnancy. Levodopa alone and with carbidopa has been associated with fetal abnormalities in *animals* given high doses; no teratogenic effect has been noted with carbidopa alone. However, 2 women with parkinsonism who received levodopa with carbidopa or levodopa alone throughout their pregnancies gave birth to normal infants.[1]

1. Cook DG, Klawans HL. Levodopa during pregnancy. *Clin Neuropharmacol* 1985; **8**: 93–5.

Withdrawal. For adverse effects associated with withdrawal of levodopa, see under Adverse Effects, p. 906.2.

Interactions

The therapeutic or adverse effects of levodopa may be affected by interactions with a variety of drugs. Mechanisms may include effects on catecholamine metabolising enzymes, neurotransmitters, or receptor sites, effects on the endocrine system, and effects on gastrointestinal absorption. Drugs that modify gastric emptying may affect the absorption of levodopa.

Antibacterials. A study[1] in 7 healthy subjects showed that use of *spiramycin* with levodopa and carbidopa resulted in reduced plasma-levodopa concentrations and an increase in its peripheral metabolism.

A hypertensive reaction and severe tremor occurred when *isoniazid* was given to a patient receiving levodopa;[2] it was not certain whether isoniazid was acting as an MAOI.

1. Brion N, *et al.* Effect of a macrolide (spiramycin) on the pharmacokinetics of L-dopa and carbidopa in healthy volunteers. *Clin Neuropharmacol* 1992; **15**: 229–35.
2. Morgan JP. Isoniazid and levodopa. *Ann Intern Med* 1980; **92**: 434.

Antidepressants. *BUPROPION.* Caution has been advised with bupropion because of reports of a higher incidence of adverse effects during use with levodopa.

MAOIS. Giving levodopa with non-specific MAOIs such as *phenelzine, nialamide,* or *tranylcypromine* may cause dangerous hypertension;[1-4] it is recommended that levodopa should not be given with, or within at least 14 days of stopping, an MAOI. Hypertensive reactions to levodopa with tranylcypromine were inhibited by carbidopa,[5] but licensed product information for preparations containing levodopa with carbidopa or benserazide still contra-indicates their use with MAOIs. The incidence of adverse effects may be increased if levodopa is used with *moclobemide,* a monoamine oxidase type A inhibitor (see Dopaminergics, p. 438.2). *Selegiline,* a monoamine oxidase type B inhibitor, is used to enhance the antiparkinsonian effect of levodopa, see p. 914.3.

1. Hodge JV. Use of monoamine oxidase inhibitors. *Lancet* 1965; **i**: 764–5.

5. Teychenne PF, *et al.* Interactions of levodopa with inhibitors of monoamine oxidase and L-aromatic amino acid decarboxylase. *Clin Pharmacol Ther* 1975; **18**: 273–7.

SSRIS. There was some evidence from a prescribing study that *SSRIs might* exacerbate parkinsonism resulting in increased doses of levodopa or addition of adjunctive drugs.[1]

1. van de Vijver DAMC, *et al.* Start of a selective serotonin reuptake inhibitor (SSRI) and increase of antiparkinsonian drug treatment in patients on levodopa. *Br J Clin Pharmacol* 2002; **54**: 168–70.

TRICYCLIC ANTIDEPRESSANTS. Although tricyclic antidepressants have generally been used safely with levodopa,[1] hypertensive crises have occurred in some rare cases. Such events have been reported in patients receiving *amitriptyline* or *imipramine* and levodopa with carbidopa.[2,3] Imipramine has been reported to impair the rate of levodopa absorption,[4] presumably due to its antimuscarinic properties (for the effect of antimuscarinics on the absorption of levodopa, see below).

1. Hunter KR, *et al.* Use of levodopa with other drugs. *Lancet* 1970; **ii**: 1283–5.

4. Morgan JP, *et al.* Imipramine-mediated interference with levodopa absorption from the gastrointestinal tract in man. *Neurology* 1975; **25**: 1029–34.

TRYPTOPHAN. See Amino Acids under Nutritional Agents, below.

Antiepileptics. *Phenytoin* has been shown to diminish the therapeutic effect of levodopa in patients with parkinsonism or chronic manganese poisoning.[1] The mechanism of the interaction was considered uncertain.

1. Mendez JS. Diphenylhydantoin: blocking of levodopa effects. *Arch Neurol* 1975; **32**: 44–6.

Antihypertensives. Use of levodopa with *guanethidine* may cause increased hypotension.[1] *Clonidine* has been reported to inhibit the therapeutic effect of levodopa, possibly by stimulating central alpha-adrenoceptors.[2] *Methyldopa* and levodopa may enhance each other's therapeutic or adverse effects, although there has been mention of the inhibitory effect of methyldopa on the therapeutic response to levodopa.[3,4] *Reserpine and other rauwolfia alkaloids* may oppose the antiparkinsonian effects of levodopa by central depletion of dopamine; UK licensed product information advises that use together should be avoided.

2. Shoulson I, Chase TN. Clonidine and the anti-parkinsonian response to L-dopa or piribedil. *Neuropharmacology* 1976; **15**: 25–7.
3. Cotzias GC, *et al.* L-Dopa in Parkinson's syndrome. *N Engl J Med* 1969; **281**: 272.
4. Kofman O. Treatment of Parkinson's disease with L-dopa: a current appraisal. *Can Med Assoc J* 1971; **104**: 483–7.

Antimuscarinics. Antimuscarinic antiparkinsonian drugs may enhance the therapeutic effects of levodopa but by delaying gastric emptying they may also reduce its absorption.[1]

1. Algeri S, *et al.* Effect of anticholinergic drugs on gastro-intestinal absorption of L-dopa in rats and in man. *Eur J Pharmacol* 1976; **35**: 293–9.

Antineoplastics. A patient with Parkinson's disease noted[1] that the efficacy of levodopa was reduced each time he received *dacarbazine* for the treatment of melanoma. As serum-dopamine concentrations were unchanged it was suggested[1] that dacarbazine might compete with levodopa at the blood-brain barrier.

1. Merello M, *et al.* Impaired levodopa response in Parkinson's disease during melanoma therapy. *Clin Neuropharmacol* 1992; **15**: 69–74.

Antipsychotics. The therapeutic effects of levodopa may be diminished by CNS dopamine inhibitors including phenothiazine derivatives[1] such as *prochlorperazine.*[2] Butyrophenones such as *haloperidol* and thioxanthenes such as *flupentixol* might be expected to have a similar effect due to their antidopaminergic properties.

2. Duvoisin RC. Diphenidol for levodopa induced nausea and vomiting. *JAMA* 1972; **221**: 1408.

Anxiolytics. Reversible deterioration of parkinsonism has been reported in patients receiving levodopa who were also given *benzodiazepines* such as *diazepam,*[1,2] *nitrazepam*[1] (although the evidence was equivocal), or *chlordiazepoxide.*[3] In one case parkinsonian symptoms resolved without alteration in the medication.[1]

3. Yosselson-Superstine S, Lipman AG. Chlordiazepoxide interaction with levodopa. *Ann Intern Med* 1982; **96**: 259–60.

Baclofen. Adverse effects including hallucinations, confusion, headache, and nausea and worsening of symptoms have been reported[1,2] in patients with Parkinson's disease taking levodopa when also given baclofen.

2. Lees AJ, *et al.* Baclofen in Parkinson's disease. *J Neurol Neurosurg Psychiatry* 1978; **41**: 707–8.

Gastrointestinal drugs. *ANTACIDS.* Some studies have suggested that taking an antacid before a dose of levodopa enhances the absorption of levodopa, apparently by enhancing gastric emptying and reducing metabolism of levodopa in the stomach.[1,2] This was particularly marked in a case report in a patient with prolonged gastric emptying time.[1] However, another study in 8 patients with presumably normal gastric motility, only 3 of whom had Parkinson's disease, found no significant increase in overall absorption of levodopa when given with an antacid although there was some evidence of increased absorption in some of the patients.[3] UK licensed product information (*Madopar CR; Roche*) states that antacids reduce the absorption of levodopa from the modified-release preparation by 32%.

3. Leon AS, Spiegel HE. The effect of antacid administration on the absorption and metabolism of levodopa. *J Clin Pharmacol* 1972; **12**: 263–7.

ANTIEMETICS. Metoclopramide is a dopamine antagonist and may cause extrapyramidal symptoms including parkinsonism; however, it accelerates gastric emptying and has been reported[1] to increase the rate of levodopa absorption. The importance of timing has been noted[2] since levodopa delays gastric emptying and metoclopramide antagonises this effect. Licensed product information advises caution when using metoclopramide with levodopa. *Domperidone* has been reported to increase the bioavailability of levodopa slightly.[3]

1. Neira WD, *et al.* The effects of cisapride on plasma L-dopa levels and the clinical response in Parkinson's disease. *Mov Disord* 1995; **10**: 66–70.

General anaesthetics. The general anaesthetics *cyclopropane* and *halothane* lower the threshold for ventricular arrhythmias to sympathomimetic amines, including dopamine, and should probably not be used within 6 to 8 hours of levodopa.[1,2] Although other general anaesthetics are now usually preferred, it was suggested that, in any case, levodopa could safely be taken before surgery when given with a peripheral dopa-decarboxylase inhibitor.[3]

Nutritional agents. *AMINO ACIDS.* The transport of levodopa into the brain is subject to competition from chemically related L-amino acids, especially the other aromatic amino acids *phenylalanine, tyrosine, tryptophan,* and *histidine.*[1] A high-protein diet or the large neutral amino acids pheny-

lalanine, *leucine*, or *isoleucine* have been shown to reduce the therapeutic effect of levodopa given by intravenous infusion to parkinsonian patients; such alterations in the absorption and transport of levodopa may contribute to the fluctuating responses seen in Parkinson's disease, the so-called 'on-off' phenomenon[2] (see also Parkinsonism, p. 889.1). In contrast, a study in healthy subjects[3] found that while a low-protein meal appeared to cause a small reduction in levodopa absorption, a high-protein meal had no such effect. Other reported interactions with amino acids include *methionine*-antagonism of the therapeutic effect of levodopa in parkinsonism[4] and *tryptophan*-reduced blood concentrations of levodopa.[5]

IRON SALTS. Levodopa forms complexes with iron salts and *ferrous sulfate* has reduced bioavailability of levodopa by about 50% in healthy subjects.[1] Giving ferrous sulfate to 9 patients with Parkinson's disease receiving levodopa with carbidopa reduced the area under the concentration-time curve for levodopa by 30%; the reduction was greater than 75% for carbidopa. Although this was associated with deterioration in some patients' disability, the average reduction in efficacy of therapy did not achieve statistical significance.[2]

2. Campbell NRC, *et al.* Sinemet-ferrous sulphate interaction in patients with Parkinson's disease. *Br J Clin Pharmacol* 1990; 30: 599–605.

PYRIDOXINE. The enzyme responsible for the decarboxylation of levodopa, L-amino acid decarboxylase, is dependent on pyridoxine and pyridoxine supplements have been reported to enhance the peripheral metabolism of levodopa to dopamine leaving less available to cross the blood-brain barrier for central conversion to dopamine;[1-4] pyridoxine therefore inhibits the action of levodopa but this can be stopped by use of a peripheral dopa-decarboxylase inhibitor.[2,3]

4. Carter AB. Pyridoxine and parkinsonism. *BMJ* 1973; 4: 236.

Papaverine. Antagonism of the beneficial effects of levodopa in parkinsonism has been reported when patients were also given papaverine,[1,2] and it was recommended that the combination should be avoided. However, a later study[3] in 9 patients receiving levodopa with a peripheral dopa-decarboxylase inhibitor found no changes in the control of Parkinson's disease when they were also given papaverine for 3 weeks.

3. Montastruc JL, *et al.* Does papaverine interact with levodopa in Parkinson's disease? *Ann Neurol* 1987; 22: 558–9.

Penicillamine. Isolated case reports suggest that penicillamine increases plasma-levodopa concentrations.[1]

1. Mizuta E, *et al.* Effect of D-penicillamine on pharmacokinetics of levodopa in Parkinson's disease. *Clin Neuropharmacol* 1993; 16: 448–50.

Sympathomimetics. It has been suggested that sympathomimetics such as *adrenaline* or *isoprenaline* may enhance the cardiac adverse effects of levodopa.[1]

1. Goldberg LI, Whitsett TL. Cardiovascular effects of levodopa. *Clin Pharmacol Ther* 1971; 12: 376–82.

Pharmacokinetics

Levodopa is rapidly absorbed from the gastrointestinal tract by an active transport system. Most absorption takes place in the small intestine; absorption is very limited from the stomach, and since decarboxylation may take place in the stomach wall, delays in gastric emptying may reduce the amount of levodopa available for absorption. Peak plasma concentrations occur within 2 hours of oral doses. Levodopa is about 10 to 30% bound to plasma proteins.

Levodopa is rapidly decarboxylated by the enzyme aromatic L-amino acid decarboxylase, mostly in the gut, liver, and kidney, to dopamine, which is metabolised in turn, principally to dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA). Other routes of metabolism include *O*-methylation, transamination, and oxidation, producing a variety of minor metabolites including noradrenaline and 3-*O*-methyldopa; the latter may accumulate in the CNS due to its relatively long half-life. The elimination half-life of levodopa itself is reported to be about 30 to 60 minutes.

Unlike dopamine, levodopa is actively transported across the blood-brain barrier, but because of the extent of peripheral decarboxylation very little is available to enter the CNS unless it is given with a peripheral dopa-decarboxylase inhibitor. In the presence of a peripheral dopa-decarboxylase inhibitor the major route of metabolism of levodopa becomes the formation of 3-*O*-methyldopa by the enzyme catechol-*O*-methyltransferase.

About 80% of an oral dose of levodopa is excreted in the urine within 24 hours, mainly as dihydroxyphenylacetic and homovanillic acids. Only small amounts of levodopa are excreted unchanged in the faeces.

Levodopa crosses the placenta and is distributed into breast milk.

Pharmacopoeial Preparations

BP 2014: Co-beneldopa Capsules; Co-careldopa Tablets; Dispersible Co-beneldopa Tablets; Levodopa Capsules; Levodopa Tablets; Prolonged-release Co-beneldopa Capsules;
USP 36: Carbidopa and Levodopa Orally Disintegrating Tablets; Carbidopa and Levodopa Tablets; Levodopa Capsules; Levodopa Tablets.

Lisuride Maleate *(BANM, rINNM)*

Lisurid Maleat; Lisurida, maleato de; Lisuride, Maléate de; Lisuridi Hydrogenomaleas; Lisuridi Maleas; Lisuridivetymaleaatti; Lisuridvätemaleat; Lysuride Maleate; Maleato de lisurida; Methylergol Carbamide Maleate; Лизурида Малеат.
3-(9,10-Didehydro-6-methylergolin-8α-yl)-1,1-diethylurea hydrogen maleate; 8-Decarboxamido-8-(3,3-diethylureido)-D-lysergamide maleate.
$C_{20}H_{26}N_4O.C_4H_4O_4$=454.5

CAS — 18016-80-3 (lisuride); 19875-60-6 (lisuride maleate).
ATC — G02CB02; N02CA07.
ATC Vet — QG02CB02; QN02CA07.
UNII — UV1635N8XW.

Uses and Administration

Lisuride maleate, an ergot derivative, is a dopamine D_2-agonist with actions and uses similar to those of bromocriptine (p. 895.3). It is also reported to have serotonergic activity. It is used similarly in the management of Parkinson's disease (p. 909.1) and has been used in disorders associated with hyperprolactinaemia (below), including amenorrhoea, galactorrhoea, and infertility. It is also used to suppress puerperal lactation for medical reasons; it is not recommended for the routine suppression of physiological lactation or for the treatment of postpartum breast pain and engorgement that can be adequately relieved with simple analgesics and breast support. Lisuride has been used in some countries for the treatment of acromegaly, and for the prophylaxis of migraine. It is normally given orally; doses should be taken with food.

In the management of **Parkinson's disease**, lisuride maleate has been added to treatment with levodopa or other antiparkinsonian drugs. Initially 100 micrograms is taken at bedtime and additional doses of 100 micrograms may be added, at intervals of one week, first in the morning and then at midday. Further increases are made, until an optimum response is obtained, by adding 100 micrograms each week using the same sequence of increases, starting with the bedtime dose; dosage should not normally exceed 2 mg daily given in 3 or 4 divided doses.

When used to **suppress lactation**, the usual dose of lisuride maleate is 200 micrograms two or three times daily for 14 days; treatment should be started within the first 24 hours of delivery.

In the treatment of disorders associated with **hyperprolactinaemia**, 100 micrograms of lisuride maleate may be given in the evening of the first day, followed by 100 micrograms at midday and in the evening of the second day, and 100 micrograms in the morning, at midday, and in the evening of the third day; thereafter doses may be adjusted according to prolactin levels. Similar doses are also used in **acromegaly** with adjustments made according to growth hormone levels (see also below).

Acromegaly. Dopaminergics can produce a paradoxical reduction in growth hormone secretion and may be used in the treatment of acromegaly as adjunctive therapy to surgery, radiotherapy, or somatostatin analogues to reduce circulating growth hormone levels, although they are less effective than somatostatin analogues (p. 1921.1). While bromocriptine and cabergoline have been the main dopamine agonists used, lisuride has been used in some countries.

Hyperprolactinaemia and prolactinomas. Dopamine agonists have been widely used for the treatment of hyperprolactinaemia secondary to a prolactinoma (p. 2252.2). Lisuride has been used as an alternative to bromocriptine. There is a report of plasma-prolactin concentrations being reduced to normal in 4 female patients with macroprolactinomas given lisuride 400 to 800 micrograms daily for 2 years.[1] Subsequent dosage reduction in 3 was followed by a rise in prolactin values. In the fourth patient prolactin remained in the normal range when the dose was progressively reduced from 400 to 50 micrograms daily, although complete withdrawal was followed by an increase in prolactin concentration within 3 months.

Vaginal dosage of lisuride has been studied in an attempt to avoid adverse effects associated with oral therapy. In a study[2] involving 40 women with hyperprolactinaemia a 200-microgram standard oral tablet placed in the vagina at night produced a similar reduction in prolactin concentrations to that obtained with 400 micrograms taken orally and was better tolerated.

2. Tasdemir M, *et al.* Vaginal lisuride for hyperprolactinaemia. *Lancet* 1995; 346: 1362.

Lactation inhibition. Lisuride is used in some countries for the prevention of puerperal lactation (p. 2130.1). However, the routine use of dopaminergics is not recommended for the suppression of physiological lactation.

Mastalgia. In a small placebo-controlled study,[1] lisuride 200 micrograms daily was effective in the treatment of cyclical mastalgia. However, since mastalgia (p. 2265.) can improve spontaneously, treatment should rarely be

considered unless pain has been present for about 6 months.

1. Kaleli S, *et al.* Symptomatic treatment of premenstrual mastalgia in premenopausal women with lisuride maleate: a double-blind placebo-controlled randomized study. *Fertil Steril* 2001; 75: 718–23.

Migraine. Although lisuride has been used in some countries for the prophylaxis of migraine (p. 670.3) it is not usually considered to be the drug of choice or even one of the main alternatives.

Parkinsonism. While some neurologists use dopamine agonists such as lisuride early in the treatment of parkinsonism (p. 889.1) in an attempt to delay therapy with levodopa, others reserve them for adjunctive use when levodopa is no longer effective alone or cannot be tolerated. They are sometimes useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations in mobility in the later stages of the disease.

ADMINISTRATION. Lisuride has been of benefit when given by continuous intravenous or subcutaneous infusion in patients having fluctuations in mobility with levodopa therapy[1–4] but severe psychiatric effects have been associated with the use of these routes.[3] Transdermal lisuride has also been investigated for the treatment of Parkinson's disease and restless legs syndrome.[5,6]

Adverse Effects and Precautions

As for Bromocriptine, p. 896.3. Infusion of lisuride in parkinsonian patients has been associated with severe psychiatric adverse effects.

Effects on mental function. For reports of **daytime somnolence** occurring in patients receiving dopamine agonists including lisuride, see under Levodopa, p. 905.2.

For reference to **disturbed behaviour** including **excessive gambling** reported in patients with Parkinson's disease receiving dopamine agonists, see under Levodopa, p. 905.2.

Fibrosis. For reports of fibrotic reactions occurring in patients with Parkinson's disease receiving ergot derivative dopamine agonists including lisuride, see under Adverse Effects of Bromocriptine, p. 897.3.

Interactions

As for Bromocriptine, p. 899.1.

Pharmacokinetics

Plasma concentrations varied widely after a single oral dose of lisuride maleate 300 micrograms in 11 patients with Parkinson's disease.[1] Absorption was rapid and the mean plasma elimination half-life was 2.2 hours. Only a mean of 0.05% of the dose was excreted unchanged in the urine in 24 hours. The mean oral bioavailability of lisuride maleate has been reported[2] to be 10% after a 100-microgram dose and 22% after a 300-microgram dose.

A single dose of lisuride 25 micrograms given by intravenous, intramuscular, or subcutaneous injection reduced plasma-prolactin concentrations by up to 60% in 11 of 12 healthy subjects, the effect lasting for about 10 hours.[3] Plasma-lisuride concentrations after intravenous injection fell in 2 phases with half-lives of 14 minutes and 1.5 hours, respectively. Peak plasma concentrations after subcutaneous and intramuscular injection were obtained after 12 and 15 minutes, respectively.

$C_{20}H_{23}NS,HCl,H_2O$=363.9

CAS — 4969-02-2 (metixene); 1553-34-0 (anhydrous metixene hydrochloride); 7081-40-5 (metixene hydrochloride monohydrate).

ATC — N04AA03.

ATC Vet — QN04AA03.

UNII — 84L8XK6N1G.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Metixene Hydrochloride). A white or almost white, crystalline or fine crystalline powder. Soluble in water, in alcohol, and in dichloromethane. A 1.8% solution in water has a pH of 4.4 to 5.8. Protect from light.

Profile

Metixene hydrochloride is a tertiary antimuscarinic with actions similar to those of atropine (p. 1312.1); it also has antihistaminic and direct antispasmodic properties.

It is used for the symptomatic treatment of parkinsonism (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. The usual oral dose of metixene hydrochloride is 2.5 mg three to six times daily initially, gradually increased according to response to a total of 20 to 60 mg daily in divided doses.

Metixene hydrochloride has also been used in preparations to relieve gastrointestinal spasms.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies metixene as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

(*RS*)-Dimethyl[2-(2-methylbenzhydryloxy)ethyl]amine hydrochloride.

$C_{18}H_{23}NO,HCl$=305.8

CAS — 341-69-5.

ATC — N04AB02.

ATC Vet — QN04AB02.

UNII — UBY910DUXH.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Orphenadrine Hydrochloride). A white or almost white crystalline powder. Freely soluble in water and in alcohol. Protect from light.

Uses and Administration

Orphenadrine, which is a congener of diphenhydramine (p. 626.1) without sharing its soporific effect, is a tertiary amine antimuscarinic with actions and uses similar to those of trihexyphenidyl (p. 917.3). It also has weak antihistaminic and local anaesthetic properties. Orphenadrine is used as the hydrochloride and the citrate; doses are expressed in terms of the relevant salt.

Orphenadrine is used as the hydrochloride in the symptomatic treatment of **parkinsonism** (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. The initial oral dose of orphenadrine hydrochloride is 150 mg daily in divided doses gradually increased by 50 mg every 2 or 3 days according to response; the usual maintenance dose is in the range of 150 to 300 mg daily, but some patients may require a total of up to 400 mg daily. Orphenadrine hydrochloride has also been given intramuscularly.

Orphenadrine is also used as the citrate to relieve pain due to **skeletal muscle spasm** (below). It is given orally in a dose of 100 mg twice daily or by intramuscular or slow intravenous injection in a dose of 60 mg which has been repeated every 12 hours.

Combinations of orphenadrine with an NSAID, usually diclofenac, or with paracetamol, have been used in the treatment of musculoskeletal and joint disorders.

Hiccup. Orphenadrine citrate has been used in some countries for the treatment of intractable hiccup. For the management of intractable hiccups see under Chlorpromazine, p. 1046.3.

Muscle and joint disorders. References to the use of orphenadrine in the management of leg cramps and other painful conditions associated with skeletal muscle spasm,[1,2] and with diclofenac in osteoarthritis and other musculoskeletal disorders.[3,4]

3. Ulitz E, *et al.* Diclofenac/Orphenadrin-Infusionstherapie bei Patienten mit aktivierten Arthrosen. *Wien Med Wochenschr* 1998; 148: 179–82.
4. Aglas F, *et al.* Ergebnisse einer Anwendungsbeobachtung mit Diclofenac/Orphenadrin-Infusionen bei Patienten mit muskuloskelettalen Krankheiten und Funktionsstörungen. *Acta Med Austriaca* 1998; 25: 86–90.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p. 1312.1. Orphenadrine may cause insomnia.

Abuse. A 23-year-old schizophrenic man, whose treatment included orphenadrine 100 mg three times daily, obtained illicit supplies and increased the dose for euphoric effect.[1] On one occasion he had an epileptic convulsion after a 600-mg dose.

See also under Trihexyphenidyl Hydrochloride, p. 918.1.

Overdosage. A report[1] of acute poisoning with orphenadrine after massive overdosage in a schizophrenic patient, who responded to intensive supportive treatment, including large doses of adrenaline, dopamine, and dobutamine to restore blood pressure following asystole. Between 1977

and 1980 twelve deaths due to orphenadrine were recorded by the UK National Poisons Unit.

1. Clarke B, *et al.* Acute poisoning with orphenadrine. *Lancet* 1985; i: 1386.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies orphenadrine as porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be taken in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Withdrawal. A suspected withdrawal syndrome was reported in a 56-year-old woman who showed slow neurological postoperative recovery after her orphenadrine treatment had been stopped abruptly;[1] her status improved when the drug was restarted.

1. Esler MD, *et al.* Postoperative orphenadrine withdrawal. *Br J Anaesth* 2000; 85: 497.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3). Orphenadrine is an inhibitor of the cytochrome P450 isoenzyme CYP2B6, which is involved in the metabolism of bupropion to its major metabolite; licensed product information advises that orphenadrine should be used with caution in patients also receiving bupropion.

Chlorpromazine. For the effect of orphenadrine on plasma concentrations of chlorpromazine, see Antiparkinsonian Drugs, p. 1052.3.

Dextropropoxyphene. A suggested interaction between orphenadrine and dextropropoxyphene was open to question.[1,2]

1. Pearson RE, Salter FJ. Drug interaction? — orphenadrine with propoxyphene. *N Engl J Med* 1970; 282: 1215.
2. Puckett WH, Visconti JA. Orphenadrine and propoxyphene (corr.). *N Engl J Med* 1970; 283: 544.

Pharmacokinetics

Orphenadrine is readily absorbed from the gastrointestinal tract and after intramuscular injection. It is almost completely metabolised to at least 8 metabolites. It is mainly excreted in the urine as metabolites and small amounts of unchanged drug. The half-life of orphenadrine has been reported to be 14 hours (but see below).

Half-life. While the mean elimination half-life of orphenadrine in 5 healthy subjects given a single dose of the hydrochloride was found to be 15.5 hours, elimination half-lives of 30.5 and 40 hours were calculated in 2 patients given repeated oral doses.[1]

$C_{19}H_{26}N_2S,CH_4O_3S$=410.6

CAS — 66104-22-1 (pergolide); 66104-23-2 (pergolide mesilate).

ATC — N04BC02.

ATC Vet — QN04BC02.

UNII — 55B9HQY616.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Pergolide Mesilate). A white or almost white crystalline powder. Slightly soluble in water, in alcohol, and in dichloromethane; very slightly soluble in acetone; sparingly soluble in methyl alcohol. Protect from light.

USP 36: (Pergolide Mesylate). A white to off-white powder. Slightly soluble in water, in dehydrated alcohol, and in chloroform; very slightly soluble in acetone; practically insoluble in ether; sparingly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Uses and Administration

Pergolide mesilate, an ergot derivative, is a dopamine D_2-agonist with actions and uses similar to those of bromocriptine (p. 895.3), but in contrast to bromocriptine (a dopamine D_2-agonist) it also has agonist properties at D_1 and D_3 receptors. Pergolide is used in the management of Parkinson's disease (below) as monotherapy, or as an adjunct to levodopa therapy to reduce 'end-of-dose' or 'on-off' fluctuations in response; in the UK pergolide is restricted to patients who are intolerant of, or who fail to respond to, non-ergot drug treatment. Pergolide is given orally as the mesilate with doses expressed as the base. Pergolide mesilate 65.3 mg is equivalent to about 50 mg pergolide.

For use as *monotherapy* an initial dose equivalent to 50 micrograms of pergolide is given on the first evening of therapy. The dose is thereafter gradually increased: 50 micrograms twice daily is taken on days 2 to 4, then increased by 100 to 250 micrograms every 3 or 4 days, given in 3 divided doses, up to a daily dose of 1.5 mg at day 28. After day 30, the dose should be increased further by a maximum of 250 micrograms twice a week until an optimum response is achieved. Usual maintenance doses are 2.1 to 2.5 mg daily; doses above 3 mg daily are not recommended by the EMEA. The daily dose is usually given in 3 divided doses.

For use as *adjunctive therapy* with levodopa, pergolide should be introduced gradually and during this period patients can have their levodopa dosage decreased gradually until an optimum response is achieved. The initial dose of pergolide is the equivalent of 50 micrograms daily for the first 2 days, increased gradually by 100 or 150 micrograms every third day over the next 12 days of therapy. Further increases of 250 micrograms may then be made every third day until an optimum response is achieved. A usual maintenance dose is 3 mg daily; doses above 3 mg daily are not recommended by the EMEA. The daily dose is usually given in 3 divided doses.

Acromegaly. Dopaminergics can produce a paradoxical reduction in growth hormone secretion and may be used in the treatment of acromegaly as adjunctive therapy to surgery, radiotherapy, or somatostatin analogues to reduce circulating growth hormone levels, although they are less effective than somatostatin analogues (p. 1921.1). While bromocriptine and cabergoline have been the main dopamine agonists used pergolide has also been tried.[1]

1. Kleinberg DL, *et al.* Pergolide for the treatment of pituitary tumors secreting prolactin or growth hormone. *N Engl J Med* 1983; 309: 704–9.

Hyperprolactinaemia and prolactinomas. Dopamine agonists are widely used for the treatment of hyperprolactinaemia secondary to a prolactinoma (p. 2252.2). Pergolide has been suggested as an alternative to bromocriptine in this condition.

Studies[1-3] of pergolide mesilate in patients with hyperprolactinaemia indicate that single doses reduce serum-prolactin concentrations for more than 24 hours. In most patients, the effective dose was between 50 and 150 micrograms daily. Adverse effects were similar to those seen with bromocriptine, although some patients who could not take bromocriptine were able to tolerate pergolide (and vice versa). Pergolide reportedly lost favour for this indication after reports of an increased incidence of uterine neoplasms in *rodents* receiving high doses. However, licensed product information states that no cases of uterine malignancies have to date been reported in humans receiving pergolide. The long-term outcome of treatment of macroprolactinomas with pergolide has been examined in 23 patients,[4] and efficacy and relative safety of pergolide was shown after an average of 27 months (range: 9 to 64 months) treatment.

4. Preda PU, *et al.* Long-term treatment of prolactin-secreting macroadenomas with pergolide. *J Clin Endocrinol Metab* 2000; 85: 8–13.

Parkinsonism. Dopamine agonists such as pergolide are often used to begin the treatment of parkinsonism (p. 889.1) in an attempt to delay therapy with levodopa, particularly in younger patients. They also have an adjunctive use when levodopa is no longer effective alone or cannot be tolerated, and may sometimes be useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations in mobility in the later stages of the disease. Pergolide has a relatively long duration of action compared with other dopamine agonists commonly used. Although the duration of the clinical antiparkinsonian effect of pergolide remains to be determined, studies suggest it is of the order of 5 to 8 hours. Depending on the dose used the response to other dopamine agonists in late parkinsonism is 1 to 4 hours for levodopa, 2 to 4 hours for lisuride, and 4 to 6 hours for bromocriptine.

Restless legs syndrome. The aetiology of restless legs syndrome (see Sleep-associated Movement Disorders, p. 1034.2) is obscure and treatment has largely been empirical although dopaminergic therapy has emerged as a common first-line choice. Pergolide has produced some benefit in several studies.[1-6] In a randomised placebo-controlled study,[6] therapeutic effects were seen with mean daily doses of pergolide 400 micrograms after 6 weeks and maintained after 12 months with doses of up to 720 micrograms daily.

Adverse Effects and Precautions

As for Bromocriptine, p. 896.3.

An increased incidence of uterine neoplasms has been reported in *rodents* given high doses of pergolide mesilate.

Effects on mental function. For reports of **daytime somnolence** occurring in patients receiving dopamine agonists including pergolide, see under Levodopa, p. 905.2.

For reference to **disturbed behaviour** including **excessive gambling** reported in patients with Parkinson's disease receiving dopamine agonists, see under Levodopa, p. 905.2.

Fibrosis. For reports of fibrotic reactions occurring in patients with Parkinson's disease receiving ergot derivative dopamine agonists including pergolide, see under Adverse Effects of Bromocriptine, p. 897.3.

In Australia,[1] Canada,[2] and Europe[3] regulatory authorities recommended that patients undergo a cardiovascular evaluation before starting treatment with pergolide; periodic clinical monitoring for development of valvular disease or fibrosis is also recommended. Doses of pergolide above 3 mg daily are not recommended by the EMEA.[3] Furthermore, use is restricted to patients who are intolerant of, or who fail to respond to, non-ergot drug treatment and it is contra-indicated in patients with a history of fibrotic disorders or in those with anatomical evidence of cardiac valvulopathy.[4] In 2007, based on further evidence from 2 studies,[5,6] pergolide was withdrawn from the market in the USA[7] and Canada.[8]

Interactions

As for Bromocriptine, p. 899.1.

Pharmacokinetics

Pergolide mesilate is absorbed from the gastrointestinal tract. It is reported to be about 90% bound to plasma proteins. It is excreted mainly in the urine in the form of metabolites.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Arg.***: Aroltex; Celance; Geranil; ***Austral.***: Permax; ***Austria***: Permax; ***Belg.***: Permax; ***Braz.***: Celance†; ***Cz.***: Permax; ***Fr.***: Celance†; ***Ger.***: Parkotil†; ***Gr.***: Celance†; ***Irl.***: Celance; ***Ital.***: Nopar; ***Mex.***: Permax; ***Neth.***: Permax†; ***NZ***: Permax; ***Port.***: Permax; ***S.Afr.***: Permax†; ***Singapore***: Celance; ***Spain***: Pharken†; ***Switz.***: Permax†; ***Turk.***: Permax; ***UK***: Celance†.

Pharmacopoeial Preparations
USP 36: Pergolide Tablets.

Piribedil *(rINN)*

ET-495; EU-4200; Piribédil; Piribedilum; Пирибедил.
2-(4-Piperonylpiperazin-1-yl)pyrimidine.
$C_{16}H_{18}N_4O_2$=298.3
CAS — 3605-01-4.
ATC — N04BC08.
ATC Vet — QN04BC08.
UNII — DO22K1PRDJ.

Profile

Piribedil is a non-ergot dopamine agonist that has been given orally in the treatment of parkinsonism (below) and in circulatory disorders. Piribedil mesilate has been given by injection for circulatory disorders. Preparations of piribedil are licensed in some countries for the management of impaired memory and cognitive function in the elderly.

Adverse effects reported include nausea and vomiting, dizziness, hallucinations, confusion, drowsiness, hypothermia, dyskinesias, and occasional changes in liver function.

When used as monotherapy in Parkinson's disease a usual daily oral dose of piribedil is 150 to 250 mg in divided doses; a daily dose of 80 to 140 mg may be suitable when used as an adjunct to levodopa.

Effects on mental function. For reports of **daytime somnolence** occurring in patients receiving dopamine agonists including piribedil, see under Adverse Effects of Levodopa, p. 905.2.

For reference to **disturbed behaviour** including **excessive gambling** reported in patients with Parkinson's disease receiving dopamine agonists, see under Adverse Effects of Levodopa, p. 905.2.

Parkinsonism. Piribedil is a dopamine D_2-agonist while its metabolite is reported to act on D_1 receptors. It has been mainly used as an adjunct to levodopa therapy in the treatment of Parkinson's disease (p. 889.1).

Pramipexole Hydrochloride

(BANM, rINNM)

Hidrocloruro de pramipexol; PNU-98528-E; Pramipexol, hidrocloruro de; Pramipexole, Chlorhydrate de; Pramipexole, dichlorhydrate de; Pramipexole Dihydrochloride (USAN); Pramipexoli dihydrochloridum; Pramipexoli Hydrochloridum; SND-919-CL-2Y (pramipexole hydrochloride); SUD-919Y (pramipexole); Прамипексола Гидрохлорид.
(*S*)-2-Amino-4,5,6,7-tetrahydro-6-(propylamino)benzothiazole dihydrochloride monohydrate.
$C_{10}H_{17}N_3S,2HCl, H_2O$=302.3
CAS — 104632-26-0 (pramipexole); 104632-25-9 (anhydrous pramipexole hydrochloride); 191217-81-9 (pramipexole hydrochloride monohydrate).
ATC — N04BC05.
ATC Vet — QN04BC05.
UNII — 3D867NP06J.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Pramipexole Dihydrochloride Monohydrate). A white or almost white, crystalline powder. Freely soluble in water; sparingly soluble to slightly soluble in alcohol; soluble in methyl alcohol; practically insoluble in dichloromethane. pH of a 2% solution in water is 2.8 to 3.4.

USP 36: (Pramipexole Dihydrochloride). A white to almost white crystalline powder. Freely soluble in water; slightly soluble in alcohol; soluble in methyl alcohol; practically insoluble in dichloromethane. Protect from moisture and light.

Uses and Administration

Pramipexole is a non-ergot dopamine agonist with actions similar to those of bromocriptine (p. 895.3). It is used similarly in the management of Parkinson's disease (below), either alone or as an adjunct to levodopa therapy to reduce 'end-of-dose' or 'on-off' fluctuations in response. Pramipexole is also used for the treatment of moderate to severe restless legs syndrome (below). It is given orally as the hydrochloride; doses have been described in terms of the hydrochloride (as below) or of the base. In terms of equivalency:

- pramipexole hydrochloride 125 micrograms is equivalent to about 88 micrograms of pramipexole
- pramipexole hydrochloride 250 micrograms is equivalent to about 180 micrograms of pramipexole
- pramipexole hydrochloride 500 micrograms is equivalent to about 350 micrograms of pramipexole
- pramipexole hydrochloride 1 mg is equivalent to about 700 micrograms of pramipexole

In the treatment of **Parkinson's disease**, the dose of pramipexole should be increased gradually and the dose of levodopa gradually reduced during the dose-titration and maintenance phases until an optimum response is achieved. The initial dose of pramipexole *hydrochloride* is 125 micrograms three times daily increased to 250 micrograms three times daily in the second week and then to 500 micrograms three times daily in the third week according to response. Thereafter the daily dose may be increased if necessary by 750 micrograms at weekly intervals to a maximum of 4.5 mg daily. Modified-release preparations are also available for once-daily use. The dosage should be reduced in patients with renal impairment (see below).

If it is necessary to stop pramipexole therapy, it should be withdrawn gradually. The dose of pramipexole hydrochloride should be tapered off at a rate of 750 micrograms daily until a daily dose of 750 micrograms has been reached; thereafter, the dose should be reduced by 375 micrograms daily.

Pramipexole is also given as a single daily dose, 2 to 3 hours before bedtime, in the treatment of **restless legs syndrome**. The initial dose of pramipexole *hydrochloride* is 125 micrograms daily. This may be increased if necessary after 4 to 7 days to 250 micrograms daily. Subsequent doses may be increased if necessary by 250 micrograms every 4 to 7 days to a maximum of 750 micrograms daily. Response to therapy should be evaluated after 3 months; if treatment is interrupted for more than a few days, it should be restarted at 125 micrograms daily, and then increased, if required, as described above. For this indication, pramipexole may be withdrawn without gradual tapering of the dose.

Administration in renal impairment. The elimination of pramipexole is dependent on renal function and the oral dosage of pramipexole hydrochloride should therefore be reduced in patients with renal impairment.

In the treatment of *Parkinson's disease*, the following dosage schedule has been suggested in UK licensed product information adjusted according to the patient's creatinine clearance (CC):

- CC 20 to 50 mL/minute: initially 125 micrograms twice daily increased, if necessary, to a maximum of 2.25 mg daily
- CC less than 20 mL/minute: initially 125 micrograms once daily increased, if necessary, to a maximum of 1.5 mg daily

Similar reductions are suggested in US licensed information for patients with a CC of 30 to 50 mL/minute and 15 to less than 30 mL/minute, respectively; no recommendation is made for those with a CC of less than 15 mL/minute.

If renal function declines during maintenance therapy it is recommended that the daily dose of pramipexole should be reduced by the same percentage as the decline in CC.

Lower doses are used in the treatment of *restless legs syndrome* and UK licensed information considers dosage reductions unnecessary in patients with CC of more than 20 mL/minute. US licensed information recommends that the interval between titration steps is increased to 14 days in those patients with CC of 20 to 60 mL/minute.

Parkinsonism. Pramipexole is a dopamine agonist used in the treatment of Parkinson's disease (p. 889.1) as an adjunct to levodopa therapy to reduce 'off' periods with levodopa and ameliorate other fluctuations of mobility in the later stages of the disease. It is also used as monotherapy early in the course of the disease in an attempt to delay therapy with levodopa.

Restless legs syndrome. The aetiology of restless legs syndrome (RLS—see Sleep-associated Movement Disorders, p. 1034.2) is obscure and treatment has largely been empirical, although dopaminergic therapy has emerged as a common first-line choice. Low-dose pramipexole has produced some benefit in several studies[1-8] and is licensed for the treatment of moderate to severe RLS in some countries.

Adverse Effects and Precautions

As for Bromocriptine, p. 896.3.

Pramipexole should be used with caution in patients with renal impairment and reduced doses are recommended.

Ophthalmological monitoring is recommended at regular intervals or if vision abnormalities occur.

Incidence of adverse effects. References.

1. Etminan M, *et al.* Comparison of the risk of adverse events with pramipexole and ropinirole in patients with Parkinson's disease: a meta-analysis. *Drug Safety* 2003; 26: 439–44.

Effects on mental function. Pramipexole has been associated with attacks of sudden onset of sleep, sometimes without any prior feeling of drowsiness, that can occur at any time during treatment. Licensed product information states that the incidence of **daytime somnolence** is increased at daily doses of pramipexole hydrochloride higher than 1.5 mg. A retrospective analysis[1] of data to evaluate the incidence and nature of somnolence in patients receiving pramipexole in clinical studies showed that for patients with moderate or severe somnolence, the onset of worst-reported somnolence occurred at a mean daily dose of around 4 mg (range: 0.75 to 4.5 mg).

For further reports of daytime somnolence occurring in patients receiving dopamine agonists including pramipexole, see under Levodopa, p. 905.2.

For reference to **disturbed behaviour** including **excessive gambling** reported in patients with Parkinson's disease receiving dopamine agonists, including pramipexole, see under Levodopa, p. 905.2.

1. Hauser RA, *et al.* Pramipexole-induced somnolence and episodes of daytime sleep. *Mov Disord* 2000; 15: 658–63.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies pramipexole as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Interactions

As for Bromocriptine, p. 899.1. Cimetidine is reported to reduce the renal clearance of pramipexole.

Caution is advised when other sedating drugs or alcohol are used with pramipexole because of possible additive effects and the risk of precipitating sudden onset of sleep (see above).

References.

1. Wright CE, *et al.* Influence of probenecid and cimetidine on pramipexole pharmacokinetics. *Clin Pharmacol Ther* 1996; 59: 183.

Pharmacokinetics

Pramipexole is readily absorbed from the gastrointestinal tract and peak plasma concentrations have occurred within about 2 hours in fasting patients and in about 3 hours when given with food. Oral bioavailability is reported to be about 90%. Pramipexole is widely distributed throughout the body and plasma-protein binding is less than 20%. Metabolism is minimal and more than 90% of a dose is excreted via renal tubular secretion unchanged into the urine. Elimination half-lives of 8 to 12 hours have been reported. On the basis of studies in *rats*, it is thought to be distributed into breast milk.

Procyclidine Hydrochloride

(BANM, rINNM)

Hidrocloruro de prociclidina; Prociclidina, hidrocloruro de; Procyclidine, Chlorhydrate de; Procyclidini Hydrochloridum; Прециклидина Гидрохлорид.

1-Cyclohexyl-1-phenyl-3-(pyrrolidin-1-yl)propan-1-ol hydrochloride.

$C_{19}H_{29}NO,HCl$=323.9

CAS — 77-37-2 (procyclidine); 1508-76-5 (procyclidine hydrochloride).

ATC — N04AA04.

ATC Vet — QN04AA04.

UNII — CQC932Z7YW.

Pharmacopoeias. In *Br.* and *US.*

BP 2014: (Procyclidine Hydrochloride). A white, odourless or almost odourless, crystalline powder. Sparingly soluble in water; soluble in alcohol; practically insoluble in acetone and in ether. A 1% solution in water has a pH of 4.5 to 6.5.

USP 36: (Procyclidine Hydrochloride). A white crystalline powder, having a moderate characteristic odour. Soluble 1 in 35 of water, 1 in 9 of alcohol, 1 in 6 of chloroform, and 1 in 11 000 of ether; insoluble in acetone. pH of a 1% solution in water is between 5.0 and 6.5. Store in a dry place in airtight containers. Protect from light.

Uses and Administration

Procyclidine hydrochloride is a tertiary amine antimuscarinic with actions and uses similar to those of trihexyphenidyl (p. 917.3). It is used for the symptomatic treatment of parkinsonism (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. It has been used in the treatment of dystonias (but see under Uses and Administration of Levodopa, p. 903.3); for doses in children, see below.

In **parkinsonism**, the initial oral dose of 2.5 mg three times daily may be increased gradually by 2.5 to 5 mg every 2 or 3 days (or by 2.5 mg daily if used for drug-induced extrapyramidal syndrome) until the optimum maintenance dose, usually 10 to 30 mg daily in 3 (or occasionally 4) divided doses, is reached; daily doses of up to 60 mg have occasionally been required. As a rule, postencephalitic patients tolerate and require the larger doses; elderly and arteriosclerotic patients may require smaller doses.

In an emergency such as **acute dystonias**, 5 to 10 mg may be given by intravenous injection; higher doses have sometimes been used. The intramuscular route has also been employed: 5 to 10 mg may be given as a single injection, repeated if necessary after 20 minutes to a maximum of 20 mg daily. Parenteral doses are usually effective within 5 to 10 minutes but may need 30 minutes to produce relief.

Administration in children. Although procyclidine hydrochloride is not licensed in the UK for management of dystonias (p. 903.3) in children, the *BNFC* suggests that oral doses of 1.25 mg 3 times daily may be given to those aged 7 to 12 years, and 2.5 mg 3 times daily to those aged 12 to 18 years. In an emergency, a single dose may be given by intramuscular or intravenous injection according to age as follows: under 2 years, 0.5 to 2 mg; 2 to 10 years, 2 to 5 mg; 10 to 18 years, 5 to 10 mg or occasionally more. Parenteral doses are usually effective within 5 to 10 minutes but may need 30 minutes to produce relief.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p. 1312.1. Psychotic episodes may be precipitated in patients with mental disorders when procyclidine is used for the treatment of drug-induced extrapyramidal syndrome.

Abuse. Like other antimuscarinics (see also under Trihexyphenidyl Hydrochloride, p. 918.1) procyclidine has been abused for its euphoriant effects.[1,2]

1. McGucken RB, *et al.* Teenage procyclidine abuse. *Lancet* 1985; I: 1514.
2. Dooris B, Reid C. Feigning dystonia to feed an unusual drug addiction. *J Accid Emerg Med* 2000; 17: 311.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

Paroxetine increases plasma-procyclidine concentrations and it is recommended that the dose of procyclidine should be reduced if antimuscarinic effects are seen in patients receiving both drugs.

Pharmacokinetics

Procyclidine hydrochloride is absorbed from the gastrointestinal tract and bioavailability has been reported to be 75% after oral doses; it disappears rapidly from the tissues. Procyclidine given intravenously acts within 5 to 20 minutes and has a duration of effect of up to 4 hours. The mean plasma elimination half-life after oral or intravenous doses is about 12 hours. About one-fifth of an oral dose is metabolised in the liver, mainly by the cytochrome P450 isoenzymes, followed by conjugation with glucuronic acid. A small amount of unchanged drug is excreted in the urine.

Profenamine Hydrochloride *(BANM, rINNM)*

Cloridrato de Profenamina; Ethopropazine Hydrochloride; Hidrocloruro de profenamina; Isothazine Hydrochloride; Profenamina, hidrocloruro de; Profénamine, Chlorhydrate de; Profenamini Hydrochloridum; Prophenamini Chloridum; Профенамина Гидрохлорид.

10-(2-Diethylaminopropyl)phenothiazine hydrochloride.

$C_{19}H_{24}N_2S,HCl$=348.9

CAS — 522-00-9 (profenamine); 1094-08-2 (profenamine hydrochloride).

ATC — N04AA05.

ATC Vet — QN04AA05.

UNII — O007111VRN.

Profile

Profenamine hydrochloride is a phenothiazine derivative with antimuscarinic, adrenergic-blocking, antihistaminic, local anaesthetic, and ganglion-blocking properties. Adverse effects associated with phenothiazines may occur, especially with high doses (see under Chlorpromazine, p. 1047.2). Profenamine has been used in the symptomatic treatment of parkinsonism (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as other phenothiazines, but, like other antimuscarinics (see Atropine Sulfate, p. 1310.2), is of no value against tardive dyskinesias. It has been used in a usual initial oral dose of 50 mg three times daily, gradually increased to 500 mg or more daily in divided doses, according to response.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Canad.***: Parsitan.

Rasagiline Mesilate *(rINNM)*

Mesilato de rasagilina; Rasagiline, Mésilate de; Rasagiline Mesylate (USAN); Rasagilini Mesilas; TV-1030 (rasagiline); TVP 1012; Разагилина Мезилат.

(R)-*N*-2-Propynyl-1-indanamine methanesulfonate.

$C_{12}H_{13}N,CH_4O_3S$=267.3

CAS — 136236-51-6 (rasagiline); 161735-79-1 (rasagiline mesilate).

ATC — N04BD02.

ATC Vet — QN04BD02.

UNII — LH8C2JI290.

Uses and Administration

Rasagiline is an irreversible selective inhibitor of monoamine oxidase type B, an enzyme involved in the metabolic degradation of dopamine in the brain. It enhances the effects of levodopa and is used in the treatment of Parkinson's disease (p. 889.1), either alone or as an adjunct to levodopa therapy to reduce 'end-of-dose' fluctuations in response. Rasagiline is given orally as the mesilate and doses are expressed in terms of the base; rasagiline mesilate 1.56 mg is equivalent to about 1 mg of rasagiline. The usual dose is the equivalent of rasagiline 1 mg once daily. In the USA, an initial daily dose of 500 micrograms is recommended for adjunctive therapy.

The dose of rasagiline may need to be reduced when given with drugs that inhibit the cytochrome P450 isoenzyme CYP1A2 (see Interactions, below for details) and in patients with hepatic impairment (see below).

Administration in hepatic impairment. UK licensed product information for rasagiline advises caution when used in patients with mild hepatic impairment whereas US licensed information recommends that the oral dose be reduced to 500 micrograms daily. Rasagiline should not be used in those with moderate or severe impairment.

Adverse Effects and Precautions

Common adverse effects reported with rasagiline monotherapy include headache, flu-like syndrome, malaise, neck pain, angina pectoris, dyspepsia, anorexia, leucopenia, arthralgia, arthritis, depression, vertigo, rhinitis, conjunctivitis, skin rashes, melanoma, and urinary urgency. Cerebrovascular accidents and myocardial infarction have been reported rarely. Other adverse effects include orthostatic hypotension and hallucinations.

Rasagiline should not be used in patients with severe hepatic impairment; use in moderate impairment should also be avoided. It should be used with caution in patients with mild hepatic impairment and therapy should be stopped in those who progress to moderate impairment.

Interactions

As for Selegiline Hydrochloride, p. 916.1. Unlike the non-selective MAOIs, such as phenelzine, rasagiline can be used safely without dietary tyramine restrictions, although these have been recommended in some countries.

Rasagiline should not be given with other MAOIs because of the risk of non-selective MAO inhibition that may lead to hypertensive reactions.

It is metabolised by the cytochrome P450 isoenzyme CYP1A2 and potent inhibitors of this enzyme such as ciprofloxacin may increase the plasma levels of rasagiline. UK licensed product information for rasagiline advises caution when such drugs are used with rasagiline whereas US licensed product information recommends that the dose of rasagiline be reduced to 500 micrograms daily when given with CYP1A2 inhibitors. Tobacco smoking induces hepatic metabolic enzymes and may decrease the plasma levels of rasagiline.

Entacapone has been reported to increase the clearance of oral rasagiline by 28% when used together.

Pharmacokinetics

Rasagiline is rapidly absorbed from the gastrointestinal tract and peak plasma concentrations occur in about 30 minutes to 1 hour. Bioavailability is reported to be about 36%. Rasagiline is about 60 to 70% bound to plasma proteins.

It is extensively metabolised in the liver by *N*-dealkylation and hydroxylation, via the cytochrome P450 isoenzyme CYP1A2, and conjugation. 1-Aminoindan is a major metabolite and is stated to be active although it is not a monoamine oxidase B inhibitor. Metabolites are excreted mainly in the urine and partly in the faeces; less than 1% of a dose is excreted as unchanged drug in the urine. The terminal half-life is 0.6 to 2 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Ropinirole Hydrochloride

(BANM, USAN, pINNM)

Hidrocloruro de ropinirol; Ropinirol, hidroclaruro de; Ropinirole, Chlorhydrate de; Ropiniroli Hydrochloridum; SKF-101468 (ropinirole); SKF-0101468-A (ropinirole hydrochloride); Ропинирола Гидрохлорид.

4-[2-(Dipropylamino)ethyl]-2-indolinone hydrochloride.

$C_{16}H_{24}N_2O,HCl=296.8$

CAS — 91374-21-9 (ropinirole); 91374-20-8 (ropinirole hydrochloride).

ATC — N04BC04.

ATC Vet — QN04BC04.

UNII — D7ZD41RZI9.

Pharmacopoeias. In *US*.

USP 36: (Ropinirole Hydrochloride). A pale cream to yellow powder. Soluble in water.

Uses and Administration

Ropinirole is a non-ergot dopamine D_2-agonist with similar actions to those of bromocriptine (p. 895.3), but in contrast to bromocriptine it also has agonist properties at D_3 receptors. It is used similarly in the management of Parkinson's disease (below), either alone or as an adjunct to reduce 'on-off' fluctuations in levodopa response. Ropinirole is also used for the treatment of moderate to severe idiopathic restless legs syndrome (below). It is given orally as the hydrochloride; doses are expressed in terms of the base. Ropinirole hydrochloride 1.14 mg is equivalent to about 1 mg of ropinirole.

In the treatment of **Parkinson's disease**, ropinirole should be introduced gradually and during this period patients already receiving levodopa can have their levodopa dosage decreased gradually until an optimal response is achieved; the concurrent dose of levodopa may be reduced by about 20 to 30%. The daily dosage of ropinirole should be given in three divided doses, preferably with food. The initial daily dose of ropinirole is 750 micrograms increased at weekly intervals in steps of 750 micrograms for the first 4 weeks. After week 4, the weekly increments may be made in steps of 1.5 mg up to a dose of 9 mg daily according to response; subsequent weekly increments may be made in steps of up to 3 mg. The daily dosage should not exceed 24 mg. Optimal response is usually achieved within the range of 3 to 9 mg daily; higher doses may be required if used with levodopa. If it is necessary to stop ropinirole therapy, it should be withdrawn gradually by reducing the number of daily doses over a period of 1 week. Once adequate symptomatic control has been established, ropinirole may be given as once-daily modified-release tablets.

Ropinirole is also given as a single daily dose, 1 to 3 hours before bedtime, in the treatment of **restless legs syndrome**. The initial dose of ropinirole is 250 micrograms daily for 2 days; if tolerated, the dose is then increased to 500 micrograms daily for the rest of the first week. Dosage is then increased as necessary up to a maximum of 4 mg daily. Increases are made weekly in steps of 500 micrograms up to a dose of 3 mg daily; a final increase after one further week of 1 mg to a dose of 4 mg daily can then be made. In the UK, it has been recommended that treatment should be reassessed 3 months after starting therapy. For this indication, ropinirole may be withdrawn without gradual tapering of the dose.

If treatment with ropinirole is interrupted for more than a few days it should be restarted at the low initial dose and increased gradually as required.

Reviews.
1. Tulloch IF. Pharmacologic profile of ropinirole: a nonergoline dopamine agonist. *Neurology* 1997; **49** (suppl 1): S58–S62.

Parkinsonism. Dopamine agonists such as ropinirole may be used to begin treatment of parkinsonism (p. 889.1) in an attempt to delay therapy with levodopa, particularly in younger patients. They also have an adjunctive use when levodopa is no longer effective alone or cannot be tolerated, and may be useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations of mobility in the later stage of the disease.

Restless legs syndrome. The aetiology of restless legs syndrome (RLS—see Sleep-associated Movement Disorders, p. 1034.2) is obscure and treatment has largely been empirical although dopaminergic therapy has emerged as a common first-line choice. Ropinirole is licensed for the treatment of moderate to severe RLS in some countries.

Adverse Effects and Precautions

As for Bromocriptine, p. 896.3. Hypersensitivity reactions including angioedema, pruritus, rash, and urticaria have been reported with ropinirole therapy. Licensed product information states that the pharmacokinetics of ropinirole have not been studied in patients with hepatic or severe renal impairment and therefore it should be used with caution, if at all, in such patients. No pharmacokinetic changes were noted in those with mild to moderate renal impairment.

In the treatment of restless legs syndrome, earlier onset of symptoms in the afternoon or evening (augmentation) and recurrence of symptoms in the early morning hours (rebound) have been reported with ropinirole.

Incidence of adverse effects. References.

Effects on mental function. For reports of **daytime somnolence** occurring in patients receiving dopamine agonists including ropinirole, see under Levodopa, p. 905.2.

For reference to **disturbed behaviour** including **excessive gambling** reported in patients with Parkinson's disease receiving dopamine agonists, see under Levodopa, p. 905.2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies ropinirole as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Interactions

Since it is a dopamine agonist, ropinirole may share some of the pharmacological interactions of bromocriptine, p. 899.1. In addition, high doses of oestrogens can increase plasma concentrations of ropinirole and dosage adjustments may be necessary if oestrogen therapy is started or withdrawn during treatment with ropinirole. Ropinirole is metabolised by the cytochrome P450 isoenzyme CYP1A2 and there is therefore the potential for interactions between ropinirole and other drugs that are metabolised similarly or more particularly with inducers or inhibitors of this enzyme. Dosage adjustments may be necessary if therapy with such drugs is started or withdrawn during treatment with ropinirole.

Pharmacokinetics

Ropinirole is rapidly absorbed from the gastrointestinal tract and mean peak plasma concentrations have occurred 1.5 hours after oral doses; the rate of absorption, but not the extent, may be reduced if taken with food. Bioavailability is reported to be about 50%. It is widely distributed throughout the body and plasma protein binding is low (10 to 40%).

Ropinirole is extensively metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP1A2, and excreted in the urine as inactive metabolites; less than 10% of an oral dose is excreted as unchanged drug. A mean elimination half-life of about 6 hours has been reported for ropinirole. It is thought to be distributed into breast milk on the basis of studies in *rats*.

Pharmacopoeial Preparations
USP 36: Ropinirole Tablets.

Rotigotine *(BAN, USAN, rINN)*

N-0923; Rotigotina; Rotigotinum; SPM-962; Ротиготин.
(-)-(*S*)-5,6,7,8-Tetrahydro-6-[propyl[2-(2-thienyl)ethyl]amino]-1-naphthol.
$C_{19}H_{25}NOS$=315.5
CAS — 99755-59-6 (rotigotine); 125572-93-2 (rotigotine hydrochloride).
ATC — N04BC09.
ATC Vet — QN04BC09.
UNII — 87T4T88O2E.

Uses and Administration

Rotigotine is a non-ergot dopamine D_2-agonist with similar actions to those of bromocriptine (p. 895.3), but in contrast to bromocriptine (a dopamine D_2-agonist) it also has agonist properties at D_1 and D_3 receptors. It is used as monotherapy in the management of Parkinson's disease (p. 889.1), mainly in the early stage. It may also be used as an adjunct to levodopa therapy. Rotigotine is also used for the treatment of moderate to severe idiopathic restless legs syndrome (see Sleep-associated Movement Disorders, p. 1034.2). Rotigotine is given as transdermal patches delivering amounts ranging from 1 to 8 mg per 24 hours.

In the treatment of **Parkinson's disease**, when given as *monotherapy*, the initial dose is 2 mg daily, increased in weekly steps of 2 mg if necessary, to a maximum of 8 mg daily. Rotigotine may also be used as *adjunctive therapy* with levodopa in an initial dose of 4 mg daily, increased in weekly steps of 2 mg if necessary, to a maximum of 16 mg daily. Treatment with rotigotine should be withdrawn gradually; the daily dose should be reduced in steps of 2 mg every other day until complete withdrawal is achieved.

In the treatment of **restless legs syndrome**, the initial dose is 1 mg daily, increased in weekly steps of 1 mg according to response, to a maximum of 3 mg daily. The need for treatment continuation should be assessed every 6 months. If stopping treatment, the daily dose should be reduced in steps of 1 mg every other day until complete withdrawal is achieved.

Patches are applied once daily and should be replaced every 24 hours with the new patch being applied to a different site.

Adverse Effects and Precautions

As for Bromocriptine, p. 896.3. Reactions may occur at the site of application and are usually mild or moderate in intensity. The site should be rotated on a daily basis and the same site should not be used within 14 days.

Licensed product information recommends that rotigotine should be used with caution in patients with severe hepatic impairment and reduced doses may be necessary in cases of worsening impairment; however, this is based on a lack of evidence in such patients.

Interactions

Since it is a dopamine agonist, rotigotine may share some of the pharmacological interactions of bromocriptine, p. 899.1.

Caution is advised when other sedating drugs or alcohol are used with rotigotine because of possible additive effects.

Pharmacokinetics

Rotigotine has poor oral bioavailability as it undergoes extensive first-pass metabolism via glucuronidation in the gut wall and liver. Peak plasma concentrations occur 24 hours after transdermal application. Steady-state concentrations are reached after 24 to 48 hours of continuous daily application. It undergoes *N*-dealkylation and conjugation to form inactive metabolites. Rotigotine is excreted mainly in the urine and about 23% appears in the faeces. The elimination half-life is 5 to 7 hours. It is distributed into milk of *rats*.

$C_{13}H_{17}N,HCl$=223.7
CAS — 14611-51-9 (selegiline); 2079-54-1 (selegiline hydrochloride); 14611-52-0 (selegiline hydrochloride).
ATC — N04BD01.
ATC Vet — QN04BD01.
UNII — 6W731X367Q ((-)-selegiline hydorchloride); 63G7R4955A ((±)-selegiline hydrochloride).

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Selegiline Hydrochloride). A white or almost white, crystalline powder. M.p. about 143 degrees. Freely soluble in water and in methyl alcohol; slightly soluble in acetone and in ethyl acetate. A 2% solution in water has a pH of 3.5 to 4.5. Protect from light.

USP 36: (Selegiline Hydrochloride). A white, odourless crystalline powder. Freely soluble in water, in chloroform, and in methyl alcohol. Store in airtight containers. Protect from light.

Uses and Administration

Selegiline is an irreversible selective inhibitor of monoamine oxidase type B, an enzyme involved in the metabolic degradation of dopamine in the brain. It enhances the effects of levodopa and is used in the treatment of Parkinson's disease mainly as an adjunct to levodopa therapy to reduce 'end-of-dose' or 'on-off' fluctuations in response, but see Parkinsonism, p. 915.1. Addition of selegiline to levodopa therapy may enable the dosage of levodopa to be reduced by about 10 to 30%. Selegiline may be given alone in early Parkinson's disease in an attempt to delay the need for levodopa therapy. It is also used in the treatment of depression (p. 915.1).

In the treatment of **Parkinson's disease**, selegiline hydrochloride is given orally as conventional preparations such as capsules, tablets, or liquid, or as lyophilisate tablets. The dose of the conventional preparations is 10 mg daily, either as a single dose in the morning or in 2 divided doses of 5 mg at breakfast and lunchtime. The initial dose of the oral lyophilisate tablets is 1.25 mg daily at least 5 minutes before breakfast; patients already receiving 10 mg of conventional preparations can be transferred to 1.25 mg of the oral lyophilisate. US product information states that the initial oral lyophilisate dose of 1.25 mg daily may be increased, after at least 6 weeks, to 2.5 mg given once daily, if necessary.

In the USA, transdermal patches delivering 6, 9, or 12 mg of selegiline over 24 hours are available for the treatment of **depression**. The initial dose is 6 mg daily, increased in steps of 3 mg every 2 weeks if necessary, to a maximum of 12 mg daily. Patches are applied once daily and should be replaced every 24 hours with the new patch being applied to a different site. Dose increases should be made with caution in the elderly and patients should be closely observed for postural changes in blood pressure during treatment. Dietary restrictions are necessary at doses of 9 mg daily and above, see Interactions, p. 916.1.

Other conditions in which selegiline has been tried include dementia.

Some references to the actions of selegiline.

2. Lange KW, *et al.* Biochemical actions of l-deprenyl (selegiline). *C in Pharmacol Ther* 1994; 56: 734–41.

Cocaine dependence. Cocaine use may affect the dopaminergic modulation of CNS function; selegiline is one of several drugs that interact with dopaminergic systems and have been tried in treatment of cocaine abuse and dependence (p. 1990.1).

References.
1. Houtsmuller EJ, *et al.* Transdermal selegiline and intravenous cocaine: safety and interactions. *Psychopharmacology (Berl)* 2004; 172: 31–40.

Dementia. The hypothesis that neurodegeneration in Alzheimer's disease (p. 388.1) might be due to free radical formation has led to drugs such as selegiline being tried as antoxidant therapy.

Early double-blind studies[1,2] indicated that oral selegiline 10 mg daily might produce beneficial effects in patients with Alzheimer's disease but it was suggested that improvements in mood and cognitive function may have been due to a reduction in tension and depression.[3] A 15-month study in Alzheimers's patients with mild cognitive impairment showed oral selegiline 10 mg daily to have little effect,[4] although the authors pointed out that those with more severe dementia have shown more response in other studies. The conclusion of a later study[5] that oral selegiline 10 mg daily slowed progression in patients with moderate disease has been criticised[6] on the grounds that any effect was only evident after statistical adjustment to the original analysis. In addition a systematic review[7] examining the effects of selegiline concluded that there was no meaningful evidence of a beneficial effect of oral selegiline in patients with Alzheimer's disease. They also considered that there

was no longer any justification for its use in patients with Alzheimer's disease.

Depression. Selegiline is a selective inhibitor of monoamine oxidase type B and there are reports[1-3] of it producing improvement in depression (p. 398.1). However, at the doses usually required to produce an antidepressant effect the specificity of oral selegiline is reported to be lost and it has been suggested that the efficacy of selegiline as an antidepressant might depend on inhibition of monoamine oxidase A rather than inhibition of monoamine oxidase B alone. Such a loss of specificity would mean that patients taking selegiline for depression would need to observe the dietary restrictions applicable to non-selective MAOIs.

To overcome the problems associated with the oral route, transdermal selegiline has also been tried and may be more effective than placebo in the treatment of depression.[4] The use of the transdermal route allows sustained blood levels of selegiline to be delivered without extensive inhibition of peripheral monoamine oxidase A. Transdermal patches of selegiline are licensed for the treatment of depression in the USA.

Narcoleptic syndrome. Small controlled studies[1,2] have suggested that oral selegiline 20 to 40 mg daily has a beneficial effect on symptoms of narcolepsy and cataplexy (p. 2314.3); at such a dosage a low-tyramine diet is considered necessary.

Parkinsonism. As a selective monoamine oxidase type B inhibitor, selegiline reduces the metabolism of dopamine and thereby enhances its actions. It reduces levodopa's 'end-of-dose' effect and has a dose-sparing effect. Some have used it as **monotherapy** in an attempt to delay the need for levodopa. If progression of Parkinson's disease (p. 889.1) were due to a cytotoxic effect of free radicals, generated during the metabolism of dopamine, on dopaminergic neurones in the substantia nigra, selegiline might slow the process by reducing their formation. In a large early study,[1] the DATATOP study, selegiline monotherapy delayed the need to start levodopa in patients with early Parkinson's disease. These findings were corroborated by other smaller studies.[2,3] There has been much debate over whether the benefit was due to a neuroprotective or symptomatic effect. Re-analysis of the DATATOP data by independent workers[4,5] and findings of other studies[6] supported a symptomatic effect. Subsequent studies involving DATATOP patients were also consistent with a symptomatic effect; any benefit produced by selegiline appeared to be less pronounced as the duration of treatment increased[7] and was lost completely long term.[8,9] However, a later study[10] designed to minimise any symptomatic effect cast doubt on whether the delay in progression of the signs and symptoms of Parkinson's disease obtained with selegiline was entirely due to a symptomatic effect.

Studies of the use of selegiline as an **adjunct** to levodopa therapy[6,11,12] indicate that selegiline permits a modest reduction in the dosage requirements of levodopa. An interim analysis of a study of the early addition of selegiline to levodopa has also suggested that selegiline might stabilise the long-term daily levodopa dosage.[13] As with monotherapy, combined therapy has been reported to slow symptom progression.[14]

The use of selegiline in Parkinson's disease has been questioned after a UK study[11] found an unexpected increase in mortality in patients taking levodopa with selegiline compared with those taking levodopa alone. No difference in mortality had been detected at the 3-year follow-up[15] but after an average follow-up time of 5.6 years[11] mortality was 60% higher in the group also receiving selegiline. The study has been criticised on many grounds including the fact that mortality was very high in both arms of the study[16] and has been the subject of much debate.[17,18] The authors of the study[11] had stated that they would advise the study patients to withdraw selegiline therapy. Analysis of follow-up data[19] until the selegiline arm of the study was terminated (average 6.8 years) found an excess mortality of about 35%, a figure calculated[20] to be no longer significant. However, because of the premature termination of the study such results were considered[21] to be biased. Whether any excess in mortality is causally related to selegiline is still unclear. Some consider that changes in prescribing practice based on this study are not warranted.[17] Others[21] have made a cautious recommendation not to start combination treatment in patients with newly diagnosed Parkinson's disease but consider that there is little evidence to advise patients who have been using selegiline with levodopa for years without problem to change their treatment. An evaluation of mortality among patients taking antiparkinsonian drugs (using the UK General Practice Research Database) provided evidence against there being substantial excess mortality associated with the use of selegiline.[22] These results are supported by systematic reviews[23,24] and meta-analyses[25,26] of randomised, double-blind studies which found no increase in mortality associated with selegiline treatment regardless of concurrent levodopa. Furthermore, increased mortality was not seen in patients in the original DATATOP study[1] after an average follow-up time of 8.2 years. However, it was noted that the delay of disability seen in the early phase of selegiline therapy[1,7] was not associated with longer life during follow-up.[27] A later systematic review[23] has also found no convincing evidence that selective monoamine oxidase type B inhibitors (selegiline and lazabemide) significantly delay disease progression in early Parkinson's disease and routine use is not recommended. Similarly, another recent systematic review[24] found insufficient evidence to recommend the routine use of selegiline over the use of levodopa and dopamine agonists (bromocriptine and lisuride) in early disease.

Adverse Effects

Selegiline is often given as an adjunct to levodopa therapy and many of the adverse effects reported may be attributed to enhanced levodopa activity; dosage of levodopa may have to be reduced. However, most reported adverse effects, with the possible exception of increased dyskinesias and cardiac arrhythmias, have also been seen with selegiline monotherapy. Adverse effects have included orthostatic hypotension, chest pain, nausea, vomiting, constipation, diarrhoea, confusion, headache, tremor, vertigo, dizziness, psychosis, depression, hallucinations, agitation, dry mouth, sore throat, difficulty in micturition, skin reactions, back pain, muscle cramps, joint pain, and myopathy. The amfetamine metabolites of selegiline may cause insomnia and abnormal dreams; evening doses should be avoided. Transient increases in liver enzymes have been reported. Mouth ulcers and stomatitis may occur with the oral lyophilisate.

Since the selectivity of selegiline is lost at higher doses, signs and symptoms of overdosage may resemble those of non-selective MAOIs such as phenelzine (see p. 442.2).

Effects on carbohydrate metabolism. Profound hypoglycaemia developed in a 70-year-old man after selegiline was added to his existing medication for Parkinson's disease.[1] Hypoglycaemia was accompanied by hyperinsulinaemia and resolved 1 week after stopping selegiline.

1. Rowland MJ, *et al.* Hypoglycemia caused by selegiline, an antiparkinsonian drug: can such side effects be predicted? *J Clin Pharmacol* 1994; 34: 80–5.

Effects on mortality. For reference to a study that found an increased mortality rate in patients with Parkinson's disease taking selegiline and levodopa compared with those taking levodopa alone, see Parkinsonism, under Uses and Administration, above.

Precautions

Selegiline should be used with caution in patients with a history of peptic ulceration and avoided in those with active ulceration. It should also be used with caution in uncontrolled hypertension, arrhythmias, angina, severe liver or kidney dysfunction, or psychosis.

When selegiline is used in the management of depression, patients should be closely monitored during early therapy until significant improvement in depression occurs because suicide is an inherent risk in depressed patients. For further details, see under Depression, p. 398.1.

Cardiovascular disorders. An investigation[1] of the autonomic effects of selegiline as a potential cause of the unexpected mortality seen in a study[2] in patients with Parkinson's disease receiving selegiline and levodopa (see Parkinsonism, above) suggested that the risk of orthostatic hypotension with this combination may have been underestimated. It was considered prudent to withdraw selegiline from those with symptomatic orthostatic hypotension or cardiovascular or cerebrovascular disease. For those without symptomatic morbidity, but a greater than 20 mmHg fall in blood pressure on standing for 2 minutes, gradual withdrawal of selegiline with adjustment of levodopa dosage should be considered.

2. Parkinson's Disease Research Group of the United Kingdom. Comparison of therapeutic effects and mortality data of levodopa and levodopa combined with selegiline in patients with early, mild Parkinson's disease. *BMJ* 1995; 311: 1602–7.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies selegiline as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Interactions

Selegiline is less likely than non-selective MAOIs, such as phenelzine, to interact with tyramine in food; such hypertensive reactions have been reported rarely at usual doses but UK licensed product information for oral formulations states that its selectivity is lost at higher doses and it must be assumed that selegiline can usually only be used safely without dietary restrictions at doses of up to 10 mg daily. US licensed information for the transdermal preparation states that dietary restrictions are necessary at doses of 9 mg daily and above: patients should be warned not to eat any tyramine-rich foods while being treated with, and for at least 14 days after discontinuation of, these doses or after dose reduction to 6 mg daily. For further details on dietary restrictions applicable to patients taking MAOIs, see p. 444.3.

Even when given in therapeutic doses life-threatening interactions can occur between selegiline and pethidine. Serious reactions, sometimes fatal, have also been reported when selegiline was used with tricyclic antidepressants or serotonin reuptake inhibitors including the SSRIs and venlafaxine. Licensed product information states that 14 days should elapse between stopping selegiline and starting treatment with tricyclic or serotonergic antidepressants. Conversely, selegiline should not be given to patients who have recently received these antidepressants; at least 5 weeks should elapse between stopping fluoxetine and starting treatment with selegiline. Use of selegiline with non-selective MAOIs may cause severe hypotension and such use is not recommended.

Antidepressants. Although there have been studies in which patients with parkinsonism have received selegiline with *SSRIs* such as fluoxetine[1] or paroxetine[2] (apparently without any problems) there have been reports of reactions[3-5] such as shivering and sweating, hypertension, hyperactivity, and ataxia occurring when selegiline and fluoxetine have been used together. The FDA noted[6] that reactions similar to those between SSRIs and non-selective MAOIs had also been reported in patients taking selegiline with paroxetine or sertraline.

Severe reactions, sometimes fatal, have also occurred in patients taking selegiline and *tricyclic antidepressants*.[6] For a report of serotonin syndrome developing when *venlafaxine* was given after selegiline (despite a drug-free period), see p. 457.1.

There has been a report[7] of a patient receiving the non-selective MAOI *iproniazid* who had severe orthostatic hypotension when given selegiline. Selegiline given with the reversible MAOI *moclobemide* to healthy subjects markedly increased the pressor response to tyramine compared with the effects of each drug used alone.[8] The authors concluded that dietary restriction of tyramine-containing foods would be necessary if these drugs were to be used together.

One UK manufacturer (*Cephalon, UK*) states that oral selegiline should not be given with any type of antidepressant, while another (*Orion, UK*) advises that use with SSRIs or venlafaxine be avoided and recommends caution when used with the tricyclics. The US manufacturer of transdermal selegiline (*Bristol-Myers Squibb, USA*), used for depression, states that use with other antidepressants such as *bupropion, mirtazapine,* serotonin reuptake inhibitors, *St John's wort,* and tricyclics is contra-indicated.

6. Anonymous. Eldepryl and antidepressant interaction. *FDA Med Bull* 1995; 25 (Feb.): 6.
7. Pare CMB, *et al.* Attempts to attenuate the 'cheese effect': combined drug therapy in depressive illness. *J Affect Disord* 1985; 9: 137–41.
8. Korn A, *et al.* Tyramine pressor sensitivity in healthy subjects during combined treatment with moclobemide and selegiline. *Eur J Clin Pharmacol* 1996; 49: 273–8.

Antimigraine drugs. Some serotonin agonists including *rizatriptan, sumatriptan,* and *zolmitriptan* are metabolised via monoamine oxidase type A and therefore it is considered unlikely that selegiline, a monoamine oxidase type B inhibitor, would interact with these drugs. Nevertheless, one manufacturer (*Cephalon, UK*) of oral selegiline contra-indicates its use in patients also receiving serotonin agonists; it is also recommended that at least 24 hours should elapse between stopping selegiline and starting treatment with these drugs.

Opioid analgesics. Selegiline can produce life-threatening reactions when given with *pethidine*.[1]

Some manufacturers contra-indicate use of selegiline with pethidine and other opioid analgesics such as *dextropropoxyphene, methadone,* and *tramadol*.

1. Zornberg GL, *et al.* Severe adverse interaction between pethidine and selegiline. *Lancet* 1991; 337: 246. Correction. *Ibid.*; 440.

Oral contraceptives. The total area under the concentration-time curve for selegiline given in single doses of 5 to 40 mg was raised ten- to twentyfold in 4 women who were using oral hormonal contraceptives when compared with 4 women receiving no other medication.[1] It was suggested that use of selegiline and oral hormonal contraceptives should be avoided or the dosage of selegiline reduced.

1. Laine K, *et al.* Dose linearity study of selegiline pharmacokinetics after oral administration: evidence for strong drug interaction with female sex steroids. *Br J Clin Pharmacol* 1999; 47: 249–54.

Sympathomimetics. Licensed information for a US product (*Eldepryl; Somerset, USA*) states that there has been a report of hypertensive crisis in a patient taking recommended doses of selegiline and *ephedrine*. A hypertensive reaction after low-dose *dopamine* infusion has been reported[1] in a 75-year-old patient taking selegiline 10 mg daily for Parkinson's disease. The authors suggest that this may indicate a non-specific action of selegiline at usual doses on peripheral monoamine oxidase type-A. UK licensed product information states that dopamine should be used with caution in patients taking selegiline.

1. Rose LM, *et al.* A hypertensive reaction induced by concurrent use of selegiline and dopamine. *Ann Pharmacother* 2000; 34: 1020–4.

Pharmacokinetics

Selegiline is readily absorbed from the gastrointestinal tract and peak plasma concentrations occur in 30 minutes after oral doses of conventional preparations. Although subject to large interindividual variation, bioavailability is about 10% and is increased when given with food. Selegiline is rapidly distributed throughout the body and crosses the blood-brain barrier. It undergoes extensive first-pass metabolism in the liver to produce at least 5 metabolites, including *l*-(-)-desmethylselegiline (norselegiline), *l*- (-)-*N*-methylamfetamine, and *l*- (-)-amfetamine. Plasma concentrations of selegiline metabolites are greatly reduced after doses of the oral lyophilisate preparation, the majority of which undergoes absorption through the buccal mucosa. Topical use also avoids first-pass metabolism and about 25 to 30% of the stated content is available systemically. Selegiline is excreted as metabolites mainly in the urine and about 15% appears in the faeces. At steady state the elimination half-life is reported to be 10 hours.

UNII — 21OJT43Q88.

Profile

Terguride, an ergot derivative, is a partial dopamine agonist with general properties similar to those of bromocriptine (p. 895.3). It is used in the treatment of disorders related to hyperprolactinaemia (p. 2252.2) in a usual oral dose of 500 micrograms twice daily. It is also being investigated in the management of parkinsonism and pulmonary hypertension.

Pharmacopoeias. In *US*.

USP 36: (Tolcapone). A yellow, fine powder or fine powder with lumps. Insoluble in water and in *n*-hexane; Freely soluble in acetone and in tetrahydrofuran; sparingly soluble in chloroform and in dichloromethane; soluble in methanol alcohol and in ethyl acetate. Store in airtight containers at a temperature between 20 degrees and 25 degrees. Protect from light.

Uses and Administration

Tolcapone is a peripheral inhibitor of catechol-*O*-methyltransferase (COMT), an enzyme involved in the metabolism of dopamine and levodopa. It is used as an adjunct to levodopa and dopa-decarboxylase inhibitor combinations in the management of Parkinson's disease (p. 917.1) for patients who cannot be stabilised on these levodopa combinations or for those who have 'end-of-dose' deterioration. Because of the risk of serious hepatotoxicity (see Effects on the Liver, p. 917.1) the FDA in the USA restricted its use to when other adjunctive therapy was ineffective or contra-indicated. In the EU, tolcapone was withdrawn from the market in November 1998 and subsequently returned in 2004, its use being similarly restricted to patients who fail to respond to, or are intolerant of, other COMT inhibitors.

The usual recommended dosage of tolcapone is 100 mg given orally three times daily; up to a maximum of 200 mg three times daily may be considered if the clinical benefit justifies the increased risk of hepatotoxicity. The first dose of the day should be taken at the same time as the combined levodopa preparation. Most patients already taking more

than 600 mg of levodopa daily will require a reduction in their dosage of levodopa; patients on lower levodopa doses may also require a dose reduction.

Tolcapone should be withdrawn if a substantial clinical benefit is not obtained within the first 3 weeks of treatment. An adjustment in the levodopa dose may be necessary following tolcapone withdrawal.

Parkinsonism. Tolcapone is a reversible peripheral inhibitor of catechol-*O*-methyltransferase (COMT), an enzyme involved in the metabolism of levodopa and dopamine.[1] It appears to differ from entacapone (p. 901.2) by being a more potent COMT inhibitor in the periphery and by penetrating into the brain (although the significance of any central effects of COMT inhibition are not known).[1] When given to patients with Parkinson's disease (p. 889.1) and levodopa-related fluctuations in disability or 'end-of-dose' effects, it has prolonged the clinical benefit obtained with levodopa and allowed the total daily dosage of levodopa to be reduced.[2,3] Benefit has also been reported[4] when added to levodopa therapy in patients with stable Parkinson's disease. However, a systematic review[5] concluded that there were insufficient data to show any significant difference in efficacy between tolcapone and bromocriptine or pergolide in the adjunctive treatment of levodopa-induced motor complications.

The use of tolcapone is restricted in some countries because of the risk of serious hepatotoxicity (see Effects on the Liver, below).

Adverse Effects

The most common adverse effects associated with tolcapone are diarrhoea, nausea, vomiting, constipation, abdominal pain, dry mouth, anorexia, dyskinesia, dystonia, dizziness, orthostatic hypotension, hallucinations, confusion, excessive dreaming, somnolence, headache, increased sweating, and sleep disorders. Diarrhoea may be severe enough for treatment to be stopped. Behavioural disturbances including intense urges to gamble and increased sexual urges have also been reported (see Effects on Mental Function, in Levodopa, p. 905.2). Increases in liver enzyme values have occurred and hepatitis and hepatic failure, sometimes fatal, have been reported. Isolated cases of neuroleptic malignant syndrome have also been reported after dose reduction or stopping tolcapone; rhabdomyolysis may develop as a complication of the syndrome. Tolcapone and its metabolites can produce a yellow intensification in the colour of urine.

Effects on the liver. The UK CSM had noted[1] that, after a report[2] in September 1998 of fatal acute hepatic failure associated with tolcapone, the European Committee for Proprietary Medicinal Products (CPMP) had reviewed all reports of hepatic injury with tolcapone. There had been 10 reports of serious hepatic adverse reactions since tolcapone was marketed in October 1997, which included 7 reports of hepatitis, 3 of which had a fatal outcome. Serious hepatic reactions occurred unpredictably and their development was not always predicted by liver function monitoring. Consequently, in the EU, the marketing authorisation for tolcapone was suspended in November 1998. This suspension was lifted in April 2004 by the CPMP after further review.

In some countries such as the USA, tolcapone has always remained available albeit with restricted indications and strict monitoring requirements (see Precautions, below). Up to 2003, there had been no further reports of fatal hepatic failure after the introduction of these measures although the number of patients eligible to receive the drug has been reduced.[3]

1. CSM/MCA. Withdrawal of tolcapone (Tasmar). *Current Problems* 1999; 25: 2. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023233&RevisionSelectionMethod=LatestReleased (accessed 11/08/08)

3. Borges N. Tolcapone-related liver dysfunction: implications for use in Parkinson's disease therapy. *Drug Safety* 2003; 26: 743–7.

Effects on the skin. For reference to the development of vitiligo in a patient following addition of tolcapone to levodopa/carbidopa treatment, see under Levodopa, p. 906.1.

Precautions

Tolcapone should not be given to patients with hepatic impairment or raised liver enzyme values. Liver enzymes should be monitored:

- when starting treatment with tolcapone or on increasing the dose to 200 mg three times daily
- every 2 weeks during the first year of therapy
- every 4 weeks for a further 6 months
- every 8 weeks thereafter

Tolcapone should be stopped if liver enzyme levels exceed the upper limit of normal or if signs or symptoms suggestive of the onset of hepatic failure occur. Patients who have developed evidence of hepatic injury while receiving tolcapone should not be given the drug again.

Tolcapone should be used with caution in patients with severe renal impairment.

It is contra-indicated in patients with severe dyskinesia or with a history of neuroleptic malignant syndrome (NMS). It is also contra-indicated in patients with a history of nontraumatic rhabdomyolysis or symptoms of hyperpyrexia and confusion possibly related to NMS. Patients with phaeochromocytoma should not be given tolcapone.

Use with levodopa may cause dizziness and orthostatic hypotension; if affected patients should not drive or operate machinery. Excessive daytime sleepiness and sudden onset of sleep may also occur with combination use (see Effects on Mental Function, under Adverse Effects of Levodopa, p. 905.2) and again, caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring.

Abrupt withdrawal or dose reduction of tolcapone should be monitored carefully because of the risk of developing symptoms resembling NMS.

The elderly. Confusion occurred in 3 elderly patients with severe Parkinson's disease after the addition of tolcapone to their antiparkinsonian therapy.[1] It was suggested that a starting dose of tolcapone 100 mg daily might be more suitable in frail patients with severe disease. It was noted[2] that a reduction in levodopa dosage is generally recommended when tolcapone is given to patients such as these, who were receiving 500 to 600 mg of levodopa daily.

2. Harper J, Vieira B. Catechol-O-methyltransferase inhibitors in Parkinson's disease. *Lancet* 1998; 352: 578.

Genetic polymorphism. Two patients who developed elevated liver enzyme values while receiving tolcapone, one of whom also had hepatic dysfunction while receiving entacapone, were found to be poor metabolisers with regard to UDP-glucuronosyltransferase activity.[1] Such patients may be predisposed to COMT-inhibitor induced hepatotoxicity.

1. Martignoni E, *et al.* Two patients with COMT inhibitor-induced hepatic dysfunction and UGT1A9 genetic polymorphism. *Neurology* 2005; 65: 1820–2.

Interactions

Tolcapone may influence the pharmacokinetics of drugs metabolised by catechol-*O*-methyltransferase; a dose reduction of such drugs should be considered when given with tolcapone. Increased concentrations of benserazide and its active metabolite have been reported when given with tolcapone. Licensed product information advises that non-selective MAOIs should not be used with tolcapone.

Pharmacokinetics

Tolcapone is rapidly absorbed from the gastrointestinal tract and maximum plasma concentrations have occurred within 2 hours of an oral dose; food delays and decreases the absorption. Absolute bioavailability is reported to be about 65%. Tolcapone is more than 99% bound to plasma proteins (mainly albumin) and is not widely distributed into body tissues. It is extensively metabolised, mainly by conjugation to the inactive glucuronide, but methylation by catechol-*O*-methyltransferase to 3-*O*-methyltolcapone and metabolism by cytochrome P450 isoenzymes CYP3A4 and CYP2A6 also occurs. About 60% of a dose is excreted in the urine with the remainder appearing in the faeces. The elimination half-life has been reported to be about 2 to 3 hours. The clearance of unbound tolcapone may be reduced by 50% in patients with moderate cirrhotic liver disorders.

ATC — N04AA01.

ATC Vet — QN04AA01.

UNII — AO61G82577.

Street names. The following terms have been used as 'street names' (see p. vii) or slang names for various forms of trihexyphenidyl:

Artanes.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Trihexyphenidyl Hydrochloride). A white or almost white, crystalline powder. Slightly soluble in water; sparingly soluble in alcohol and in dichloromethane. A 1% solution in water has a pH of 5.2 to 6.2.

USP 36: (Trihexyphenidyl Hydrochloride). A white or slightly off-white, crystalline powder, having not more than a very faint odour. Slightly soluble in water; soluble in alcohol and in chloroform. Store in airtight containers.

Uses and Administration

Trihexyphenidyl hydrochloride is a tertiary amine antimuscarinic with actions similar to those of atropine (p. 1310.3). It also has a direct antispasmodic action on smooth muscle.

Trihexyphenidyl hydrochloride is given orally in the symptomatic treatment of parkinsonism (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. It has been used in the treatment of dystonias in adults and children, but see p. 918.1. Trihexyphenidyl hydrochloride is given in 3 or 4 divided doses daily before or with food.

In **Parkinson's disease** the usual initial dose of 1 mg daily is gradually increased at intervals of 3 to 5 days by increments of 2 mg to 6 to 10 mg daily, according to response; for advanced cases, 12 to 15 mg daily or even more (up to 20 mg daily) may be needed. As a rule, postencephalitic patients tolerate and require the larger doses.

Usual doses for **drug-induced extrapyramidal symptoms** lie within the range of 5 to 15 mg daily, although as little as 1 mg daily may be sufficient in some cases.

Since the elderly and arteriosclerotic patients are more susceptible to the adverse effects of antimuscarinics a dose at the lower end of the range is usually recommended.

Antimuscarinic treatment of parkinsonism should never be terminated suddenly and it is usual when changing from one drug to another to withdraw one in small amounts while gradually increasing the dose of the other.

Trihexyphenidyl hydrochloride may be given with other drugs used for the relief of parkinsonism, such as levodopa, but the dose of each drug may need to be reduced. Trihexyphenidyl hydrochloride 3 to 6 mg daily is usually adequate.

Administration in children. Although unlicensed, trihexyphenidyl hydrochloride has been used for the management of dystonias in children; for suggested doses, see p. 918.1.

Dystonias. Antimuscarinics such as trihexyphenidyl are used in the management of dystonias (p. 903.3) although only about half of all children and adolescents, and fewer adults (who tolerate antimuscarinics less well) show any response. Adverse effects may be limited by starting with a low dose: one suggested regimen[1] starts with trihexyphenidyl 1 mg daily and rises up to 12 mg daily over the next 4 to 6 weeks; some patients may require up to 60 to 100 mg daily. The *BNFC* suggests that children aged 3 months to 18 years may be given oral doses of 1 to 2 mg daily as a single dose or in 2 divided doses; if necessary, the dose can be increased every 3 to 7 days by 1 mg daily to a maximum of 2 mg/kg daily.

1. Jankovic J. Dystonia: medical therapy and botulinum toxin. *Adv Neurol* 2004; 94: 275–86.

Adverse Effects, Treatment and Precautions

As for Atropine Sulfate, p. 1312.1. In some patients, such as those with arteriosclerosis or a history of drug idiosyncrasy, trihexyphenidyl may produce mental disturbances, excitement, or nausea and vomiting; such patients should be allowed to develop a tolerance by starting with a small initial dose and gradually increasing it until an effective level is reached. If a severe reaction occurs, trihexyphenidyl should be stopped for a few days and resumed at a lower dose. Trihexyphenidyl may provoke or exacerbate tardive dyskinesia.

Abuse. Trihexyphenidyl hydrochloride has been abused for its euphoric effect[1,2] especially by psychiatric patients.[3] Its abuse potential in schizophrenic patients has been questioned[4] and its unpleasant antimuscarinic effects tend to limit its repeated use,[5] but a small survey among psychiatric patients found that trihexyphenidyl was reported to be the antimuscarinic most frequently abused;[6] procyclidine, benzatropine, and orphenadrine (in decreasing order of frequency) were also misused. A later analysis of health insurance data from one region of France[7] examined prescriptions for trihexyphenidyl in 3028 subjects, most of whom were also receiving antipsychotics, and concluded that there was evidence of an abnormal pattern of use in about 2%. Patients in this subgroup were mostly young, male, and also receiving benzodiazepines or high doses of buprenorphine.

7. Prauger E, *et al.* Détournement d'usage du trihexyphénidyle (Artane, Parkinane): tendances récentes. *Therapie* 2003; 58: 541–7.

Effects on the heart. Paradoxical sinus bradycardia developed in a schizophrenic patient after receiving trihexyphenidyl for extrapyramidal effects due to antipsychotic medication.[1] Normal sinus rhythm was restored after trihexyphenidyl was stopped. The patient had previously received trihexyphenidyl and suffered bradycardia which at the time was attributed to haloperidol.

1. Blumensohn R, *et al.* Bradycardia due to trihexyphenidyl hydrochloride. *Drug Intell Clin Pharm* 1986; 20: 786–7.

Effects on mental function. Oral trihexyphenidyl 2 mg significantly impaired memory function compared with placebo in a study in 13 elderly patients.[1] Impairment of memory has also been noted in patients with Parkinson's disease given antimuscarinics such as trihexyphenidyl.[2] However, impairment may be reversible on stopping the antimuscarinic (see Atropine, p. 1312.2).

1. Potamianos G, Kellett JM. Anti-cholinergic drugs and memory: the effects of benzhexol on memory in a group of geriatric patients. *Br J Psychiatry* 1982; 140: 470–2.
2. Sadeh M, *et al.* Effects of anticholinergic drugs on memory in Parkinson's disease. *Arch Neurol* 1982; 39: 666–7.

Overdosage. A 34-year-old woman developed a toxic reaction with widely dilated pupils, dry skin, and visual hallucinations within 24 hours of taking about 300 mg of trihexyphenidyl hydrochloride with suicidal intent.[1] After 3 to 4 days the hallucinations were replaced by illusions; complete recovery occurred after a week, with no special treatment. Death associated with moderate blood concentrations of trihexyphenidyl (0.12 micrograms/mL) has been reported[2] in a schizophrenic patient recovering from a respiratory infection. It was thought possible that he had increased his dose to counteract developing tardive dyskinesia, and that the toxic effects had been exacerbated by respiratory inflammation; there was no evidence of suicidal intent.

2. Gall JAM, *et al.* Death due to benzhexol toxicity. *Forensic Sci Int* 1995; 71: 9–14.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies trihexyphenidyl as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 30/09/11)

Withdrawal. A 61-year-old woman who had taken trihexyphenidyl 6 mg daily for a year for Parkinson's disease developed encephalopathy and miosis on two occasions when treatment was abruptly withdrawn.[1] Slowly tapered withdrawal avoided these effects.

1. Johkura K, *et al.* Trihexyphenidyl withdrawal encephalopathy. *Ann Neurol* 1997; 41: 133–4.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

Chlorpromazine. For the effect of trihexyphenidyl on plasma concentrations of chlorpromazine, see Antiparkinsonian Drugs, p. 1052.3.

Pharmacokinetics

Trihexyphenidyl hydrochloride is well absorbed from the gastrointestinal tract and has been stated to exert an effect within 1 hour of an oral dose.

Half-life. The reported half-life of trihexyphenidyl has varied according to the assay method used. Values reported when using radioreceptor and chromatographic techniques have ranged from about 1 to more than 24 hours[1] and from 10 to 29 hours,[2] respectively, but the sensitivity and specificity of these methods have been criticised.[3] With a more recently developed radio immunoassay it was found that after oral doses there was an initial elimination phase with an estimated half-life of 5.33 hours followed by a terminal elimination phase with an estimated half-life of 32.7 hours.

CAS — 27574-24-9 (tropatepine); 27574-25-0 (tropatepine hydrochloride).

ATC — N04AA12.

ATC Vet — QN04AA12.

UNII — 17N1U39U3Z.

Profile

Tropatepine hydrochloride is an antimuscarinic with actions and uses similar to those of trihexyphenidyl (p. 917.3). It is used in the management of parkinsonism (p. 889.1), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value in tardive dyskinesia. Tropatepine hydrochloride is given orally in usual doses of 10 to 30 mg daily; it is also given intramuscularly or by slow intravenous injection in doses of 10 to 20 mg daily.

The drugs described in this chapter are those used mainly in the treatment of parasitic protozoal infections. In addition to their use as antiprotozoals, metronidazole and related nitroimidazole derivatives are also important in the treatment of anaerobic bacterial infections. Some veterinary antiprotozoal drugs are included. Drugs used in the treatment of malaria are described in the Antimalarials chapter; some of these are also used in other protozoal infections.

The principal antiprotozoal drugs are listed in Table 1, below.

Choice of Antiprotozoal

Protozoal infections occur throughout the world and are a major cause of morbidity and mortality in some regions. The choice of treatment for the principal protozoal diseases in humans is discussed below.

Amoebic infections

The most common amoebic infection of man is **amoebiasis** caused by infection with the protozoan parasite *Entamoeba histolytica* and related species. Free-living amoebae occur worldwide and are distributed in soil and water. They can also cause disease in man, though these infections are rare. Diseases include:

- **amoebic keratitis** caused by *Acanthamoeba* spp.
- **disseminated amoebic infections** including granulomatous amoebic encephalitis and cutaneous, pulmonary, and nasopharyngeal infections caused by *Acanthamoeba* spp., *Balamuthia mandrillaris* (previously referred to as leptomyxid amoebae), and very rarely by *Sappinia diploidea*
- **primary amoebic meningoencephalitis** caused by *Naegleria fowleri*

Amoebiasis. Amoebiasis[1-3] is a parasitic infection caused mainly by the protozoan *Entamoeba histolytica*. Although about 10% of the world's population is infected with *Entamoeba* spp., most individuals are infected with *E. dispar*, one of 2 non-pathogenic species recognised in humans (the other being *E. moshkovskii*). Transmission of *E. histolytica* is usually by the faeco-oral route and infection results from the ingestion of cysts, usually in contaminated food and water. Amoebiasis occurs throughout the world, but the incidence is higher in developing countries and is closely related to sanitation and socio-economic status.

Colonisation of the bowel lumen with *E. histolytica* usually results in asymptomatic infection, although infected people chronically pass cysts in stools. In about 10% of cases symptomatic (invasive) disease may occur days to years after the initial infection; factors increasing susceptibility to tissue invasion include malnutrition, immunosuppression, and pregnancy. Symptomatic (invasive) amoebiasis may be classified as intestinal or extra-intestinal amoebiasis.

- *Intestinal amoebiasis* comprises two main states, amoebic dysentery and non-dysenteric amoebic colitis; amoeboma, a localised form of intestinal amoebiasis, and amoebic appendicitis may also occur. A few patients may develop fulminant or necrotising amoebic colitis which is associated with a mortality rate of more than 40%.
- The most common form of *extra-intestinal amoebic disease* is hepatic amoebiasis, which may present as acute non-suppurative disease or as amoebic liver abscess. Amoebic infection is a less common cause of liver abscess than bacterial infection. Amoebiasis may also involve the skin, genito-urinary tract, or organs such as the lungs and brain.

Drugs used in the **treatment** of amoebiasis may be classified according to their site of action as follows:

- *luminal amoebicides* acting mainly in the bowel lumen. Diloxanide furoate is widely used as the luminal amoebicide of choice, although clefamide, etofamide, and teclozan are also effective. Paromomycin and diiodohydroxyquinoline have also been used[1,2] although most oral preparations of halogenated hydroxyquinolines have been withdrawn because of the association between clioquinol and subacute myelo-opticoneuropathy
- *tissue* or *systemic amoebicides* acting mainly in the intestinal wall and liver. These have included the alkaloid emetine, its synthetic derivative dehydroemetine, and the antimalarial chloroquine which acts mainly in the liver
- *mixed amoebicides* acting at all sites of infection, that is within the intestinal lumen and in the intestinal wall and other tissues. These have included metronidazole and other 5-nitroimidazole derivatives (such as ornidazole, secnidazole, and tinidazole). However, because of their rapid absorption from the gastrointestinal tract, the nitroimidazoles are less effective against parasites in the lumen

Patients with proven *E. histolytica* **asymptomatic** amoebiasis should be treated with a luminal amoebicide to prevent transmission of cysts to others and because of the small but definite risk of potentially severe invasive disease.[2,3] The choice of drug is influenced by availability; diloxanide furoate is generally used in the UK while diiodohydroxyquinoline or paromomycin are also used in the USA.[4] Infection with *E. dispar* and probably infection with *E. moshkovskii* do not need treatment.[3] Those with symptomatic intestinal or extraintestinal **invasive** disease should be treated with a 5-nitroimidazole derivative (usually metronidazole), followed by a luminal amoebicide to eradicate any surviving organisms from the lumen of the large intestine and prevent relapse.[1-3] However, a systematic review[5] to evaluate antiamoebic drugs for the treatment of amoebic colitis found that tinidazole was more effective than metronidazole in reducing clinical failure and better tolerated. Uncomplicated cases usually respond to a 5-day treatment course with metronidazole, while more severe infections are treated for 10 days.[3] In cases of **fulminant** or necrotising amoebic colitis and for severely ill patients, broad-spectrum antibacterials are given with a systemic amoebicide to decrease the risk of superinfection with bowel flora and peritonitis.[1-3] Nitazoxanide has been used in mild to moderate intestinal disease.[4] Standard treatment for amoebic **liver abscess** is metronidazole followed by a luminal amoebicide. The majority of patients with amoebic liver abscess defervesce after 3 to 4 days of treatment with metronidazole.[2,3]

In acute diarrhoea of any aetiology the priority is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Oral rehydration therapy is discussed under Diarrhoea on p. 1808.2.

Table 1. Classification of principal antiprotozoals.

Antimony compounds	*Nitrofurans*
Meglumine antimonate	Furazolidone
Sodium stibogluconate	Nifuratel
	Nifurtimox
Aromatic diamidines	
Pentamidine	*5-Nitroimidazoles*
	Metronidazole
Arsenicals, pentavalent	Nimorazole
Acetarsol	Ornidazole
Tryparsamide	Secnidazole
	Tinidazole
Arsenicals, trivalent	
Melarsoprol	*Miscellaneous*
	Atovaquone
Dichloroacetamides	Benznidazole
Diloxanide	Dehydroemetine
	Eflornithine
Halogenated hydroxyquinolines	Mepacrine
Diiodohydroxyquinoline	Nitazoxanide
	Paromomycin
	Suramin

The symbol † denotes a preparation no longer actively marketed

Acanthamoeba keratitis. *Acanthamoeba* keratitis may result from corneal trauma or exposure to contaminated water, but is most commonly associated with the wearing of soft contact lenses as well as the use of home-made sodium chloride solutions for cleaning them. Infection usually occurs in otherwise healthy persons. Rare cases have been associated with laser-assisted *in-situ* keratomileusis. Keratitis is a local infection that typically begins with a foreign-body sensation followed by pain, tearing, photophobia, and blurred vision. The infection may progress to involve the sclera and loss of vision may follow.

If the disease is recognised early it usually responds well to topical **antiamoebic treatment**; severe infection and late-presenting cases may require penetrating keratoplasty.[1,2] A combination of antiamoebic drugs is generally used because the cyst form is highly resistant to therapy and may persist for years. Two weeks may be required before a response is seen, and the total duration of therapy is a minimum of 3 to 4 weeks; some recommend treating for 3 to 4 months,[3] or even longer. Infection can recur after treatment due to persistence of the cystic form.

The first drug used with some success was 0.1% propamidine isetionate applied topically.[1,4] It was used with an aminoglycoside such as neomycin or a neomycin-polymyxin-gramicidin preparation and a cure was achieved in about 50% of cases. However, most cysts are resistant to neomycin and due to surface toxicity and poor *in-vitro* sensitivity,[1,5] neomycin is no longer recommended.[1,6] Since then the biguanide cationic antiseptics, chlorhexidine and polihexanide have also been shown to be effective in a 0.02% concentration against trophozoites and cysts and have become the drugs of choice.[2,3,5,7] Propamidine has been tried with these agents, however, poor cysticidal activity, chronic conjunctival infection, and resistance to some strains of *Acanthamoeba* to propamidine has prompted the suggestion that it should be replaced by another diamidine such as hexamidine.[1] Biguanides may also be used alone,[6] and are particularly effective in early infection.

Other drugs that have been tried include the topical imidazoles; when applied in a 1% solution they may be effective against trophozoites but probably not against cysts.[1,5] They should never be used as monotherapy. Voriconazole 1% eye drops have, however, been effective for salvage therapy.[8] Oral ketoconazole and, to a lesser extent, itraconazole penetrate into the cornea and have been used as adjunctive therapy to polihexanide and chlorhexidine, but the levels obtained in the cornea are probably too low to be trophozoiticidal.[2] Possible new therapies include antineoplastic and antimalarial drugs; the biguanide antidiabetic drugs metformin and phenformin, and the antibacterial ofloxacin have been shown to have activity against trophozoites *in vitro*, but not against cysts.[1]

Topical cycloplegic therapy and oral NSAIDs may be given for **symptomatic management** of pain, although opioid analgesics are often necessary.[2] Some authorities suggest the use of topical NSAIDs.[1] The use of topical corticosteroids to control inflammation remains controversial because they suppress macrophage activity, which is essential in scavenging and destroying the amoeba.[1] It is recommended that the use of corticosteroids should be delayed and limited as much as possible. They may be considered with antiamoebic agents in those patients with severe pain, scleritis, or severe anterior-chamber inflammation.[2,9,10] A retrospective study[9] found that the use of topical corticosteroids was not associated with treatment failure, but was associated with a prolonged course of antiamoebic therapy. In patients with severe scleral involvement, systemic immunosuppressants such as oral corticosteroids, ciclosporin, and azathioprine may be needed.[11]

Acanthamoeba keratitis in contact lens wearers should be **preventable** by good lens hygiene (see Contact Lens Care, p. 1731.2).

Disseminated amoebic infections. Granulomatous amoebic encephalitis (GAE) and disseminated granulomatous amoebic disease (involving the skin, lungs, and sinuses) are caused by infection with free-living amoebae, usually *Acanthamoeba* spp. or sometimes *Balamuthia mandrillaris* (previously referred to as leptomyxid amoebae). They are opportunistic infections occurring mainly in debilitated or immunocompromised individuals. In GAE the protozoa spread haematogenously to the CNS from the sinuses, lungs, or skin lesions and produce focal neurological deficits that progress over days or weeks to a diffuse meningoencephalitis. The infection is usually fatal and most cases have been diagnosed postmortem so little is known about effective treatments, although many drugs have been tried.

Drugs that have been used in combinations to treat disseminated and CNS infections caused by *Acanthamoeba* spp. include co-trimoxazole, pentamidine, sulfadiazine, flucytosine, rifampicin, and azoles such as ketoconazole, itraconazole, or fluconazole;[1,2] susceptibilities of species and strains appear to vary widely, and susceptibility testing is advisable.

Successful treatment has been reported in 2 apparently immunocompetent children with chronic meningitis caused by *Acanthamoeba* after prolonged treatment with oral co-trimoxazole, rifampicin, and ketoconazole.[3] Successful treatment has also been reported with topical and oral miltefosine in an immunocompromised patient with disseminated acanthamoebiasis, amoebic encephalitis, and underlying miliary tuberculosis and tuberculous meningitis; the patient initially failed treatment with parenteral co-trimoxazole (later changed to oral sulfadiazine), fluconazole, liposomal amphotericin B, and flucytosine.[4]

Similar drugs have been used to treat CNS infections caused by *B. mandrillaris* and 2 patients have been successfully treated with pentamidine, sulfadiazine, flucytosine, fluconazole, a macrolide (such as azithromycin or clarithromycin), and a phenothiazine (such as thioridazine or trifluoperazine).[5]

Clinical responses to chemotherapy have also been reported in a few patients[6-9] with disseminated infection but no evidence of CNS involvement. Disseminated *Acanthamoeba* infection in an immunocompromised patient was successfully treated with intravenous pentamidine followed by maintenance therapy with oral itraconazole.[6] Skin lesions were treated topically with chlorhexidine and ketoconazole.[1] Clinical improvement of disseminated acanthamoebiasis in a patient with AIDS followed treatment with intravenous pentamidine and oral flucytosine; an infant with HIV infection was treated with fluconazole, flucytosine, and sulfadiazine.[7] A lung transplant patient with disseminated acanthamoebiasis was also successfully treated with pentamidine, flucytosine, and azithromycin, plus topical chlorhexidine and ketoconazole.[8] A case of granulomatous dermatitis secondary to *Acanthamoeba* infection in a lung transplant recipient has been successfully treated with a prolonged course of amphotericin B lipid complex and voriconazole.[9]

The use of RNA interference aimed at *Acanthamoeba* genes, using a combination of short-strand interfering RNAs (siRNAs), has been proposed following promising results *in vitro*.[10]

Primary amoebic meningoencephalitis. Primary amoebic meningoencephalitis is a rare infection usually caused by the free-living amoeba *Naegleria fowleri*. It occurs mainly in healthy children and young adults and is usually associated with swimming in warm fresh water. The protozoa invade the CNS directly through the nasal mucosa to produce a meningoencephalitis that is usually rapidly fatal (7 to 10 days).

A few cases of successful treatment have been reported, and have generally involved intravenous[1-5] and usually intrathecal[1-3] amphotericin B; some patients were also given oral rifampicin,[2-5] intravenous and intrathecal miconazole,[2] intravenous chloramphenicol,[5] or ornidazole.[4]

Babesiosis

Babesiosis (piroplasmosis) is an infection caused by intraerythrocytic protozoa of the *Babesia* genus, which are transmitted to man by the bite of infected *Ixodes* ticks. Transmission by blood transfusion has also been reported. *Ixodes scapularis*, one of the ticks that may cause babesiosis, may also be infected with, and transmit, *Anaplasma phagocytophilum* and/or *Borrelia burgdorferi* and therefore the bite from this tick may lead to babesiosis, human granulocytic anaplasmosis (see Ehrlichiosis, p. 179.1), or Lyme disease (p. 190.1) as a single infection or as a co-infection.[1] Babesiosis occurs worldwide in animals. In the US, human infection is most commonly due to *B. microti*; the disease is much rarer in Europe where it is usually caused by *B. divergens* or *B. bovis*.[1-3] Infection with the babesia-like piroplasms WA-1 and MO-1 has also been reported in the USA.[1,2]

Clinical features of babesiosis acquired in the USA differ from that acquired in Europe. Infection in the USA is often asymptomatic and self-limiting, but may produce prolonged severe viral-like illness with fever and haemolytic anaemia, particularly in patients who are asplenic, elderly, debilitated, or immunocompromised (including those infected with HIV). Symptoms include chills, sweating, myalgia, arthralgia, weakness, fatigue, anorexia, nausea, vomiting, jaundice, and headache. The most common complications are heart failure, disseminated intravascular coagulation, acute respiratory distress syndrome, and renal failure.[1-3] Co-infection with *B. microti* and *Borrelia burgdorferi* has resulted in more severe symptoms. In Europe, infections have mostly been described in asplenic persons, in many of whom the infection was rapidly fatal. Clinical features include severe haemolytic anaemia, jaundice, pulmonary oedema, and renal failure.

There is no established specific **treatment** for babesiosis. Treatment is not recommended for asymptomatic patients although all symptomatic patients should be treated with antibacterials to prevent the development of complications.[1] For serious infections, supportive therapies include red blood cell exchange transfusions to reduce parasitaemia. *Clindamycin with quinine* was the first regimen used[4] for the treatment of *B. microti* infections, but has been associated with significant toxicity. A prospective randomised study[5] in 58 patients found *azithromycin with atovaquone* to be as effective as clindamycin and quinine and associated with less toxicity. *Azithromycin with quinine* has been reported to be effective in 2 patients who had not responded to quinine plus clindamycin.[6,7] *Pentamidine* has also been reported to produce clinical improvement in patients with *B. microti* infection,[8] but the efficacy and safety of pentamidine has been questioned.[9] *Other drugs* that have been tried with variable results include chloroquine, primaquine, pyrimethamine, sulfadiazine, and tetracycline.[2,3]

The Infectious Diseases Society of America[1] recommends a combination of either clindamycin plus quinine or atovaquone plus azithromycin, both orally for 7 to 10 days; the combination of intravenous clindamycin plus oral quinine should be used in severe babesiosis. In immunocompromised patients higher doses of azithromycin may be used; they are prone to relapsing disease, and treatment should be given for 6 weeks or more, including 2 weeks after parasites are no longer detectable in blood smears.[10] Partial or complete exchange transfusion may also be given. Patients with persistent infection should be re-treated.

Patients *co-infected* or suspected to be co-infected with *Anaplasma phagocytophilum* and/or *Borrelia burgdorferi* should also be given doxycycline for 10 days.[1,3] For information on the treatment of co-infected patients see Lyme Disease, p. 190.1. In *B. divergens* infections, treatment is complicated by the rapid progression of the disease. Antiprotozoal and antimalarial drugs have been tried with limited success, although pentamidine with co-trimoxazole was successful in a patient,[11] and a marked reduction in parasite load was seen in a patient treated with pentamidine plus exchange transfusions.[12] The combination of clindamycin plus quinine with exchange transfusion has also been suggested.[2]

Preventive measures against babesiosis include the use of tick repellents, physical protection, and prompt removal of attached ticks.[1]

Balantidiasis

Balantidiasis is an uncommon infectious disease of the large intestine caused by a ciliated protozoan, *Balantidium coli*, that frequently infects pigs. Humans and usually resistant but may become infected by eating food or drinking water that has been contaminated by human or animal faeces containing *B. coli* cysts, or by handling infected animals. Those with poor nutrition and achlorhydria appear more vulnerable to infection.

Most cases of balantidiasis are asymptomatic and the organism lives in the large intestine as a luminal commensal, however, asymptomatic people can transmit the disease. Those with symptomatic infections may develop a chronic illness characterised by intermittent diarrhoea, abdominal cramps, and weight loss; colitis with mucus and bloody stools occurs less commonly. Colonic ulceration resulting in a syndrome resembling amoebic dysentery may occur in some individuals, while others may develop a fulminating form of balantidiasis. Untreated cases have proved fatal.

Oral tetracycline for 10 days is the **treatment** of choice; metronidazole, diiodohydroxyquinoline,[1] paromomycin, or nitazoxanide are alternatives. Treatment courses of up to 20 days may be required in immunosuppressed patients, including those who are infected with HIV.

1. Abramowicz M, ed. *Drugs for parasitic infections.* 3rd ed. New Rochelle NY: The Medical Letter, 2013.

Blastocystis hominis infection

There is controversy over whether the protozoan parasite *Blastocystis hominis* is a pathogen or a harmless commensal of the intestinal tract. It has been reported both in immunocompetent and immunocompromised subjects,[1,2] with transmission probably by the faeco-oral route. Diarrhoea and other gastrointestinal symptoms have been ascribed to the organism.

Treatment with standard antiprotozoals, especially metronidazole, has had variable success; metronidazole resistance may occur.[3,4] Co-trimoxazole was reported to have eliminated *B. hominis* from the stools of all but one of 47 otherwise healthy subjects with diarrhoea in one study,[1] and similarly in 36 of 38 children, and 14 of 15 adults, in another.[6] In patients heavily infected with *B. hominis*, only 4 of 12 treated with metronidazole and 2 of 9 given co-trimoxazole achieved eradication of the organism.[1] Diiodohydroxyquinoline,[5] nitazoxanide,[4,5] or paromomycin[4] may be effective in some cases.

Coccidiosis

Coccidiosis is a term sometimes applied to infections with protozoa of the order *Eucoccidiorida*. The predominant coccidian infections in man are caused by *Cryptosporidium* (below), *Cyclospora cayetanensis* (below), *Isaspora* (below), *Plasmodium* (see Malaria, p. 644.1), and *Toxoplasma* (p. 924.2). Coccidian protozoa, mainly *Eimeria*, cause economically important infections in domesticated animals.

Cryptosporidiosis

Cryptosporidiosis[1] is a gastrointestinal infection caused by species of the coccidian protozoan parasite *Cryptosporidium*. It has a worldwide distribution and occurs in many animal species as well as in man. Infection is acquired through ingestion, and perhaps inhalation, of oocysts. Infection in immunocompetent individuals usually causes a self-limiting watery, non-bloody diarrhoea lasting up to 2 weeks. In immunocompromised patients and particularly AIDS patients with a CD4+ count below 100 cells/microlitre, there may be profuse and persistent diarrhoea (for 2 months or longer), profound weight loss, and severe abdominal pain, and the infection may be life-threatening. Other sites of infection include the respiratory and biliary tracts.

There is currently no consistently effective specific treatment[2,3] and priority should be given to maintaining hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Beneficial responses to octreotide have been reported in a few cases,[4–6] but US guidelines for the prevention and treatment of opportunistic infection in HIV-infected patients[7] consider that octreotide is no more effective than oral antidiarrhoeals and its use is not recommended. Oral rehydration therapy is discussed under Diarrhoea on p. 1808.2. In patients with AIDS the severity of the infection may be controlled if the immune function is improved with HAART,[2,3,7,8] but where this is not possible, therapy with an antimicrobial and an antidiarrhoeal drug continues to be standard.[2] Several drugs have been studied in small clinical studies; for nitazoxanide, paromomycin,[7,8] spiramycin,[7] and azithromycin,[9,10] benefits were at best moderate,[2] although evidence is perhaps best for nitazoxanide,[11] particularly in patients not infected with HIV.[3] Other treatments reported to have produced benefit in a few patients include hyperimmune bovine colostrum,[12–16] eflornithine,[17] rifabutin or rifaximin,[3] or normal immunoglobulin with high cryptosporidium antibody titres.[18]

Guidelines for the treatment of opportunistic infection in HIV-infected patients in the USA suggest that, in addition to optimising the HAART regimen, the addition of nitazoxanide[7,8] or alternatively paromomycin[7] therapy may be considered; azithromycin[8] is not recommended.

Clarithromycin and rifabutin may be useful for disease prophylaxis,[19] although the efficacy of clarithromycin has been questioned.[20] Guidelines for the prevention and treatment of opportunistic infection in HIV-infected patients in the USA[7,8] consider that the data on these drugs are insufficient to recommend their use for chemoprophylaxis.

Cyclosporiasis

An organism originally described as cyanobacterium-like or coccidian-like bodies, but now identified as the coccidian protozoan *Cyclospora cayetanensis*, has been reported to be a cause of diarrhoea in both immunocompromised and immunocompetent patients. Infection results from ingestion of spores or oocysts in contaminated food or water and can result in diarrhoea, nausea, vomiting, abdominal cramps, loss of appetite, and flu-like symptoms. In immunocompetent patients, infection may be asymptomatic or self-limiting while immunocompromised patients may develop severe or persistent symptoms. Prolonged *C. cayetanensis* infection has been associated with various extraintestinal complications including biliary disease, acalculous cholecystitis, Guillain-Barré syndrome, and reactive arthritis.

Successful treatment of cyclosporiasis has been reported with oral co-trimoxazole;[1–4] treatment is usually given for 7 to 10 days, but HIV-infected patients can relapse after treatment and higher doses[4] or long-term suppressive treatment may be required. Alternative treatments have not yet been found for those allergic to sulfonamides.[1,3] However, a small, randomised study[2] comparing co-trimoxazole and ciprofloxacin for treatment of and secondary prophylaxis for *Cyclospora* infection in HIV infected patients found ciprofloxacin to be moderately effective, but less active than co-trimoxazole. Successful use of nitazoxanide has also been reported.[5]

Gastro-enteritis

Although bacteria and viruses are responsible for many cases of infective diarrhoea, protozoal infections are also a cause of diarrhoea,[1,2] which can be severe (especially in immunocompromised patients, including those with AIDS). Patients with diarrhoea lasting for more than 7 days should be tested for protozoal parasites.[3] In acute diarrhoea of any aetiology the priority is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly.[3] Oral rehydration therapy is discussed under Diarrhoea on p. 1808.2. Specific therapy with antiprotozoals may also be necessary to control enteric protozoal infections.

For the management of the protozoal infections that are generally associated with diarrhoea, see under Amoebiasis (p. 919.1), Balantidiasis (p. 920.3), *Blastocystis hominis* infections (p. 920.3), Cryptosporidiosis (above), Cyclosporiasis (above), Giardiasis (below), Isosporiasis (below), and Microsporidiosis (p. 924.1).

Giardiasis

Infection with *Giardia intestinalis* (*G. duodenalis*, *G. lamblia*; *Lamblia intestinalis*) is one of the commonest intestinal protozoal infections throughout the world, especially in areas with poor sanitation and unsafe water. Infection is acquired by oral ingestion of *Giardia* cysts, either from direct contact with infected animals or humans, or by ingestion of water and foodstuffs contaminated by the faeces of infected animals or humans.

Many infected people are asymptomatic and most infections are self-limited. However, asymptomatic people may still act as carriers. Symptomatic giardiasis is usually characterised by diarrhoea, fatigue, abdominal cramps, bloating, nausea, and weight loss. Symptoms usually improve in 2 to 6 weeks but some people have chronic symptoms. Malabsorption of fat, lactose, and vitamins A and B_{12}, and failure of children to thrive have been reported in those with chronic giardiasis.

Priority in the management of acute diarrhoea of any aetiology is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Oral rehydration therapy is discussed under Diarrhoea on p. 1808.2.

One of the most effective antiprotozoal treatments is metronidazole or another nitroimidazole derivative such as tinidazole,[1–3] ornidazole, and secnidazole.[1] Nitazoxanide is also effective[4–6] and some consider it a drug of choice.[3] Other alternatives include furazolidone, and mepacrine.[1,3] Paromomycin has been suggested;[3] although it is less effective than other drugs, it is not absorbed systemically and may be a useful alternative in resistant infection and during pregnancy.[1] The benzimidazoles (albendazole and mebendazole) have been tried with mixed results, but they might be useful in the developing world where their broad antiparasitic effect would be an advantage,[1] and some suggest[7] that albendazole is comparable in efficacy to metronidazole. Treatment may sometimes need to be repeated, possibly due to resistance or relapse,[1] and drug combinations such as a nitroimidazole with mepacrine[1,8] have been reported to be of value in such cases.

Infections in immunocompromised patients

Patients with a defective immune system are at particular risk of infection. Primary immune deficiency is rare, whereas secondary deficiency is more common: immunosuppressive therapy, cancer and its treatment, HIV infection, and splenectomy may all cause neutropenia and impaired humoral and cellular immunity in varying degrees. The risk of infection is linked to the duration and severity of neutropenia. Most protozoal infections present in a more severe form in immunocompromised patients than in immunocompetent patients. Those of particular concern in patients with HIV infection include Cryptosporidiosis (above), Isosporiasis (below), Leishmaniasis (p. 922.1), Microsporidiosis (p. 924.1), and Toxoplasmosis (p. 924.2).

Detailed guidelines for the treatment and prevention of opportunistic infections (including some protozoal infections) among HIV-infected adults, adolescents, and children have been developed in the USA.[1,2]

Isosporiasis

Isosporiasis is a coccidian protozoal infection of the gastrointestinal tract caused by *Cystoisospora belli*, formerly

called *Isospora belli*. It has a worldwide distribution but occurs more frequently in tropical and subtropical regions. Oocysts are excreted in faeces and infection is acquired when sporulated oocysts are ingested.

In immunocompetent individuals the infection is usually mild and self-limiting but in immunocompromised patients, including those with AIDS, the infection can vary from a chronic and intermittent illness to a severe, life-threatening diarrhoeal disease.

Treatment is usually with co-trimoxazole for 10 days.[1-3] Immunocompromised patients may need higher doses and treatment for up to 3 to 4 weeks.[2,3] Ciprofloxacin may be an alternative in those unable to tolerate co-trimoxazole, although it is somewhat less effective.[1,2] Pyrimethamine has been used successfully in individual patients with sulfonamide sensitivity.[2] In acute diarrhoea of any aetiology the priority is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Oral rehydration therapy is discussed under Diarrhoea on p. 1808.2.

HIV-infected patients with a CD4+ count below 200 cells/microlitre should receive long-term suppressive therapy (secondary **prophylaxis**) with co-trimoxazole. Pyrimethamine may be used in patients allergic to sulfonamides; ciprofloxacin may be given as an alternative.[2] Secondary prophylaxis may be stopped in those patients taking effective antiretroviral therapy who have a CD4+ count above 200 cells/microlitre for at least 6 months.[2]

Leishmaniasis

Leishmaniasis[1,2] is caused by parasitic protozoa of the genus *Leishmania*; the species involved depends on the geographical distribution. It occurs throughout Africa, the Middle East, Central Asia, and the Mediterranean (Old World leishmaniasis), and throughout Central and South America (New World leishmaniasis). In endemic areas there is generally a reservoir of disease in a mammalian host, often dogs or rodents. The usual vectors are sandflies of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World. Some species of *Leishmania* may also be transmitted by blood transfusions or contaminated needles; congenital transmission has been reported.

Leishmaniasis ranges from self-limiting, localised, cutaneous ulcers to widely disseminated progressive disease with involvement of the reticuloendothelial system, and can be categorised as:

- cutaneous (below)
- mucocutaneous (mucosal) (p. 923.1)

or

- visceral (p. 923.1)

Incubation periods can be prolonged, with clinical features not appearing until several months or even years after the primary infection.

Leishmaniasis has also emerged as an opportunistic infection in immunocompromised patients (including HIV and AIDS), in whom it is particularly difficult to treat. For further information see also p. 923.3. The most common clinical presentation of leishmaniasis in persons with AIDS is visceral disease, but the distribution varies geographically; in Europe visceral disease has been reported in 95% of cases, while in Brazil, mucocutaneous (43%) and cutaneous (20%) are common. Clinical manifestations in patients with AIDS may be atypical and severe, and relapse after treatment is common. Since the introduction of HAART the incidence of leishmaniasis has decreased substantially in developed countries, but co-infection is a growing problem in Asia and Africa.

In endemic areas an integrated approach to controlling leishmaniasis involves case detection and treatment of patients, vector and animal reservoir control, environmental management to reduce suitable vector habitats, and personal protection against sandfly bites including the use of insect repellents and bednets. Strategies aimed at controlling malaria are believed to have reduced leishmaniasis transmission dramatically.

2. Roberts MTM. Current understandings on the immunology of leishmaniasis and recent developments in prevention and treatment. *Br Med Bull* 2005; 75-76: 115–30.

Cutaneous leishmaniasis. Cutaneous leishmaniasis is caused by various species of *Leishmania*. Old World disease is normally caused by *L. tropica*, *L. major*, or *L. aethiopica*, although cutaneous lesions due to *L. infantum* and *L. donovani* have been reported. New World cutaneous leishmaniasis (American cutaneous leishmaniasis) is caused by many species and subspecies of *Leishmania* including *L. braziliensis*, *L. mexicana*, *L. panamensis*, and *L. peruviana*. Worldwide, about 90% of cases occur in Algeria, Pakistan, Saudi Arabia, Syria, Afghanistan, Brazil, and Peru. In general, New World forms tend to be more severe and longer lasting than Old World forms.

Cutaneous leishmaniasis has been categorised into different clinical forms:

- *localised* disease is confined to the skin and lesions are mainly on exposed parts of the body. The disease ranges from single, self-healing lesions which are troublesome and unsightly but not a threat to life, to multiple, deep, and destructive ulcers which cause considerable disfigurement and disability. A 'classical' lesion starts as a nodule at the site of inoculation. A crust develops centrally which may fall away exposing an ulcer which heals gradually. Satellite nodules at the edge of the lesion are common
- *diffuse* cutaneous leishmaniasis occurs occasionally after infection with *L. aethiopica* or members of the *L. mexicana* complex and involves dissemination of the disease from the original site of infection to distant skin sites, typically the face and exterior surfaces of the limbs. The lesions resemble lepromatous leprosy, do not heal spontaneously, and are resistant to treatment
- *leishmaniasis recidivans* is a lupoid or tuberculoid form caused by infection with *L. tropica*. This chronic disease often occurs as slowly progressive, destructive and disfiguring lesions on the face which are very resistant to most forms of therapy

There is no consensus on the optimum **treatment** for cutaneous leishmaniasis[1] and a systematic review[2] on the treatment of Old World cutaneous leishmaniasis found 49 randomised controlled studies covering at least 19 different treatments. Current methods include physical interventions, topical ointments, local injection, and systemic anti-protozoals;[3] vaccines containing *Leishmania* spp. are under investigation, see p. 2397.2. The decision to treat depends upon the site and extent of the lesions and the likelihood of dissemination. Small lesions, particularly in Old World cutaneous leishmaniasis, may be left untreated if they are not troublesome to the patient; most lesions heal spontaneously within 2 to 15 months depending on the infecting species. The aim of treatment is to accelerate cure, reduce scarring, and prevent parasitic dissemination or relapse. Treatment is usually given to those patients with persistent lesions (6 months or more), lesions located over joints or on the face, or multiple or large lesions. Systemic therapy should be given to those with large and disfiguring lesions and those caused by *L. braziliensis* or other New World *Leishmania* species associated with mucocutaneous disease. Healing occurs slowly and may be incomplete at the end of a treatment course; patients who fail to respond after the initial course may be given a second or third treatment course of the same drug or treatment with an alternative drug. Drugs mainly used for the treatment of cutaneous leishmaniasis include:[1,2,4]

- intralesional, intramuscular, or intravenous pentavalent antimonials (meglumine antimonate, sodium stibogluconate)
- oral azoles
- topical paromomycin
- oral miltefosine
- intramuscular pentamidine

Old World cutaneous leishmaniasis. The pentavalent antimonials have been widely used and are the current mainstays of systemic treatment. Lesions at exposed sites that are small and few in number have been successfully treated with intralesional pentavalent antimonials.[3,5,6] Oral azole antifungals have been investigated for potential use in cutaneous leishmaniasis. Ketoconazole given for 4 to 6 weeks has been reported to be effective in about 70% of patients with *L. major* infections, but is not effective against infections caused by *L. tropica* and *L. aethiopica*.[7,8] Itraconazole has been found to be effective[9,10] and a systematic review[2] reported that for *L. tropica* infections there was reasonable evidence that a 6-week itraconazole regimen was more effective than placebo. Similarly a 6-week course of fluconazole was more effective than placebo for infections caused by *L. major*.[11] Conventional amphotericin B is an effective alternative, but has been associated with substantial toxicity and there is little experience with liposomal amphotericin B. The use of oral miltefosine is being investigated[1] and there is a case report of successful treatment in a patient with infection caused by *L. major*.[12] A small study[13] in Iran found oral miltefosine to be at least as good as intramuscular meglumine antimonate for the treatment of infections caused by *L. major*; another retrospective, observational study[14] also reported successful treatment with oral miltefosine of *L. major* infection acquired in northern Afghanistan. Topical paromomycin has been studied with variable results;[3,15-18] the vehicle may affect benefit. A systematic review[2] reported that for *L. major* infections there was reasonable evidence that topical paromomycin (15%) with methylbenzethonium (12%) twice daily for 28 days was more effective than placebo. Oral nitazoxanide has also been tried.[19] Local cryotherapy or, alternatively, application of heat to bring the temperature of the lesion to about 40 degrees which may aid healing have been tried for both Old World[20] and New World leishmaniasis.[3] Some suggest a step-wise approach to treatment of Old World cutaneous leishmaniasis.[21] They propose that patients with single, small lesions of short duration (less than 6 months) may be treated with cryotherapy, while those with multiple, atypical, large or extensive lesions, recidivans-type lesions, and relapsed cases should be treated with a combination of systemic and topical treatments. Combination therapies found to be effective are topical imiquimod (5%) with either oral dapsone or oral itraconazole, and cryotherapy with oral itraconazole.[21]

New World cutaneous leishmaniasis. Disease caused by *L. mexicana* may be treated with a parenteral pentavalent antimonial for 10 days, while disease caused by other species is treated for 20 days.[1] (However, a systematic review,[22] while noting the poor quality of the evidence, failed to find a significant difference in cure rates of *L. braziliensis* or *L. panamensis* infections when treated for 10 versus 20 days with parenteral antimonials.) In regions where the risk for mucosal disease is very low, topical treatment with paromomycin sulfate 15% plus methylbenzethonium chloride 12% has produced promising responses;[23,24] but in Columbia, the addition of topical paromomycin did not augment the clinical response to a short course of treatment with parenteral meglumine antimonate.[25] The addition of topical imiquimod to a standard treatment regimen with parenteral meglumine antimonate accelerated healing of lesions and decreased scar prominence in patients who had failed an initial course of antimony therapy[26] and in those with newly diagnosed disease.[27] Patients treated only with imiquimod cream all relapsed after treatment was stopped.[27] Results for the use of oral miltefosine have varied. A placebo-controlled study[28] found oral miltefosine to be effective (91%) in Columbia but much less effective in Guatemala (53%). Another study[29] in Bolivia reported that cure rates with miltefosine (88%) were similar to those with an intramuscular pentavalent antimonial (94%) in the treatment of infection caused by *L. braziliensis*. The authors concluded that oral miltefosine was more effective for *L. braziliensis* in Bolivia than for *L. braziliensis* in Guatemala. A small study[30] in Venezuela reported good initial cure rates with oral miltefosine given daily for between 75 and 218 days in patients with diffuse cutaneous leishmaniasis; however, most patients developed new lesions after treatment was stopped. Another small study[31] in Brazil reported that high-dose oral fluconazole, given daily for a median duration of 6 weeks, was effective for infections caused by *L. braziliensis*. There is limited and sometimes inconsistent evidence of benefit from the use of oral allopurinol or oral pentoxifylline as an adjuvant to parenteral antimonial therapy.[22]

Among the **non-specific therapies** tried in cutaneous leishmaniasis, topical application of the nitric oxide donor *S*-nitroso-*N*-acetylpenicillamine (SNAP)[32] and intralesional injection of hypertonic sodium chloride solution[33] have produced beneficial responses. Immunomodulation using leishmania antigens mixed with BCG,[34] or interferon gamma,[35] has produced encouraging results.

Mucocutaneous leishmaniasis. Mucocutaneous leishmaniasis of the New World (espundia) is most commonly caused by *L. braziliensis* with about 90% of cases occurring in Brazil, Bolivia, and Peru. In mucocutaneous leishmaniasis the primary lesions do not heal spontaneously. Metastatic spread to the mucosa may occur during the presence of the primary lesion or up to 30 years later. The nasal mucosa is always affected. Ulceration and erosion progressively destroy the soft tissue and cartilage of the oronasal/pharyngeal cavity. Mutilation is severe and secondary bacterial infection is frequent and can be fatal.

The most commonly used drugs for the treatment of mucocutaneous leishmaniasis are:[1-3]

- intramuscular or intravenous pentavalent antimonials (meglumine antimonate, sodium stibogluconate)
- intravenous amphotericin B (conventional and liposomal)

Mucocutaneous leishmaniasis responds poorly to treatment and relapses are common. Initial treatment with pentavalent antimony for 28 days usually results in a cure in 75% of mild cases.[1] Failure to respond is an indication to use amphotericin B[1] or pentamidine, but toxicity limits the use of the latter. A non-randomised study[4] in 72 Bolivian patients given oral miltefosine daily for 28 days reported a cure rate of 83% in those who had mild disease (affecting nasal skin and nasal mucosa) and 58% in those with more extensive disease (involving the palate, pharynx, and larynx); treatment was at least as effective as a course of parenteral amphotericin B. Mucosal disease in Old World leishmaniasis is much less common than visceral or cutaneous forms, but treatment with antimony compounds or ketoconazole has been described.[5]

Visceral leishmaniasis. Visceral leishmaniasis[1-4] is caused by *L. donovani* in the Indian subcontinent, Asia, and Africa and by *L. infantum* or *L. chagasi* elsewhere in the New and Old World. The majority of cases occur in Bangladesh, Brazil, Ethiopia, India, Nepal, and Sudan. The incubation period typically varies from 3 to 8 months, and many infections result in sub-clinical or self-limiting disease. Fever, malaise, shivering or chills, weight loss, anorexia, and discomfort in the left hypochondrium are common; there is often non-tender splenomegaly with or without hepatomegaly, wasting, pallor of mucous membranes, anaemia, leucopenia, and lymphadenopathy. Continued deterioration can lead to potentially fatal secondary infection. Darkening of the skin of the face, hands, feet, and abdomen (kala-azar = black sickness) is uncommon and has only been described in patients from the Indian subcontinent. Rare complications can include severe acute haemolytic anaemia, acute renal damage, and severe mucosal haemorrhage.

A small percentage of patients in India and about 50% of those in the Sudan develop post-kala-azar dermal leishmaniasis after recovery from visceral leishmaniasis caused by *L. donovani* and such patients represent a human reservoir for the disease. Longer treatment courses are needed in Indian post-kala-azar dermal leishmaniasis.

The most commonly used drugs for the treatment of visceral leishmaniasis are:[1-3]

- intramuscular or intravenous pentavalent antimonials (meglumine antimonate, sodium stibogluconate)
- intravenous amphotericin B (conventional, liposomal and lipid complex formulations)
- intramuscular paromomycin
- oral miltefosine
- intramuscular or intravenous pentamidine

The pentavalent antimonials, given daily for 28 days, are the traditional first-line drugs for the treatment of visceral leishmaniasis.[1-4] Patients relapsing after the initial course of treatment may be given a further course, or treated with an alternative drug. There is growing evidence that responsiveness to the antimonials is declining and they are no longer effective in some parts of India.[5]

The use of pentavalent antimonials has also declined in Europe, the USA, and other developed countries where treatment with liposomal amphotericin B is preferred.[1,2,4] The conventional formulation of amphotericin B is also highly effective,[6] but lipid formulations of amphotericin B are better tolerated than conventional amphotericin B, and are likely to be preferred when the toxicity and duration of therapy with conventional forms would compromise patient compliance.

Intramuscular paromomycin has been used alone[7-9] or with a pentavalent antimonial[3,10] and could be an effective alternative for pentavalent antimonials or amphotericin B. Combination treatment with a single dose of liposomal amphotericin B followed by 10 days of paromomycin was found to have a cure rate of 97.5% in patients treated in Bihar, India, where visceral leishmaniasis is more difficult to treat. The combination of paromomycin for 10 days plus oral miltefosine (see below) for 10 days was found to have a cure rate of 98.7%.[11]

Miltefosine is the first oral preparation shown to be effective against Indian visceral leishmaniasis,[12-14] including infections in children[15,16] and those previously treated with pentavalent antimonials.[14] Combination treatment with a single dose of liposomal amphotericin B followed by 7 to 14 days of miltefosine was found to be effective in more than 95% of patients treated in Bihar.[11,17] Longer treatment courses with miltefosine have also been successfully used in the treatment of post-kala-azar dermal leishmaniasis in Bihar.[18]

Pentamidine has been used as a second-line drug but its usefulness as alternative first-line therapy is doubtful[19] given its toxicity, increasing failure rates, and slow disease response. It has been suggested as an alternative for long-term secondary prophylaxis in patients with HIV infection.[20]

Sitamaquine is an orally active 8-aminoquinoline analogue that is under investigation.[3,4] Oral azoles (ketoconazole, itraconazole, and fluconazole) and allopurinol have weak activity against *Leishmania* but have not been found to be effective when used as single-drug therapy.[3] Another line of investigation has been to boost the immune response to the parasite by adding interferon gamma to conventional treatment, although results have been variable.[21-24]

Treatment of leishmaniasis in HIV co-infected patients. For HIV-infected patients with *visceral leishmaniasis*, the efficacy of conventional, liposomal, and lipid complex formulations of amphotericin B appears to be similar to that of the pentavalent antimonials, however, liposomal amphotericin B is regarded by many as the drug of choice.[1] Alternative treatments include miltefosine and paromomycin.[1] A study[2] in Ethiopia found miltefosine to be safer but less effective than sodium stibogluconate in HIV co-infected patients. Oral miltefosine was given to 39 patients with both leishmaniasis and HIV who were resistant to, or had repeatedly relapsed after, treatment with other drugs (usually amphotericin B). Initial parasitological cure was achieved in 16 patients (41%), and 9 patients (23%) had initial improvement in both parasitological and clinical status. A similar cure and improvement rate was achieved in patients who were re-treated with additional courses of miltefosine.[3] For HIV-infected patients with *cutaneous, mucocutaneous, disseminated cutaneous leishmaniasis*, and localised cutaneous disease caused by *L. braziliensis*, US guidelines[1] recommend first-line parenteral treatment with liposomal amphotericin B or a pentavalent antimonial. Alternative drugs for cutaneous leishmaniasis are miltefosine, topical paromomycin, intralesional pentavalent antimonials, and local heat therapy.[1] Patients who fail to respond to initial therapy or have a relapse after initial treatment may be given a repeat course of the initial regimen, or one of the recommended alternatives for initial therapy.[1]

Relapse after treatment is common, therefore US guidelines[1] recommend secondary prophylaxis with an effective antileishmanial drug (given at least every 2 to 4 weeks), particularly for patients with visceral leishmaniasis and CD4+ count less than 200 cells/microlitre. US guidelines note that there are insufficient data to provide a recommendation as to when secondary prophylaxis can be stopped, but that it might be considered after a sustained (more than 3 to 6 months) increase in the CD4+ count to levels more than 200 to 350 cells/microlitre after starting treatment with HAART.[1]

Malaria

For a discussion of malaria, its prophylaxis and treatment, see p. 644.1.

Microsporidiosis

Microsporidia are obligate intracellular spore-forming protozoal parasites. They were mainly regarded as a cause of disease in nonhuman species but some genera, including *Brachiola, Encephalitozoon, Enterocytozoon, Microsporidium, Nosema, Pleistophora, Trachipleistophora,* and *Vittaforma* spp., are now recognised as human pathogens. Transmission is believed to be mainly faeco-oral although inhalation and direct inoculation also occur. Infections usually occur only in immunocompromised patients and in particular those with AIDS and a CD4+ T lymphocyte count of less than 100 cells/microlitre. However, infections have also been reported in non-HIV-infected individuals including children, the elderly, and organ transplant recipients. Small bowel infection with *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* have been reported in AIDS patients as causes of chronic diarrhoea and weight loss. Other manifestations of microsporidiosis in AIDS include keratoconjunctivitis, respiratory-tract infections, renal and urinary-tract infections, encephalitis, peritonitis, cholangitis, granulomatous hepatitis, and disseminated myositis.

There is no established treatment[1-3] and supportive care should be given to maintain hydration and correct electrolyte loss. Oral rehydration therapy is discussed under Diarrhoea on p. 1808.2. In patients with AIDS the best treatment is improvement of immune function with HAART.[2,3] Beneficial responses have been reported with albendazole[4-8] and US guidelines for the treatment of opportunistic infections in HIV-infected patients recommend it for treatment of intestinal and disseminated infections caused by microsporidia other than *E. bieneusi* and *Vittaforma corneae*.[2,3] Itraconazole plus albendazole may be useful for disseminated disease.[2] There have also been reports of successful treatment of *E. bieneusi* with nitazoxanide[9] and fumagillin[10,11] (and its synthetic analogue TNP-470).[2]

Topical treatment of keratoconjunctivitis has been disappointing, although there are reports of individual patients responding to topical propamidine isetionate,[12] topical fumagillin,[13,14] oral albendazole,[15] oral albendazole plus topical fumagillin,[16] or oral itraconazole plus topical antibacterials.[17] US guidelines[2,3] recommend the use of topical fumagillin plus oral albendazole for eye infections. Treatment for these should be continued indefinitely in those with a CD4 + T lymphocyte count of less than 200 cells/microlitre, because of the risk of recurrence or relapse if treatment is stopped; treatment may be stopped in those with a relatively competent immune system (CD4+ T lymphocyte count greater than 200 cells/microlitre) once the eye infection has resolved.[2]

Pneumocystis pneumonia

Although *Pneumocystis jirovecii* was formerly classified as a protozoan, it is now accepted to be a fungus. For the management of pneumocystis pneumonia, see p. 567.2.

Toxoplasmosis

Toxoplasmosis[1] is a zoonosis with a worldwide distribution caused by the protozoan *Toxoplasma gondii*, an intestinal parasite of cats for which other mammals may act as intermediate hosts. In man, infection is usually acquired through accidental swallowing of oocysts after contact with infected cat faeces or contaminated soil, from eating raw or undercooked meat from infected animals, or from drinking contaminated water. Congenital transmission may also occur if infection is acquired for the first time during pregnancy.

Toxoplasma infection is common; in immunocompetent individuals it is usually asymptomatic and if symptoms (such as fever, headache, malaise, and lymphadenopathy) do occur they are usually self-limiting, although latent (cystic) disease may become reactivated throughout the host's lifetime. Very rarely myocarditis or encephalitis may occur. Immunocompromised patients may develop serious complications such as encephalitis, chorioretinitis, myocarditis, and pneumonitis. Toxoplasmic encephalitis is the most common presentation in patients with AIDS.

Primary infection during early pregnancy is serious because of the risk of transplacental transmission which may result in fetal death or congenital toxoplasmosis. Primary infection during later pregnancy can also result in congenital infection, although this often only becomes symptomatic later in life. Rarely, reactivation of latent infection in chronically infected severely immunocompromised women has resulted in congenital transmission.[2]

The sequelae in live-born infants with signs of infection are generally severe and include a potentially fatal syndrome in which hydrocephalus, hepatosplenomegaly with jaundice, mental retardation, and chorioretinitis may occur. Congenital disease that becomes clinically evident later in life is usually less severe, but often results in ocular or neurological impairment. Infection in the pregnant woman is usually asymptomatic and antenatal screening programmes have been set up in some countries for the diagnosis of acute infections during pregnancy. However, the value and practicality of such schemes has been debated.[2-7]

Ocular toxoplasmosis causes chorioretinitis and is often a result of congenital infection; patients may be asymptomatic until later in life.

Treatment. Toxoplasmosis in immunocompetent patients is not usually treated unless symptoms are severe. Currently there is no drug active against the cystic form, so any treatment is directed against the acute forms of the disease. Active toxoplasmosis in immunocompromised patients requires prompt treatment.

- Toxoplasmosis is normally treated with a regimen of pyrimethamine plus sulfadiazine;[8,9] folinic acid is also a standard component of regimens including pyrimethamine to counteract associated megaloblastic anaemia.
- Clindamycin plus pyrimethamine and folinic acid has been used as an alternative in patients unable to take the sulfonamide.[8,9]
- Other regimens have been studied and have been found to have activity in toxoplasmic encephalitis, notably co-trimoxazole, atovaquone plus pyrimethamine and folinic acid, or atovaquone plus sulfadiazine, or azithromycin plus pyrimethamine and folinic acid. Atovaquone has also been given alone in patients unable to tolerate pyrimethamine or sulfadiazine.[8]
- Severely ill patients needing parenteral therapy have been given intravenous co-trimoxazole or clindamycin with oral pyrimethamine.[8]

Adjunctive corticosteroids may be given occasionally for treatment of a mass effect associated with focal lesions or oedema, but should be stopped as soon as possible because of their immunosuppressant effect. Anticonvulsants should be given to patients with a history of seizures.[8,9] Acute treatment is ideally continued for 6 weeks, or for longer if disease is extensive or response is incomplete.[8,9]

Immunocompromised patients who have successfully completed a 6-week course of acute therapy should be given chronic *maintenance* therapy, which should ideally be with pyrimethamine plus sulfadiazine and folinic acid,[8,9] but alternatives are pyrimethamine plus clindamycin and folinic acid, co-trimoxazole, or atovaquone, with or without sulfadiazine or pyrimethamine and folinic acid.[8] Chronic maintenance therapy should be lifelong unless immune reconstitution occurs because of antiretroviral therapy, in which case consideration may be given to stopping prophylaxis. It should, however, be restarted if the CD4+ count falls to below 200 cells/microlitre.[8]

The management of maternal and fetal infection may vary considerably from country to country and even within a country.[1] A systematic review[10] of the treatment of women during **pregnancy** involved small studies with variations in period of gestation, duration of follow-up, and other aspects of methodology, making comparison of data problematical; consequently the evidence was inconclusive as to whether treatment was effective in preventing fetal infection or overt neonatal disease. A meta-analysis of individual patients' treatment data reported only a weak association between early treatment and reduced risk of congenital toxoplasmosis. Furthermore, it found no evidence that prenatal treatment significantly reduced the risk of clinical signs and symptoms in infected newborn infants.[11]

If treatment is given, pyrimethamine should not be used to treat primary toxoplasmosis during the first and early second trimester of pregnancy. Spiramycin has been used throughout the first 18 weeks of pregnancy but, although it reduces the risk of congenital transmission, it does not readily penetrate the cerebrospinal space and does not prevent toxoplasmic encephalitis in immunocompromised women. After 14 to 18 weeks of gestation a pyrimethamine regimen with sulfadiazine may be given.[2] Some countries advise that spiramycin be continued throughout the pregnancy, while others recommend changing to the pyrimethamine plus sulfadiazine regimen at 17 weeks of gestation.[1]

When there is evidence of placental or fetal infection acquired in late second or third trimester, treatment is usually with the pyrimethamine plus sulfadiazine regimen; some advise that pyrimethamine plus sulfadiazine treatment may be alternated with courses of spiramycin until term.[1]

In **neonates** with congenital toxoplasmosis, the preferred treatment is also a pyrimethamine plus sulfadiazine regimen.[9] Infants without HIV infection should be treated for 12 months. In infants with mild toxoplasmosis, some experts recommend alternating the pyrimethamine-sulfadiazine regimen with spiramycin on a monthly basis from months 7 to 12, in order to reduce the risk of bone marrow suppression. However, infants with HIV infection and moderate to severe toxoplasmosis should receive the full 12-month regimen of pyrimethamine-sulfadiazine.[9] Longer courses of treatment may be given in cases of extensive disease. A corticosteroid, usually dexamethasone or prednisolone, has been added in children with CNS involvement.[9]

In immunocompetent individuals, **ocular toxoplasmosis** is a self-limiting disease and requires no treatment, unless visual acuity is threatened or there is a large retinal lesion with marked vitritis.[12-14] A systematic review[15] found a lack of evidence to support routine treatment for acute toxoplasma retinochoroiditis in immunocompetent patients, but did find weak evidence to suggest that long-term treatment of patients with chronic recurrent disease may reduce recurrence. All immunocompromised patients should be treated and prolonged treatment is necessary to prevent recrudescence. The best drug regimen is unknown. The most commonly used regimens give pyrimethamine with sulfadiazine or clindamycin (which is concentrated in the choroid). Benefit has been reported from clindamycin with corticosteroids,[16] although corticosteroids should never be used alone since fulminant cases may occur. Spiramycin is not indicated for ocular toxoplasmosis.

Prophylaxis. Primary prophylaxis against *T. gondii* infection has been investigated in AIDS patients and recipients of organ transplants. In HIV-infected adults and adolescents who are seropositive for *Toxoplasma* and who have a CD4+ count of less than 100 cells/microlitre, primary prophylaxis against encephalitis should be given.[8] Primary prophylaxis should also be given to seropositive children with a CD4 percentage less than 15%.[9]

Co-trimoxazole, in regimens designed for pneumocystis pneumonia prophylaxis, was found to be effective and is therefore recommended.[8,9] Alternatively, a regimen using pyrimethamine plus dapsone, or perhaps atovaquone, with or without pyrimethamine, can also be considered.[8] A regimen involving pyrimethamine plus sulfadoxine has also been tried, with promising results.[17]

Toxoplasma-seronegative persons who are not receiving a pneumocystis prophylactic regimen known to be active against toxoplasmic encephalitis should be retested for *Toxoplasma* should their CD4+ count fall below 100 cells/microlitre and if they have seroconverted primary prophylaxis should be started.[8] Primary prophylaxis should be stopped in adult and adolescent patients whose CD4+ count rises in response to antiretroviral therapy to more than 200 cells/microlitre for 3 months or more. If the count subsequently falls to below 200 cells/microlitre it should be restarted.[8] Similarly, primary prophylaxis may be stopped in children whose CD4 percentage rises to above 15% and should be restarted if the CD4 percentage subsequently falls below 15%.[9]

Trichomoniasis

Trichomoniasis is caused by invasion of the genito-urinary tract with the protozoan *Trichomonas vaginalis*. Transmission is mainly sexual. Trichomoniasis is a common cause of vaginitis and vaginal discharge but infections vary in severity from asymptomatic (in up to 50% of cases) to an acute inflammatory vaginitis. Men are usually asymptomatic, although they may have urethritis. Asymptomatic infection in either sex should still be treated to prevent sexual transmission and symptomatic infection. *T. vaginalis* infection has been associated with HIV acquisition and adverse pregnancy outcomes, particularly premature rupture of the membranes, preterm delivery, and low birth-weight.

Guidelines for the **treatment** of trichomoniasis have been produced by an expert group in the UK,[1] by WHO,[2] and by the CDC in the USA.[3] Treatment is usually with a nitroimidazole such as metronidazole or tinidazole, often as a single oral dose of 2 g.[1-4] Alternative treatment regimens include standard oral doses of metronidazole or tinidazole given twice daily for 5 to 7 days.[1-3] Sexual partners should also be treated.[1-3] In HIV-infected women with trichomoniasis, there is evidence that metronidazole 500 mg orally given twice daily for 7 days is superior to a single 2-g oral dose; therefore, a multidose treatment regimen should be considered for HIV-infected women.[3]

Some strains of *T. vaginalis* have reduced susceptibility to nitroimidazoles[1-3] and patients who fail to respond to the first course of treatment may be re-treated with a repeat course of the initial regimen[1] or an alternative standard treatment.[2,3] If this fails and re-infection has been excluded patients may be given:

- a broad-spectrum antibacterial (such as erythromycin or amoxicillin) before re-treatment with metronidazole[1]
- oral metronidazole 400 mg three times daily with rectal metronidazole 1 g daily for 7 days or longer (zinc sulfate 1% vaginal douches or vaginal washes with 3% acetic acid may be added to the regimen)[1]
- high dose oral metronidazole[1,3] or tinidazole[3] (2 g) daily for 3 to 5 days
- high dose intravenous metronidazole[1]
- high dose oral tinidazole (2 g) twice daily for 2 weeks, with or without intravaginal tinidazole[1]
- a single dose of oral metronidazole plus intravaginal metronidazole applied at night, each for 3 to 7 days[2]

A patient with metronidazole- and tinidazole-resistant infection was successfully treated with paromomycin.[3] Vaginal preparations of metronidazole are only recommended for the treatment of refractory infections.[2] A trichomoniasis vaccine containing inactivated *Lactobacillus* spp. is available in some countries for the prophylaxis of recurrent vaginal trichomoniasis, see p. 2422.2.

Patients with hypersensitivity to nitroimidazoles can be managed by desensitisation with incremental doses of oral or intravenous metronidazole. Alternative topical therapies have been tried, but cure rates are low (less than 50%).[3,6]

African trypanosomiasis

Human African trypanosomiasis (HAT or sleeping sickness)[1] is caused by subspecies of the protozoan *Trypanosoma brucei*, transmitted by the bite of infected tsetse flies (*Glossina* spp.). Infection can follow blood transfusion and congenital trypanosomiasis has also occurred. Infection does not appear to confer immunity.

Infection can be divided into the early, first, or haematolymphatic stage (infection of the bloodstream and lymph nodes), with bouts of fever, lymphadenopathy, pruritus, headache, and muscle and joint pain, and the late, second, or meningoencephalitic stage which starts when the parasite invades the CNS. Signs and symptoms include sleep disturbances, confusion, incoordination, psychiatric disorders, and eventual deterioration of consciousness. Without treatment the patient undergoes progressive neurological degeneration and death.

HAT takes two forms that are clinically distinct, depending on the parasite involved:

- *Trypanosoma brucei gambiense* (Gambian or West African sleeping sickness) occurs in west and central Africa and causes more than 90% of reported cases of HAT. It is a chronic infection and a person may be infected for months or years without major signs or symptoms of the disease; the disease stages are relatively distinct. When symptoms do appear, the patient is often in an advanced disease stage with CNS involvement
- *Trypanosoma brucei rhodesiense* (Rhodesian or East African sleeping sickness) occurs in eastern and southern Africa and causes less than 10% of reported cases of HAT. It is an acute infection with the first signs and symptoms appearing after a few weeks or months; disease stages are indistinct. The disease progresses rapidly and invades the CNS; if left untreated, it will usually lead to death in a matter of weeks or months

Although it has proven impractical to eliminate trypanosomiasis from endemic areas, the intensity of transmission can be reduced by active and passive case detection and treatment.[2] Vector control activities have had some success in controlling *T. b. rhodesiense* disease, but seem to be less effective and less widely applied for the control of *T.b. gambiense*.[3]

The **treatment** of HAT involves the use of 5 drugs depending on the form and stage of the disease:[1-6]

- intramuscular ***pentamidine*** is used for the first stage when caused by *T. b. gambiense*
- intravenous ***suramin*** is used for the first stage when caused by *T. b. rhodesiense* and in areas where pentamidine resistance occurs, suramin may be used for *T. b. gambiense* HAT
- intravenous ***melarsoprol*** is used for the second stage caused by *T. b. rhodesiense* or in second-stage *T. b. gambiense* disease when eflornithine treatment has failed or is unavailable
- intravenous ***eflornithine*** is used for the second stage if caused by *T. b. gambiense*
- oral ***nifurtimox***, used with eflornithine in second-stage disease caused by *T. b. gambiense*, including melarsoprol-refractory disease

The treatment of patients with suramin or pentamidine in the first stage of HAT is relatively easy and safe, but diagnosis is difficult and infection often goes unnoticed since symptoms may be mild or confused with other conditions.[2] Treatment can be curative if started before the CNS has become involved. Most patients, however, are diagnosed after second-stage symptoms have occurred.[2,5] Suramin or pentamidine penetrate the blood-brain barrier poorly and cannot be used to treat second-stage disease, and the other drugs used to treat this stage have limitations.

Intravenous injections with melarsoprol are painful and are associated with severe adverse effects; about 5 to 10% of patients will suffer from reactive encephalopathy during treatment, with an average case-fatality rate of 50%.[2,3,7] Some degree of protection against this toxicity may be provided by prophylaxis with prednisolone.[8,9] High rates of melarsoprol treatment failure (up to 50%) have been reported in several regions, including the Sudan, Uganda, the Democratic Republic of Congo, and Angola.[2]

Eflornithine is also effective and is safer than melarsoprol in the treatment of second-stage *T. b. gambiense* HAT,[10-12] but is not generally used for *T. b. rhodesiense* HAT[3] because of reduced susceptibility of the parasite.[2] Eflornithine is difficult to use as it needs to be given by slow intravenous infusion every 6 hours for 14 days, and requires close patient monitoring. If relapse occurs after treatment with eflornithine, use of melarsoprol should be considered.[4]

There is concern that long-term use of eflornithine monotherapy may result in the development of resistance, and it is less effective in areas with a high prevalence of HIV infection.[10] Oral nifurtimox has been used for treatment of late stage *T.b. gambiense* HAT,[13,14] but is considered not effective enough to be used as monotherapy.[2] However, promising results have been obtained from a randomised controlled study[15] for the treatment of second stage *T.b. gambiense* infection with oral nifurtimox for 10 days plus intravenous eflornithine (given 12-hourly for 7 days). Combination therapy (NECT) required fewer eflornithine doses and the duration of treatment was reduced. Furthermore, resistance was also less likely to develop as the drugs have different modes of action.[2] Given the high incidence of adverse effects with melarsoprol, NECT was considered a candidate to replace it, although the combination still requires access to appropriate healthcare facilities.[7]

Patients should be seen every 6 months for a follow-up period of at least 2 years, to ascertain if treatment has been successful.

Various potential antitrypanosomal drugs are under investigation, including diamidine derivatives[16] and the nitroimidazole fexinidazole.[17]

American trypanosomiasis

American trypanosomiasis (Chagas' disease)[1-7] is a zoonosis caused by *Trypanosoma cruzi*, carried by Central or South American reduviid or triatomine bugs. Infected bugs defecate on the human host while feeding on blood and metacyclic trypanosomes that are shed enter the host through broken skin or by direct penetration of mucous membranes such as the conjunctiva. Infection may also occur through blood transfusion or less commonly transplanted organs; vertical transmission from infected mother to fetus can also occur. In endemic areas infection is usually acquired in childhood. Control measures include case detection and treatment, vector control by insecticide

applications within domestic buildings, and screening of blood donors.

In the early *acute phase* of infection parasites are present in the blood; clinical symptoms may or may not be apparent and most people recover spontaneously within 4 to 8 weeks. Symptomatic infection in the acute phase is characterised by fever, malaise, rash, lymphadenopathy, and hepatosplenomegaly. A swelling or chagoma may occur at the site of infection, which is often on the face; if this site is the conjunctiva a unilateral periorbital oedema occurs (Romañas sign). More rarely acute heart failure or meningoencephalitis occur and may be fatal in children. After a few months an asymptomatic latent or *indeterminate phase* develops and parasitaemia falls to low or undetectable levels. In 10 to 20 years about 15 to 30% of chronically infected persons develop *chronic* Chagas' disease (also called the chronic symptomatic phase) which is characterised by irreversible alterations of heart muscle (Chagasic cardiomyopathy) and gastrointestinal disease (mainly enlargement of the oesophagus or the rectosigmoid colon). In immunocompromised patients (including those with HIV infection) symptomatic reactivation of chronic, latent *T. cruzi* may occur.

Available treatment is generally unsatisfactory but, despite their toxicity, oral nifurtimox or oral benznidazole are of value especially in the acute phase; it is not certain whether trypanocidal treatment during the indeterminate phase can prevent the development of chronic disease although favourable results were obtained in a small study in children given benznidazole.[8] A systematic review[9] found that when given either nifurtimox or benznidazole, parasitological cure occurred in about 60 to 85% of patients in the acute phase and in more than 90% of congenitally infected infants treated in their first year of life. Although it is generally felt that there is no benefit from treatment in the chronic phase, treatment during the early chronic phase was reported to be beneficial,[10] and long-term follow-up of patients who had received benznidazole showed a reduction in cardiac complications and parasitaemia.[11]

Following a systematic review[9] it has been suggested that indications for treatment with benznidazole or nifurtimox include all cases of acute and congenital infection, reactivated infection, and all children 18 years of age or less with chronic infection; antitrypanocidal treatment should also generally be offered to adults aged 19 to 50 without advanced Chagasic cardiomyopathy, and may be considered in older adults although the risks of drug therapy are greater in the last group. It is not recommended for advanced Chagasic cardiomyopathy, since the existing pathology will not benefit, but the potential to reduce development of cardiomyopathy should be considered in patients with gastrointestinal involvement. In laboratory workers at risk of an infection after an accident, treatment with benznidazole for 10 days should be started immediately.[1]

Guidelines for the treatment of opportunistic infection in HIV-infected patients in the USA[12] suggest treatment with benznidazole or nifurtimox to reduce parasitaemia and prevent clinical symptoms in those with acute, early chronic, and reactivated disease. Re-treatment with either one of these drugs is recommended for HIV-infected patients who do not respond or who relapse after their initial therapy. Disease reactivation is also a problem in patients undergoing organ transplantation and the risk depends mainly on the degree of immunosuppression. Many experts advise close post-transplantation laboratory and clinical monitoring and treatment if reactivation is shown.[9,13] Some experts suggest treatment should be given to patients in whom future immunosuppression is anticipated, such as previously untreated *T. cruzi*-infected patients awaiting organ transplantation, or HIV-infected patients.[9]

The efficacy of treatment varies from country to country and may be linked to variations in the sensitivity of different strains of *T. cruzi*. Treatment is said to be successful when both parasitaemia and serological tests become negative and remain so for at least one year after the end of treatment.

Allopurinol, allopurinol riboside, and itraconazole have been tried for the treatment of American trypanosomiasis since they have shown trypanocidal activity in laboratory and *animal* studies; a prodrug of ravuconazole, E-1224, is also being studied. Initial clinical studies reported that oral allopurinol (600 or 900 mg daily for 60 days) was as effective as nifurtimox or benznidazole in reducing parasitaemia during the indeterminate phase and was better tolerated.[14] However, a later randomised, placebo-controlled study[15] in a small number of patients with chronic Chagas' disease reported that oral allopurinol was no more effective in clearing infection than placebo. A placebo-controlled study[16] in 404 patients with chronic Chagas' disease treated with either oral itraconazole (6 mg/kg daily for 120 days), oral allopurinol (8.5 mg/kg daily for 60 days), or placebo reported parasitologic cure in 44% and ECG normalisation in 36.5% of patients treated with allopurinol; for those given itraconazole a parasitologic cure of 53% and ECG normalisation of 48.2% was reported. A follow-up study[17] of the cardiac benefits in patients with chronic Chagas' disease 9 years after treatment with either oral itraconazole or oral allopurinol found that itraconazole and allopurinol were equally effective at reversing ECG changes but itraconazole appeared more protective against developing new ECG abnormalities in patients with a normal ECG at baseline. A further evaluation 11 years after treatment concluded that itraconazole was no less effective at preventing cardiomyopathy than allopurinol but had fewer adverse effects.[18] Posaconazole has also been tried.[19]

Acetarsol *(BAN, rINN)*

Acetaminohydroxyphenylarsonsäure; Acétarsol; Acetarsolum; Acetarsona; Acetarsone; Acetphenarsinum; Asetarsoli; Osarsolum; Ацетарсол.

3-Acetamido-4-hydroxyphenylarsonic acid.

$C_8H_{10}AsNO_5$=275.1

CAS — 97-44-9.

ATC — A07AX02; G01AB01; P01CD02.

ATC Vet — QA07AX02; QG01AB01; QP51AD05.

UNII — 806529YU1N.

Profile

Acetarsol, a pentavalent organic arsenical derivative, has been given orally in the treatment of intestinal amoebiasis and vaginally in the treatment of trichomoniasis, but the use of pentavalent arsenical compounds has generally been abandoned in favour of more effective and less toxic drugs. For the adverse effects of arsenic and their treatment, see Arsenic Trioxide, p. 2448.3.

Acetarsol suppositories were once tried in the treatment of proctitis. Acetarsol lithium and acetarsol sodium have been included in some preparations for minor mouth infections.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Rus.*: Osarbon (Осарбон); Osarcid (Осарцид).

Aminitrozole *(BAN, rINN)*

Acinitrazole; Aminitrozol; Aminitrozolum; CL-5279; Nithiamide (USAN); Nithiamide; Аминитрозол.

N-(5-Nitrothiazol-2-yl)acetamide.

$C_5H_5N_3O_3S$=187.2

CAS — 140-40-9.

UNII — 9CBM60191Z.

Profile

Aminitrozole is an antiprotozoal that is used topically, often with sulfanilamide (p. 368.1), in the treatment of susceptible skin and soft tissue infections.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Ukr.*: Nitacid (Нитацид); Streptonitol (Стрептонитол).

Amprolium Hydrochloride *(BANM, rINNM)*

Amprolii Hydrochloridum; Amprolio, hidrocloruro de; Amprolium, Chlorhydrate d'; Hidrocloruro de amprolio; Амполия Гидрохлорид.

1-(4-Amino-2-propylpyrimidin-5-ylmethyl)-2-methylpyridinium chloride hydrochloride.

$C_{14}H_{19}ClN_4HCl$=315.2

CAS — 121-25-5 (amprolium); 137-88-2 (amprolium hydrochloride).

Pharmacopoeias. In *Fr.* and *US* for veterinary use only. Also in *BP(Vet)*.

BP(Vet) 2014: (Amprolium Hydrochloride). A white or almost white, odourless or almost odourless powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in chloroform; very slightly soluble in ether.

USP 36: (Amprolium). A white to light yellow powder. Freely soluble in water, in alcohol, in dimethylformamide and in methyl alcohol; sparingly soluble in dehydrated alcohol; practically insoluble in acetone, in butyl alcohol, and in isopropyl alcohol.

Profile

Amprolium hydrochloride is an antiprotozoal used in veterinary practice, for the treatment and control of coccidiosis caused by *Eimeria* spp. It is a structural analogue of thiamine and prolonged high doses may cause thiamine deficiency. Neurological symptoms reported after overdose in *dogs* were treatable with intravenous or intramuscular thiamine.

Pentavalent Antimony Compounds

Antimonio pentavalente, compuestos de; Пятивалентные Сурьмы Соединений.

Meglumine Antimonate

CAS — 16037-91-5.

ATC — P01CB02.

ATC Vet — QP51AB02.

UNII — V08350159D.

Description. A pentavalent antimony compound of indefinite composition. It has been represented by the formula $C_6H_9Na_2O_9Sb$ but usually there are less than 2 atoms of Na for each atom of Sb. Solutions may be sterilised by autoclaving.

Pharmacopoeias. In *Br., Chin., Int.,* and *It.*

BP 2014: (Sodium Stibogluconate). It is mainly the disodium salt of μ-oxy-bis[gluconato(3-)O^2,O^3,O^4-hydroxoantimony]. It contains not less than 30.0% and not more than 34.0% of antimony(V), calculated with reference to the dried and methanol-free substance. It is a colourless, odourless or almost odourless, mostly amorphous powder. Very soluble in water; practically insoluble in alcohol and in ether. A solution in water containing 10% of pentavalent antimony has a pH of 5.0 to 5.6 after autoclaving.

Uses and Administration

Pentavalent antimony, as sodium stibogluconate or meglumine antimonate, is used as first-line treatment for most forms of leishmaniasis (see below). Cutaneous and diffuse cutaneous leishmaniasis caused by *Leishmania aethiopica* infections do not respond to standard treatment with pentavalent antimony compounds, but may respond slowly if higher doses are used.

For systemic use, meglumine antimonate or sodium stibogluconate may be given by deep intramuscular injection or by intravenous injection. Intravenous injections must be given very slowly (over at least 5 minutes) and preferably through a fine needle to avoid thrombophlebitis; as with trivalent antimony compounds, they should be stopped immediately if coughing, vomiting, or substernal pain occurs. Both products may be injected intralesionally. Meglumine antimonate and sodium stibogluconate are given as solutions containing the equivalent of pentavalent antimony 85 mg/mL and 100 mg/mL respectively. Doses are expressed in terms of the equivalent amount of pentavalent antimony.

Local variations exist in treatment schedules but WHO recommends the following regimens:

- In **visceral leishmaniasis**, initial treatment is based on daily intramuscular injection of pentavalent antimony 20 mg/kg (but see below) usually given for 28 days. The length of treatment varies from one endemic area to another, but is continued until no parasites are detected in consecutive splenic aspirates taken at 14-day intervals. Patients who relapse are re-treated at the same dose.
- Early non-inflamed lesions of **cutaneous leishmaniasis** due to all forms of *Leishmania* except *L. aethiopica*, *L. amazonensis*, and *L. braziliensis* may be treated by infiltration with intralesional injections of 1 to 3 mL of sodium stibogluconate or meglumine antimonate (about 100 to 300 mg of pentavalent antimony), repeated once or twice if necessary at intervals of 1 to 2 days. Systemic therapy with intramuscular pentavalent antimony 10 to 20 mg/kg daily is given if the lesions are more severe and continued until a few days after clinical and parasitological cure is achieved. In cutaneous leishmaniasis due to *L. braziliensis*, prolonged systemic treatment with intramuscular pentavalent antimony 20 mg/kg daily for a minimum of 4 weeks is indicated. Similar doses are required for **diffuse cutaneous leishmaniasis** due to *L. amazonensis* and are continued for several months after clinical improvement occurs. Relapses should be expected until immunity develops.
- In **mucocutaneous leishmaniasis**, daily doses of intramuscular pentavalent antimony 20 mg/kg are given for a minimum of 4 weeks; if the response is poor, 10 to 15 mg/kg may be given every 12 hours for the same period. Relapses are well known and have generally been associated with inadequate or interrupted treatment; they are treated with the same drug given for at least twice as long as the original treatment. Only when that fails should alternative treatment be given.

Administration in children. Doses of pentavalent antimony products, such as meglumine antimonate and sodium stibogluconate, for the treatment of leishmaniasis in children are usually the same as those for adults, see Uses and Administration, above. However, for those children with visceral leishmaniasis and weighing less than 10 kg the minimum daily dose is 200 mg.

Leishmaniasis. The main treatment for leishmaniasis (p. 922.1) is a pentavalent antimony compound such as meglumine antimonate or sodium stibogluconate. A maximum daily dose of 850 mg was initially recommended by WHO and is still recommended in the UK licensed product information. However, higher doses of antimony compounds have been tried in order to overcome the unresponsiveness of leishmaniasis to therapy. In the USA, the use of 20 mg/kg daily of pentavalent antimony has been recommended, without restriction to an 850-mg maximum daily dose;[1] this is now also the dose currently suggested by WHO. At 20 mg/kg daily the most common adverse effects are musculoskeletal disorders, elevated liver enzyme values, and T-wave changes on the ECG, and the CDC recommends that the ECG, blood chemistry, and blood count should be monitored throughout therapy if resources permit.[1] Severe cardiotoxicity is rare at this dose but fatal cardiotoxicity has been reported with doses of up to 60 mg/kg daily (see under Effects on the Heart, below). Drug-resistant strains of *Leishmania infantum* have been associated with unresponsiveness to treatment with meglumine antimonate.[2] It was suggested[3] that the use of suboptimal doses may be increasing the prevalence of drug-resistant strains of the parasite. However, low doses of antimony compounds (5 mg/kg daily for 30 days) have produced long-term cure in patients with cutaneous *L. braziliensis* infection followed for up to 10 years.[4]

INTRALESIONAL ADMINISTRATION. Intralesional infiltration of 3 doses of sodium stibogluconate on alternate days or once weekly was more effective than daily treatment in a study of 96 patients with cutaneous leishmaniasis in Saudi Arabia.[5] Others have reported on the use of intralesional stibogluconate in cases from Israel[6] and twice-weekly intralesional sodium stibogluconate has been suggested for the treatment of cutaneous leishmaniasis caused by *L. tropica* in India.[7] Local infiltration of meglumine antimonate in usual doses of 150 to 900 mg (maximum 1.5 g) once each week for up to 6 weeks produced microbiological and clinical cures in all of 45 patients in Italy with cutaneous leishmaniasis.[8]

Adverse Effects, Treatment, and Precautions

As for Trivalent Antimony Compounds, p. 151.3.

Adverse effects are generally less frequent and less severe with the pentavalent antimony compounds sodium stibogluconate and meglumine antimonate than with trivalent compounds such as antimony sodium tartrate. Nevertheless, similar precautions should be observed, especially in patients on high-dose therapy.

Intramuscular injections of sodium stibogluconate can be painful and intravenous use has been associated with thrombophlebitis. Elevations in serum lipase and amylase usually occur during treatment and symptomatic pancreatitis has been reported in some patients. Successful treatment of mucocutaneous leishmaniasis may cause severe inflammation around the lesion and involvement of the pharynx or trachea may be life-threatening.

Common adverse effects of pentavalent antimony are anorexia, vomiting, nausea, malaise, arthralgia and myalgia, headache, lethargy, and abdominal pain. ECG changes are dose-dependent and most commonly include T-wave flattening and inversion and prolonged *QT* interval. Renal damage is a rarely reported toxic effect. Serious adverse effects have involved the liver, musculoskeletal system, pancreas, or the heart;[1,2] when they occur it is prudent to interrupt the course temporarily.[1] Pentavalent antimony is usually well tolerated,[1] although a study[2] of 96 patients treated with sodium stibogluconate for leishmaniasis reported significant, but generally reversible, adverse effects; treatment was interrupted in 28% of the patients.

2. Aronson NE, *et al.* Safety and efficacy of intravenous sodium stibogluconate in the treatment of leishmaniasis: recent US military experience. *Clin Infect Dis* 1998; **27**: 1457–64.

Breast feeding. The amount of antimony distributed into the breast milk of a patient given sodium stibogluconate was considered not to constitute a hazard and oral absorption was not detected in an *animal* study.[1] The last available guidance from the American Academy of Pediatrics also considered that the use of antimony is usually compatible with breast feeding.[2] Others, however, have felt that more safety evaluation was required before antimony could be considered completely safe during breast feeding.[3]

3. Verschoyle RD. Comment. *Trop Dis Bull* 1990; **87**: 919.

Effects on the blood. Although thrombocytopenia is associated with leishmaniasis, there are also case reports associating it with sodium stibogluconate.[1,2] Eosinophilia and lymphocytosis were common in a small study in Brazilian patients given intravenous or intralesional meglumine antimonate for cutaneous leishmaniasis.[3]

3. Neves DB, *et al.* Antimony in plasma and skin of patients with cutaneous leishmaniasis—relationship with side effects after treatment with meglumine antimoniate. *Trop Med Int Health* 2009; **14**: 1515–22.

Effects on the heart. The ECG was monitored during 65 courses of treatment with sodium stibogluconate in 59 Kenyan patients with leishmaniasis.[1] ECG abnormalities developed during 35 treatment courses. They were qualitatively similar to those previously described during treatment with trivalent antimonial drugs, but occurred less frequently and later during the course of treatment. The most common abnormality was inversion and/or decreased amplitude of T waves. Incidence was related to total daily dose and duration of treatment. One patient died suddenly during the 4th week of treatment with antimony 60 mg/kg daily. Other deaths probably related to cardiotoxicity have been reported in patients receiving 60 mg/kg daily[2] and 30 mg/kg daily.[3] It has been recommended[1] that for treatment with sodium stibogluconate ECGs should be obtained every 3 to 4 days in patients given antimony 20 mg/kg daily for more than 20 days or a higher dose for more than 10 days. If Stokes-Adams attacks or ventricular tachyarrhythmias develop, sodium stibogluconate should be stopped and appropriate treatment given. A retrospective study[4] in patients treated with sodium stibogluconate for mostly cutaneous leishmaniasis found that the mean QT_c interval steadily increased throughout the period of treatment, reaching a potentially toxic threshold by the third week, but cardiotoxicity was seen only in one elderly patient who had hypokalaemia and pre-existing cardiovascular morbidity. Identification before treatment of factors that may increase cardiovascular risk is important. For further information on the cumulative cardiotoxicity of sodium stibogluconate and amphotericin B see Antifungals, under Interactions, p. 928.1.

4. Lawn SD, *et al.* Electrocardiographic and biochemical adverse effects of sodium stibogluconate during treatment of cutaneous and mucosal leishmaniasis among returned travellers. *Trans R Soc Trop Med Hyg* 2006; **100**: 264–9.

Effects on the kidneys. Sodium stibogluconate given for 10 days to 16 young men with cutaneous leishmaniasis had no apparent adverse effect on glomerular or tubular renal function.[1] However, evidence of renal tubular dysfunction has been reported in patients with mucocutaneous leishmaniasis given meglumine antimonate or sodium stibogluconate for 30 days or more[2] and acute renal failure has occurred in patients both with,[3] and without,[4] pre-existing renal impairment, the latter resulting in death.

4. Rodrigues MLO, *et al.* Nephrotoxicity attributed to meglumine antimoniate (Glucantime) in the treatment of generalized cutaneous leishmaniasis. *Rev Inst Med Trop Sao Paulo* 1999; **41**: 33–7.

Effects on the liver. WHO has reported that when serious adverse effects occur with sodium stibogluconate they often involve the liver or the heart.[1] There have been reports of disturbed liver function[2,3] in patients given sodium stibogluconate, although there has also been a report[4] that signs of altered liver function, which may be a feature of visceral leishmaniasis, improved during treatment with sodium stibogluconate.

1. WHO. Control of the leishmaniases. *WHO Tech Rep Ser 793* 1990. Available at: http://libdoc.who.int/trs/WHO_TRS_793.pdf (accessed 17/07/08)

4. Misbahuddin M, *et al.* Stibogluconate for leishmaniasis. *Lancet* 1993; **342**: 804.

Effects on the musculoskeletal system. Arthralgia is common with pentavalent antimony compounds. It is usually dose-dependent[1] but a patient has been described who had symptoms early in treatment.[2] Palindromic arthropathy with effusion was associated with sodium stibogluconate treatment in another patient.[3]

1. Ballou WR, *et al.* Safety and efficacy of high-dose sodium stibogluconate therapy of American cutaneous leishmaniasis. *Lancet* 1987; **ii**: 13–16.
2. Castro C, *et al.* Severe arthralgia, not related to dose, associated with pentavalent antimonial therapy for mucosal leishmaniasis. *Trans R Soc Trop Med Hyg* 1990; **84**: 362.

3. Donovan KL, *et al.* Pancreatitis and palindromic arthropathy with effusions associated with sodium stibogluconate treatment in a renal transplant recipient. *J Infect* 1990; 21: 107–10.

Effects on the nervous system. Peripheral neuropathy developed in a patient about 8 days after starting therapy with sodium stibogluconate.[1] The symptoms were generally reversible when treatment was stopped (after 17 days), although there was some slight persistent hypoaesthesia in the toes. An interaction with a single dose of amitriptyline, taken on the second day of stibogluconate therapy, seemed unlikely but could not be ruled out. Two cases of cerebellar ataxia have been reported during treatment with sodium stibogluconate for visceral leishmaniasis; toxicity might have been partly due to the neurological manifestations of the disease.[2]

Interactions

Antifungals. Cardiotoxicity, including some fatalities, has been reported in about 8 to 17% of patients treated with the standard dose of sodium stibogluconate for visceral leishmaniasis, and patients may remain at risk for cardiotoxicity for about 2 months after stopping treatment due to its slow terminal elimination phase. In contrast, cardiotoxicity is uncommon with *amphotericin B*, although it may occur in patients with pre-existing cardiopulmonary disease or electrolyte abnormalities. Cumulative cardiotoxicity, resulting in sudden clinical deterioration and death, has been reported in 3 previously stable young children given intravenous amphotericin B up to 15 days after stopping treatment with sodium stibogluconate for the treatment of visceral leishmaniasis.[1] One child had a documented ventricular tachycardia on day 2 of amphotericin B treatment, while the other children had signs and symptoms suggestive of a fatal arrhythmia on days 4 and 6 of treatment with amphotericin B. It was suggested that sodium stibogluconate increased the susceptibility of the myocardium to damage by amphotericin B. A rest period of about 14 days (or longer if ECG changes persist) and correction of electrolyte abnormalities was advised when switching treatment from sodium stibogluconate to amphotericin B.[1]

1. Maheshwari A, *et al.* Cumulative cardiac toxicity of sodium stibogluconate and amphotericin B in treatment of kala-azar. *Pediatr Infect Dis J* 2011; 30: 180–1.

Pharmacokinetics

The pentavalent antimony compounds are poorly absorbed from the gastrointestinal tract but are rapidly absorbed and distributed by the intravenous and the intramuscular routes, which have similar pharmacokinetics. Elimination occurs in two phases; a rapid initial phase, in which the majority of a dose is excreted via the kidneys within 12 hours, and a slower phase, possibly reflecting reduction to trivalent antimony. The elimination half-life of the initial phase is about 2 hours and that of the slow terminal phase is about 33 to 76 hours. Accumulation occurs on daily use and maximum tissue concentrations may not be reached for 7 days or more. Antimony has been detected in breast milk (see Breast Feeding, p. 927.2).

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Braz.*: Glucantime; *Fr.*: Glucantime; *Gr.*: Glucantime; *Israel*: Pentostam; *Spain*: Glucantime; *UK*: Pentostam; *Venez.*: Glucantime.

Pharmacopoeial Preparations
BP 2014: Sodium Stibogluconate Injection.

Atovaquone *(BAN, USAN, rINN)*

566C; 566C80; Atovacuona; Atovakon; Atovakvon; Atovakvoni; Atovaquonum; BW-566C; BW-566C80; BW-A566C; Atobaxon.

2-[*trans*-4-(4-Chlorophenyl)cyclohexyl]-3-hydroxy-1,4-naphthoquinone.

$C_{22}H_{19}O_3Cl$=366.8.

CAS — 95233-18-4.

ATC — P01AX06.

UNII — Y883P1Z2LT.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Atovaquone). A yellow, crystalline powder. Practically insoluble in water; sparingly soluble in dichloromethane; very slightly soluble in methyl alcohol. It shows polymorphism.

USP 36: (Atovaquone). A yellow powder. Insoluble in water; slightly soluble in alcohol, in butanediol, in ethyl acetate, in glycerol, in octanol, and in macrogol 200; sparingly soluble in acetone, in di-*n*butyl adipate, in dimethyl sulfoxide, and in macrogol 400; soluble in chloroform; freely soluble in *N*-methylpyrrolidone and in tetrahydrofuran; very slightly soluble in 0.1N sodium hydroxide. Store in airtight containers. Protect from light.

Uses and Administration

Atovaquone is a hydroxynaphthoquinone antiprotozoal that is also active against the fungus *Pneumocystis jirovecii*. It is used in the treatment and prophylaxis of pneumocystis pneumonia in patients unable to tolerate co-trimoxazole, and with proguanil in the treatment and prophylaxis of malaria. As well as these established uses atovaquone is also used in other protozoal infections including babesiosis and toxoplasmosis. For further information see below.

In the treatment of mild to moderate **pneumocystis pneumonia**, atovaquone is given orally in a dose of 750 mg with food twice daily as a suspension, for 21 days. For prophylaxis 1500 mg of the suspension is given once daily with food.

For the *prophylaxis* of falciparum **malaria** in adults over 40 kg oral atovaquone 250 mg with oral proguanil hydrochloride 100 mg is given once daily. The course should start 1 to 2 days before travel to the malarious area, continue daily throughout exposure, and for 7 days after leaving the area.

In the *treatment* of uncomplicated falciparum malaria in adults over 40 kg oral atovaquone 1 g with oral proguanil hydrochloride 400 mg is given as a single daily dose for 3 days.

For details of doses in children, see below.

Atovaquone with proguanil is one of the antimalarial drug combinations recommended by some experts to be carried as a *standby* for the emergency treatment of malaria. The dose recommended for self-treatment is the same as that for treatment of uncomplicated falciparum malaria.

Administration in children. Children may be given atovaquone with proguanil for the *prophylaxis* of falciparum **malaria** in the following licensed oral doses, based on the adult dose of 250 mg of atovaquone daily:

- children weighing 11 to 20 kg: one-quarter the adult dose
- 21 to 30 kg: half the adult dose
- 31 to 40 kg: three-quarters the adult dose
- over 40 kg: the adult dose The course should start 1 to 2 days before travel to the malarious area, continue daily throughout exposure, and for 7 days after leaving the area.

Licensed oral doses of atovaquone with proguanil for the *treatment* of uncomplicated falciparum malaria, based on the adult dose of 1 g of atovaquone daily for 3 days, are:

- children weighing 5 to 8 kg: one-eighth the adult dose
- 9 to 10 kg: three-sixteenths the adult dose
- 11 to 20 kg: one-quarter the adult dose
- 21 to 30 kg: half the adult dose
- 31 to 40 kg: three-quarters the adult dose
- over 40 kg: the adult dose

For doses in children with **babesiosis** or for prophylaxis of **pneumocystis pneumonia** see below.

Babesiosis. Atovaquone 750 mg twice daily with azithromycin 500 to 1000 mg on day 1 followed by 250 mg once daily thereafter, both orally for 7 to 10 days, has been recommended by some experts[1] in the USA for the treatment of babesiosis infections; higher doses of azithromycin should be used in immunocompromised patients (see Babesiosis, under Uses and Administration of Azithromycin, p. 221.3). Children may be given atovaquone 20 mg/kg (maximum 750 mg) twice daily with azithromycin 10 mg/kg (maximum 500 mg) on day 1 followed by 5 mg/kg (maximum 250 mg) once daily thereafter, both orally for 7 to 10 days.[1,2] In a prospective, randomised study[3] involving 58 patients with babesiosis (p. 920.2), atovaquone with azithromycin was found to be as effective as, and associated with fewer adverse effects than, standard therapy with quinine and clindamycin. Atovaquone with azithromycin, both given for 10 days, was also effective in the treatment of an 8-month-old child with transfusion-associated babesiosis.[4] However, the emergence of resistance to the combination has been reported in immunocompromised patients.[5]

Malaria. Atovaquone with proguanil (*Malarone*) is used in the treatment and prophylaxis of uncomplicated malaria caused by *Plasmodium falciparum* (see p. 644.1).

Atovaquone, a blood schizontocide, is associated with an unacceptably high rate of recrudescence when used alone[1] for *treatment* but is more successful in malaria when used with proguanil,[2,3] including that produced by multidrug-resistant strains.[4] Use of the combination to treat *P. ovale* and *P. malariae* malarias has also been studied.[5] Atovaquone with proguanil followed by primaquine may also be effective for the treatment of *P. vivax* malaria.[6] Some authorities recommend this combination as an alternative treatment option in patients not responsing to chloroquine monotherapy[7] or for those with chloroquine-resistant infections.[7,8]

Pneumocystis pneumonia. Atovaquone is one alternative to co-trimoxazole for the treatment of pneumocystis pneumonia (p. 567.2). In open studies, a clinical response to atovaquone was reported in 78% of patients with mild to moderate disease and in 56% of patients with severe disease who were intolerant of, or who failed to respond to, both co-trimoxazole and pentamidine.[1] Comparative studies have shown atovaquone to be less effective than co-trimoxazole[2] and probably less effective than pentamidine,[3,4] but to produce fewer treatment-limiting adverse effects than either.

Atovaquone is also an alternative to co-trimoxazole for both primary or secondary *prophylaxis*, and was as effective as dapsone[5] or inhaled pentamidine[6] in studies in patients intolerant of co-trimoxazole. Atovaquone 30 mg/kg daily plus azithromycin 5 mg/kg daily was found to be possibly as

effective as co-trimoxazole in prophylaxis of pneumocystis pneumonia in HIV-infected children.[7]

Toxoplasmosis. Atovaquone, either alone or with pyrimethamine or sulfadiazine, has produced encouraging results for treatment[1-4] or long-term suppression[4-6] of toxoplasmosis (p. 924.2) in patients with AIDS. US guidelines for prevention and treatment of opportunistic infections in HIV-infected adults and adolescents[4] suggest atovaquone with either pyrimethamine or sulfadiazine may be considered as an alternate regimen for treatment of toxoplasmosis; atovaquone may be given alone in patients unable to tolerate pyrimethamine and sulfadiazine. Atovaquone with or without pyrimethamine can be considered as an alternate regimen for primary prophylaxis, while atovaquone, with or without either pyrimethamine or sulfadiazine, may be considered as an alternate regimen for secondary prophylaxis of toxoplasmosis.[4] However, failure of atovaquone prophylaxis following haematopoietic stem-cell transplantation has been reported.[7] It has also been tried for the treatment of toxoplasmic retinochoroiditis in immunocompetent patients.[8]

For details of doses used with pyrimethamine for the prevention of toxoplasmosis, see under Pyrimethamine, p. 663.1.

Adverse Effects and Precautions

The most common adverse effects associated with the use of atovaquone plus proguanil are headache, coughing, and gastrointestinal effects such as nausea, diarrhoea, and vomiting. Other commonly occurring adverse effects include anorexia, depression, dizziness, fever, insomnia, rashes, raised liver enzyme values, hyponatraemia, and haematological disturbances such as anaemia and neutropenia. Rare cases of allergic reactions (such as angioedema, anaphylaxis, urticaria, and vasculitis), cholestasis, and hepatitis have been reported. Hepatic failure requiring liver transplantation has also been reported. Similar adverse effects have been reported in patients taking atovaquone without proguanil for prevention and treatment of pneumocystis pneumonia. Atovaquone should be avoided in patients with gastrointestinal disorders that may limit absorption of the drug. In patients with severe renal impairment, atovaquone plus proguanil is contra-indicated for the prophylaxis of malaria; it should be used with caution in the treatment of malaria.

Effects on the skin. Stevens-Johnson syndrome has been reported[1] in a patient after a few days of taking atovaquone with proguanil for malaria prophylaxis. A case[2] of bullous erythema multiforme has also been reported in a patient given atovaquone with proguanil for malaria treatment; pruritus occurred after the first and second doses and bullae developed after the third dose.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies atovaquone as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 08/07/11)

Interactions

Use of atovaquone with either metoclopramide, tetracycline, rifampicin, or rifabutin results in decreases in plasma-atovaquone concentrations. Reduced concentrations of atovaquone with proguanil have been reported in HIV-positive patients also taking efavirenz or ritonavir-boosted atazanavir or lopinavir. Other drugs which have produced small reductions in plasma-atovaquone concentrations include aciclovir, antidiarrhoeals, benzodiazepines, cephalosporins, laxatives, opioids, and paracetamol.

Atovaquone is reported to decrease the metabolism of zidovudine resulting in moderate increases in zidovudine plasma concentrations. A decrease in trough concentrations of indinavir, and in the area under the indinavir time-concentration curve has been reported when atovaquone was also given. Small decreases in the plasma concentrations of co-trimoxazole (not considered to be clinically significant) have been noted in patients taking atovaquone. There is a theoretical possibility that atovaquone could displace other highly protein-bound drugs from plasma-protein binding sites.

Anticoagulants. For reference to a case of atovaquone increasing the effect of *warfarin*, see Antiprotozoals, p. 1532.3.

Pharmacokinetics

Atovaquone is a highly lipophilic compound with a low aqueous solubility. Oral bioavailability of atovaquone shows considerable interindividual variation. Bioavailability from commercial oral liquid formulations is better than from tablets and can be further improved if taken with food, particularly meals with a high fat content. The absolute bioavailability of the tablet and liquid formulations is 23% and 47% respectively, when taken with food. Atovaquone is more than 99% bound to plasma proteins. There is indirect evidence that atovaquone may undergo limited metabolism, however, no specific metabolites have been identified. It has a long plasma half-life of 2 to 3 days in adults and 1 to 2 days in children, thought to be due to enterohepatic recycling. It is excreted almost exclusively in faeces as unchanged drug.

Pharmacopoeias. In *Int.* –

Uses and Administration

Benznidazole is a 2-nitroimidazole derivative with antiprotozoal activity. It is of value in the treatment of American trypanosomiasis (Chagas' disease—see below), especially during the early acute stage of the disease.

In the *acute* stage of the disease, uncomplicated cases in patients weighing up to 40 kg may be given benznidazole orally in a dose of 7.5 mg/kg daily while those weighing more than 40 kg should be given 5 mg/kg daily. Patients with acute meningoencephalitis should be given a dose of up to 25 mg/kg daily. Benznidazole should be given orally in equally divided doses every 8 or 12 hours and is usually given for 60 days (but see also American Trypanosomiasis, below).

Trypanosoma cruzi infected organ transplant donors should be treated for 2 weeks before the donation and recipients for 2 weeks after it. In laboratory workers at risk of an infection after an accident, treatment with benznidazole (7 to 10 mg/kg daily) for 10 days should be started immediately.

Treatment of patients in the *chronic* phase of the disease with oral benznidazole (5 mg/kg daily in equally divided doses every 8 or 12 hours) may be considered in areas where transmission by the vector has been interrupted and the 60-day treatment course can be completed under medical supervision.

For details of doses in children, see below.

Administration in children. For the treatment of the acute phase of American trypanosomiasis (Chagas' disease) in children, benznidazole may be given orally at a dose of 5 to 10 mg/kg daily in two equally divided doses for 60 days. In congenital cases, full-term neonates are given 10 mg/kg daily; treatment is started at a dose of 5 mg/kg daily and may be increased to 10 mg/kg daily after 3 days of treatment if the patient does not develop leucopenia or thrombocytopenia.

American trypanosomiasis. Available treatment for American trypanosomiasis (p. 925.3) is generally unsatisfactory, but benznidazole is of value especially in the acute phase. Guidelines[1,2] recommend that benznidazole should be given for 60 days. Although the duration of treatment has not been studied in patients co-infected with HIV, a treatment course of 30 to 60 days is recommended in these patients.[3] Treatment is usually confined to the acute phase of the disease. However, therapy during the early chronic phase was reported to be beneficial[4] (although a meta-analysis[5] suggested that benefit in late chronic phase was probably marginal); prospective long-term follow-up in patients with indeterminate- or chronic-stage disease who had received benznidazole has

shown that treatment may reduce the risk for progression of heart disease and reduce parasitaemia.[6]

Adverse Effects

Benznidazole has adverse effects similar to those of metronidazole (p. 937.3).

The most commonly reported adverse effect is a hypersensitivity reaction characterised by dermatitis with cutaneous eruptions (usually appearing 5 to 10 days after starting treatment), fever, generalized oedema, lymphadenopathy, and joint and muscle pain. The most severe adverse effects are bone marrow depression, thrombocytopenic purpura, and agranulocytosis. Other reported adverse effects include polyneuropathy, paraesthesia, and peripheral neuropathy.

Like metronidazole, benznidazole is considered to be mutagenic and should be avoided during pregnancy. Patients are also advised not to drink alcoholic beverages while taking benznidazole.

A study[1] involving 20 patients with chronic American trypanosomiasis given benznidazole 5 mg/kg daily had to be stopped because of the high incidence of rashes and neurological symptoms. A severe, debilitating pain syndrome has also been reported in a patient after treatment with benznidazole for 5 weeks.[2]

2. Moll C, *et al.* Severe invalidating pain syndrome associated with benznidazole therapy for Chagas' disease. *Clin Rheumatol* 2008; 27: 269–70.

Pharmacokinetics

Benznidazole is absorbed from the gastrointestinal tract after oral doses (>90% bioavailability) and is widely distributed throughout the body. More than 40% of the drug is bound to plasma protein. The peak plasma concentration occurs after 3 to 4 hours and the half-life is about 12 hours. It is metabolised in the liver and more than 70% of the metabolites are excreted by the kidneys; about 30% of a dose is excreted in the faeces.

UNII — RH5K1819JG.

Profile

Carnidazole is a 5-nitroimidazole derivative similar to metronidazole. It is used in veterinary practice for the treatment and prevention of trichomoniasis in pigeons.

Clazuril *(BAN, USAN, rINN)*

Clazurilo; Clazurilum; Klatsurili; Klazuril; R-62690; Клазурил.
(±)-[2-Chloro-4-(4,5-dihydro-3,5-dioxo-*as*-triazin-2(3*H*)-yl)phenyl]-(*p*-chlorophenyl)acetonitrile.
$C_{17}H_{10}Cl_2N_4O_2$=373.2
CAS — 101831-36-1.
ATC Vet — QP51AJ02.
UNII — O8W0R05772.

Pharmacopoeias. In *Eur.* (see p. vii) for veterinary use only.

Ph. Eur. 8: (Clazuril for Veterinary Use; Clazuril BP(Vet) 2014). A white or light yellow powder. Practically insoluble in water; slightly soluble in alcohol and in dichloromethane; freely soluble in dimethylformamide. Protect from light.

Profile

Clazuril is an antiprotozoal used in veterinary practice for the treatment and prophylaxis of coccidiosis in pigeons.

Clefamide *(BAN, rINN)*

Chlorphenoxamide; Clefamida; Cléfamide; Clefamidum; Клефамид.
2,2-Dichloro-*N*-(2-hydroxyethyl)-*N*-[4-(4-nitrophenoxy)benzyl]acetamide.
$C_{17}H_{16}Cl_2N_2O_5$=399.2
CAS — 3576-64-5.
ATC — P01AC02.
UNII — 4AZ2VBK4EK.

Profile

Clefamide is an antiprotozoal that has been used as a luminal amoebicide in the treatment of *Entamoeba histolytica* infections.

Clopidol *(BAN, USAN, rINN)*

Clopidolum; Clopindol; Meticlorpindol; Клопидол.
3,5-Dichloro-2,6-dimethylpyridin-4-ol.
$C_7H_7Cl_2NO$=192.0
CAS — 2971-90-6.
UNII — 8J763HFF5N.

Profile

Clopidol is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in poultry.

Decoquinate *(BAN, USAN, rINN)*

Décoquinate; Decoquinato; Decoquinatum; HC-1528; M&B-15497; Декохинат.
Ethyl 6-decyloxy-7-ethoxy-4-hydroxyquinoline-3-carboxylate.
$C_{24}H_{35}NO_5$=417.5
CAS — 18507-89-6.
ATC Vet — QP51AX14.
UNII — 534I52PVWH.

Pharmacopoeias. In *US* for veterinary use only. Also in *BP (Vet).*

BP(Vet) 2014: (Decoquinate). A cream to buff-coloured, odourless or almost odourless, microcrystalline powder. Insoluble in water; practically insoluble in alcohol; very slightly soluble in chloroform and in ether.

USP 36: (Decoquinate). Store in airtight containers.

Profile

Decoquinate is an antiprotozoal used in veterinary practice for the treatment and prophylaxis of coccidiosis in calves and lambs, and for prophylaxis of coccidiosis in chickens. It is also used for prevention of abortions due to toxoplasmosis in sheep.

Dehydroemetine Hydrochloride *(BANM, rINNM)*

BT-436; Dehidroemetina, hidrocloruro de; Déhydroémétine Chlorhydrate de; 2,3-Dehydroemetine Hydrochloride; Dehydroemetini Hydrochloridum; DHE; Hidrocloruro de dehidroemetina; Ro-1-9334; Дегидроэметина Гидрохлорид.
2,3-Didehydro-6′,7′,10,11-tetramethoxyemetan dihydrochloride; 3-Ethyl-1,6,7,11b-tetrahydro-9,10-dimethoxy-2-(1,2,3,4-tetrahydro-6,7-dimethoxy-1-isoquinolylmethyl)-4*H*-benzo[*a*]quinolizine dihydrochloride.
$C_{29}H_{38}N_2O_4$,2HCl=551.5
CAS — 4914-30-1 (dehydroemetine); 2228-39-9 (dehydroemetine hydrochloride).

NOTE. The name DHE has been used to denote a preparation of dihydroergotamine mesilate.

Pharmacopoeias. In *Int.*

Profile

Dehydroemetine, a synthetic derivative of emetine (p. 932.3), is a tissue amoebicide with similar actions and uses, although probably of a lower toxicity.

Dehydroemetine should be avoided in patients with cardiac, renal, or neuromuscular disease and patients should be monitored for cardiotoxicity during treatment.

When used in the treatment of amoebiasis (p. 919.1) dehydroemetine hydrochloride is given by intramuscular injection in a dose of 1 mg/kg daily (maximum daily dose of 60 mg), generally for 6 to 10 days, but for no more than 5 days in children. A dose of 500 micrograms/kg has been suggested for elderly or severely ill patients. At least 6 weeks should elapse before treatment is repeated. After treatment with dehydroemetine, patients should receive a luminal amoebicide to eliminate organisms from the colon. Patients with hepatic abscesses may be given supplementary treatment with chloroquine. Dehydroemetine has also been used with metronidazole.

Administration in children. Doses of dehydroemetine for the treatment of amoebiasis in children are the same as those for adults, although it may be used for shorter periods, see above.

Liver fluke infections. Dehydroemetine has been given[1,2] in the treatment of the liver fluke infection fascioliasis (see p. 146.2).

1. Farid Z, *et al.* Treatment of acute toxaemic fascioliasis. *Trans R Soc Trop Med Hyg* 1988; 82: 299.
2. Cruz López O, *et al.* Fasciolosis hepática diagnosticada en fase de estado. *Rev Gastroenterol Mex* 2006; 71: 59–62.

Diaveridine *(BAN, USAN, rINN)*

BW-49-210; Diaveridina; Diavéridine; Diaveridinum; NSC-408735; Диаверидин.
5-Veratrylpyrimidine-2,4-diyldiamine.
$C_{13}H_{16}N_4O_2$=260.3
CAS — 5355-16-8.
ATC Vet — QP51AX18.
UNII — 7KVX81XA87.

Pharmacopoeias. In *Fr.* for veterinary use.

Profile

Diaveridine is an antiprotozoal used in veterinary practice for the control of coccidiosis in poultry.

Diclazuril *(BAN, USAN, rINN)*

Diclazurilo; Diclazurilum; Diklatsurili; Diklazuril; R-64433; Диклазурил.
(±)-4-Chlorophenyl[2,6-dichloro-4-(2,3,4,5-tetrahydro-3,5-dioxo-1,2,4-triazin-2-yl)phenyl]acetonitrile.
$C_{17}H_9Cl_3N_4O_2$=407.6
CAS — 101831-37-2.
ATC Vet — QP51AJ03.
UNII — K110K1B1VE.

Pharmacopoeias. In *Eur.* (see p. vii) and *US* for veterinary use only.

Ph. Eur. 8: (Diclazuril for Veterinary Use; Diclazuril BP(Vet) 2014). A white or light yellow powder. Practically insoluble in water, in alcohol, and in dichloromethane; sparingly soluble in dimethylformamide. Protect from light.

USP 36: (Diclazuril). White to yellow powder. Practically insoluble in water, in alcohol, and in dichloromethane; sparingly soluble in dimethylformamide.

Profile

Diclazuril is an antiprotozoal that has been tried in AIDS patients for the management of diarrhoea associated with

protozoal infection. It is used in veterinary practice for the control of coccidiosis.

Diiodohydroxyquinoline *(INN)*

Diiodohidroxiquinoleína; Diiodohydroxyquin; Diiodohydroxyquinoléine; Di-iodohydroxyquinoline (BAN); Diiodohydroxyquinolinum; Diiodoidrossichinolina; Di-iodoxychinolinum; Diiodoxyquinoléine; Diiyodohidroksikinolin; Dijodhydroxikinolin; Dijodihydroksikinoliini; Iodoquinol (USAN); Yodoquinol; Дийодогидроксихинолин.

5,7-Di-iodoquinolin-8-ol.

$C_9H_5I_2NO$=397.0

CAS — 83-73-8.

ATC — G01AC01.

ATC Vet — QG01AC01.

UNII — 63W7IE88K8.

Pharmacopoeias. In *US.*

USP 36: (Iodoquinol). A light yellowish to tan, microcrystalline powder, not readily wetted in water, odourless or has a faint odour. Practically insoluble in water; sparingly soluble in alcohol and in ether.

Uses and Administration

Diiodohydroxyquinoline, a halogenated hydroxyquinoline, is a luminal amoebicide acting mainly in the bowel lumen and is used in the treatment of intestinal amoebiasis, (p. 919.1) although less toxic amoebicides such as diloxanide furoate or paromomycin are usually preferred, especially in children (see Precautions, below). It is given alone in the treatment of asymptomatic cyst passers, or as follow-up treatment after an amoebicide that acts in the tissues, such as metronidazole, in patients with symptomatic (invasive) amoebiasis. The usual oral dosage is 630 or 650 mg three times daily for 20 days.

For details of doses in children, see below.

Diiodohydroxyquinoline has also been given in the treatment of *Dientamoeba fragilis* infections, in balantidiasis (p. 920.3) as an alternative to tetracycline, and has been tried in *Blastocystis hominis* infections (p. 920.3).

Diiodohydroxyquinoline was formerly used in the treatment of acrodermatitis enteropathica; it is reported to act by enhancing zinc absorption and has now been superseded by oral zinc therapy.

Diiodohydroxyquinoline is claimed to have some antibacterial and antifungal activity and has been used topically (but see Children, under Precautions, below).

Administration in children. Diiodohydroxyquinoline is licensed in the USA and some other countries for the treatment of amoebiasis in children; however, there is concern over its safety in children (see Children, under Precautions, below).

For the treatment of asymptomatic amoebiasis (including asymptomatic cyst passers) and as follow-up treatment after a tissue amoebicide in the management of symptomatic intestinal or invasive amoebiasis, diiodohydroxyquinoline is given in the usual oral dose of 10 to 13.3 mg/kg three times daily (to a maximum of 1.95 g daily) for 20 days.

Adverse Effects

Major concerns have been expressed about the safety of the halogenated hydroxyquinolines since the recognition of severe neurotoxicity with clioquinol (p. 273.1). In Japan, the epidemic development of subacute myelo-opticoneuropathy (SMON) in the 1960s was associated with the ingestion of normal or high doses of clioquinol for prolonged periods and the sale of clioquinol and related hydroxyquinolines was subsequently banned there. Symptoms of SMON are mainly those of peripheral neuropathy, including optic atrophy, and myelopathy. Abdominal pain and diarrhoea often precede neurological symptoms such as paraesthesias in the legs, progressing to paraplegia in some patients, and loss of visual acuity sometimes leading to blindness. Cerebral disturbances, including confusion and retrograde amnesia, have also been reported. Although many patients improved when clioquinol was withdrawn, others had residual disability.

It was suggested that the Japanese epidemic might have been due to genetic susceptibility, but a few cases of SMON associated with clioquinol or related hydroxyquinoline derivatives, including broxyquinoline and diiodohydroxyquinoline, have been reported elsewhere.

Diiodohydroxyquinoline has also been associated with gastrointestinal effects such as abdominal cramps, nausea, and diarrhoea. Adverse effects which may be attributable to the iodine content of diiodohydroxyquinoline include pruritus ani, skin eruptions, and enlargement of the thyroid gland. Fever, chills, headache, and vertigo have also occurred.

Effects on the nervous system. Hypertensive encephalopathy and seizures have been reported in a 10-year-old boy taking oral diiodohydroxyquinoline for a *Dientamoeba fragilis* infection.[1] Fourteen days after starting treatment the boy had abdominal cramps and muscle pain. Four days later a pins-and-needles sensation in his feet, ataxic gait, foot drop, stiff legs, general weakness, and headache developed. These symptoms were shortly followed by tonic-clonic seizures and results from additional investigations indicated a hypertensive encephalopathy. Five months after stopping diiodohydroxyquinoline, results from a neurologic examination were normal, but the boy still had tingling and sensitivities in his legs.

1. Health Canada. Iodoquinol: suspected association with hypertensive encephalopathy and seizures. *Can Adverse React News* 2006; 16 (3): 3. Also available at: http://www.hc-sc.gc.ca/dhp-mps/alt_formats/hpfb-dgpsa/pdf/medeff/cam-bcei_v16n3-eng.pdf (accessed 11/02/09)

Precautions

Diiodohydroxyquinoline is contra-indicated in patients known to be hypersensitive to iodine or halogenated hydroxyquinolines and in those with hepatic or renal impairment. It should be used with caution in thyroid disease and may interfere with determinations of protein-bound iodine in tests for thyroid function for up to 6 months after therapy. Its use is best avoided in patients with neurological disorders. Long-term use should be avoided.

Children. Last available guidance from the Committee on Drugs of the American Academy of Pediatrics[1] considered that there was a potential risk of toxicity to infants and children from clioquinol and diiodohydroxyquinoline applied topically. Since alternative effective preparations are available for dermatitis, the Committee recommended that products containing either of these compounds should not be used.

WHO considers that the use of halogenated hydroxyquinolines for the treatment of acute diarrhoea or amoebiasis in children cannot be justified.[2] There is no evidence of their efficacy in acute diarrhoea and they have been associated with severe neurological effects. On the rare occasions when a luminal amoebicide is required, other less toxic and more effective agents are available.

1. Kaufman RE. *et al.* American Academy of Pediatrics Committee on Drugs. Clioquinol (iodochlorhydroxyquin, Vioform) and Iodoquinol (diiodohydroxyquin): blindness and neuropathy. *Pediatrics* 1990; 86: 797–8. [Re-affirmed October 2006, Retired January 2011] Also available at: http://aappolicy.aappublications.org/cgi/reprint/pediatrics;86/5/797.pdf (accessed 15/02/11)
2. WHO. The rational use of drugs in the management of acute diarrhoea in children. Geneva: WHO, 1990.

Pharmacokinetics

Diiodohydroxyquinoline is poorly absorbed from the gastrointestinal tract. Concern has been expressed about possible absorption after application to the skin (see Children, under Precautions, above).

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Canad.*: Diodoquin; *Mex.*: Ameban; Antidifar; Carsuquin; Diamebᵗ; Diodoquin; Diyosulᵗ; Entero-Diyod; Entodibaᵗ; Exoquin; Quinosul; Versamiv; *Turk.*: Floraquin; *USA*: Aloquin; *Sebaquin*; Yodoxin; *Venez.*: Diodoquin.

Pharmacopoeial Preparations
USP 36: Iodoquinol Tablets.

Diloxanide Furoate *(BANM, rINNM)*

Diloksanid Furoat; Diloxanida, furoato de; Diloxanide, Furoate de; Diloxanidi Furoas; Furoato de diloxanida; Дилоксанида Фуроат.

4-(*N*-Methyl-2,2-dichloroacetamido)phenyl 2-furoate.

$C_{14}H_{11}Cl_2NO_4$=328.1

CAS — 579-38-4 (diloxanide); 3736-81-0 (diloxanide furoate).

ATC — P01AC01.

UNII — YP4NZ2IW34.

Pharmacopoeias. In *Br., Int.*, and *US.*

BP 2014: (Diloxanide Furoate). A white or almost white, odourless or almost odourless, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol and in ether; freely soluble in chloroform. Protect from light.

USP 36: (Diloxanide Furoate). A white or almost white, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol and in ether; freely soluble in chloroform. Store in airtight containers. Protect from light.

Uses and Administration

Diloxanide furoate, a dichloroacetamide derivative, is a luminal amoebicide acting mainly in the bowel lumen and is used in the treatment of intestinal amoebiasis (p. 919.1). It is given alone in the treatment of asymptomatic cyst passers or after an amoebicide that acts in the tissues, such as metronidazole, in patients with symptomatic (invasive) amoebiasis.

Diloxanide furoate is given orally in a dosage of 500 mg three times daily for 10 days. The course of treatment may be repeated if necessary.

For details of doses in children, see below.

Administration in children. Diloxanide furoate may be given orally to children for the treatment of asymptomatic amoebiasis (including asymptomatic cyst passers) and as follow-up treatment after a tissue amoebicide in the management of symptomatic (invasive) amoebiasis in dose of 20 mg/kg daily; in 3 divided doses, for 10 days. UK licensed product information stipulates diloxanide furoate may only be given to children weighing more than 25 kg while the *BNFC* suggests it may be given to children from the age of 1 month.

Adverse Effects

Flatulence is the most common adverse effect during treatment with diloxanide furoate. Vomiting, pruritus, and urticaria may occasionally occur.

Pharmacokinetics

Diloxanide furoate is hydrolysed before absorption from the gastrointestinal tract. The resulting diloxanide is readily absorbed and excreted mainly in the urine as the glucuronide; less than 10% of a dose appears in the faeces.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *India*: Amicline.

Multi-ingredient Preparations. *India*: Aldezol-DF; Amebis Forte; Amicline Plus; Antibic-DF; Aristogyl Plus; Dialox; DLotin MPS; Dyrade-M; Eldazole; Entamizole†; Entrolate; Idometrin-D; Metrogyl Compound; Metron-DF; Novogyl-MPS; Qugyl; Tinidafyl Plus; Wotinex.

Pharmacopoeial Preparations
BP 2014: Diloxanide Tablets.

Dimetridazole *(BAN, pINN)*

Dimetridatsoli; Dimetridazol; Dimétridazole; Dimetridazolum; Диметридазол.

1,2-Dimethyl-5-nitroimidazole.

$C_5H_7N_3O_2$=141.1

CAS — 551-92-8.

ATC Vet — QP51AA07.

UNII — K59P7XN88X.

Pharmacopoeias. In *Fr.* for veterinary use. Also in *BP(Vet).*

BP(Vet) 2014: (Dimetridazole). An almost white to brownish-yellow, odourless or almost odourless powder which darkens on exposure to light. Slightly soluble in water; sparingly soluble in alcohol; freely soluble in chloroform; slightly soluble in ether. Protect from light.

Profile

Dimetridazole is a 5-nitroimidazole derivative similar to metronidazole. It is used in veterinary practice for the control of various protozoal infections in birds, fish, and reptiles. It has also been used for swine dysentery. Dimetridazole is considered to be potentially carcinogenic and use in food-producing animals has been banned in some countries.

Diminazene Aceturate (BANM, rINNM)

Aceturato de diminazeno; Diminazène, Acéturate de; Diminazeni Aceturas; Diminazeno, aceturato de; Диминазена Ацетурат.

1,3-Bis(4-amidinophenyl)triazene bis(*N*-acetylglycinate).

$C_{27}H_{29}N_9O_6$=575.5

CAS — 536-71-0 (diminazene); 908-54-3 (diminazene aceturate).

UNII — J8RSAD85NO.

NOTE. Diminazene aceturate is often referred to by its veterinary proprietary name Berenil.

Profile

Diminazene aceturate, an aromatic diamidine derivative related to pentamidine, is an antiprotozoal used in veterinary practice in the treatment of trypanosomiasis and babesiosis. It has also been tried in human infections.

Dinitolmide (BAN, rINN)

Dinitolmida; Dinitolmidum; Dinitrotoluamida; Dinitrotoluamide; Methyldinitrobenzamide; Динитолмид.

3,5-Dinitro-o-toluamide.

$C_8H_7N_3O_5$=225.2

CAS — 148-01-6.

ATC Vet — QP51AX12.

UNII — AOX68RY47V.

Pharmacopoeias. In *BP(Vet)*.

BP(Vet) 2014: (Dinitolmide). A cream to light tan powder. Practically insoluble in water; slightly soluble in alcohol, in chloroform, and in ether; soluble in acetone.

Profile

Dinitolmide is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in poultry.

Eflornithine Hydrochloride

(BANM, USAN, rINNM)

DFMO; α-Difluoromethylornithine Hydrochloride; Éflornithine; Chlorhydrate d'; Eflornithini Hydrochloridum; Eflornitina, hidrocloruro de; Hidrocloruro de, eflornitina; MDL-71782; MDL-71782A; RMI-71782; Эфлорнитина Гидрохлорид.

2-(Difluoromethyl)-DL-ornithine monohydrochloride monohydrate.

$C_6H_{12}F_2N_2O_2$,HCl,H_2O=236.6

CAS — 67037-37-0 (eflornithine); 96020-91-6 (eflornithine hydrochloride).

ATC — D11AX16; P01CX03.

ATC Vet — QD11AX16.

UNII — 4NH22NDW9H.

Uses and Administration

Eflornithine is an antiprotozoal that acts as an irreversible inhibitor of ornithine decarboxylase, the rate-limiting enzyme in polyamine biosynthesis; trypanosomes are more susceptible to the effects of eflornithine than are humans, probably because of their slower turnover of this enzyme.

Eflornithine is used in **African trypanosomiasis** due to *Trypanosoma brucei gambiense* (see below). It is effective in the late stage of the disease (when there is CNS involvement).

In the treatment of African trypanosomiasis, eflornithine hydrochloride is given by intravenous infusion. The dose is 100 mg/kg every 6 hours for at least 14 days. Each dose should be given over a period of at least 45 minutes. Dosage should be reduced in patients with renal impairment.

Eflornithine hydrochloride is also applied topically twice daily for the reduction of unwanted **facial hair** in women (see Hirsutism, below). It is available as a cream containing 15% eflornithine hydrochloride monohydrate; in the UK this content is expressed as 11.5% eflornithine and in the USA as 13.9% anhydrous eflornithine hydrochloride.

Oral formulations of eflornithine are under investigation for the treatment of familial adenomatous polyposis (see Malignant Neoplasms of the Colon and Rectum, p. 706.3).

Cryptosporidiosis. Eflornithine has been tried in the treatment of cryptosporidiosis (p. 921.1) in AIDS patients.[1]

1. Rolston KVI, *et al.* Intestinal cryptosporidiosis treated with eflornithine: a prospective study among patients with AIDS. *J Acquir Immune Defic Syndr* 1989; 2: 426–30.

Hirsutism. Topical eflornithine hydrochloride applied twice daily as a 13.9% cream is effective in reducing the growth of unwanted facial hair in females (see Hirsutism, p. 2262.1), although it must be used indefinitely to prevent regrowth.[1] Its action is thought to be due to the irreversible inhibition of ornithine decarboxylase in hair follicles. It has also been used successfully with laser hair removal.[2]

1. Barman Balfour JA, McClellan K. Topical eflornithine. *Am J Clin Dermatol* 2001; 2: 197–201.
2. Hamzavi I, *et al.* A randomized bilateral vehicle-controlled study of eflornithine cream combined with laser treatment versus laser treatment alone for facial hirsutism in women. *J Am Acad Dermatol* 2007; 57: 54–9.

Malignant neoplasms. Eflornithine has antimetabolic activity and is being studied as a potential chemopreventive agent in patients at high risk of a variety of malignant diseases, including cancer of the bladder, breast, cervix, colon, oesophagus, prostate, and skin.[1,2] It has been investigated with NSAIDs such as sulindac in the prevention of colon cancer.

1. Meyskens FL, Gerner EW. Development of difluoromethylornithine (DFMO) as a chemoprevention agent. *Clin Cancer Res* 1999; 5: 945–51.
2. Raul F. Revival of 2-(difluoromethyl)ornithine (DFMO), an inhibitor of polyamine biosynthesis, as a cancer chemopreventive agent. *Biochem Soc Trans* 2007; 35: 353–5.

African trypanosomiasis. Eflornithine is effective in the treatment of *Trypanosoma brucei gambiense* infections (p. 925.2), and is particularly valuable in providing an alternative to melarsoprol in meningoencephalitic disease.[1-3] Eflornithine 100 mg/kg intravenously every 6 hours for 7 days, rather than the standard 14 days, produced long-term responses in 42 of 47 patients who had relapsed after other treatment regimens.[4] Similar positive results in relapsing cases were obtained with a short 7-day course in a multicentre randomised controlled study,[5] although this short course was inferior to the 14-day course for new cases, in whom it could not be recommended. A patient who had relapsed after treatment with melarsoprol and eflornithine given singly was cured when the drugs were given together.[6] Eflornithine given for 4 days followed by 3 daily injections of melarsoprol, was associated with a cure rate of 93% in 42 patients with melarsoprol-resistant Gambian trypanosomiasis. Efficacy and toxicity were considered to be similar to a 7-day course of eflornithine monotherapy.[7] Promising results have been reported from use of eflornithine 400 mg/kg daily (200 mg/kg every 12 hours) intravenously for 7 days with oral nifurtimox 15 mg/kg daily (5 mg/kg every 8 hours) for 10 days;[8,9] this drug combination has now been included in the WHO List of Essential Medicines for the treatment of human African trypanosomiasis.[10]

Eflornithine is not effective when given alone in *T. b. rhodesiense* infections, and early reports of its use with suramin were not encouraging.[11]

Adverse Effects and Precautions

Intravenous eflornithine commonly causes myelosuppression that may lead to anaemia, leucopenia, and thrombocytopenia. Some patients have had hearing loss and alopecia. Gastrointestinal disturbances, especially diarrhoea, may occur. Seizures have occurred in about 8% of patients given eflornithine but they may have been related to the disease rather than treatment.

Dosage should be reduced in patients with renal impairment.

Acne and skin irritation, such as erythema or a stinging or burning sensation, has been reported after topical application of eflornithine; however, adverse effects are generally mild and usually resolve without medical treatment or stopping eflornithine.

Effects on the ears. A study in 58 patients[1] given oral eflornithine alone or with interferon alfa for the treatment of metastatic melanoma found that hearing loss was related to the cumulative dose of eflornithine and was worse in patients with pre-existing hearing deficit. Temporary hearing loss usually occurs with daily doses above 2 g/m² and when the cumulative dose exceeds 250 g/m². A case of irreversible hearing loss has been reported in a patient with Barrett's oesophagus after taking [oral] eflornithine 500 mg/m² daily for about 13 weeks (cumulative dose of 45 g/m²) for the prevention of oesophageal cancer.[2]

2. Lao CD, *et al.* Irreversible ototoxicity associated with difluoromethylornithine. *Cancer Epidemiol Biomarkers Prev* 2004; 13: 1250–2.

Effects on the heart. An AIDS patient with pneumocystis pneumonia had a fatal cardiac arrest during an intravenous infusion of eflornithine 100 mg/kg over 1 hour.[1] Sudden death after infusion of eflornithine had occurred in several other critically ill patients with AIDS.

1. Barbarash RA, *et al.* Alpha-difluoromethylornithine infusion and cardiac arrest. *Ann Intern Med* 1986; 105: 141–2.

Pharmacokinetics

Eflornithine hydrochloride is absorbed from the gastrointestinal tract. After intravenous doses about 80% is excreted unchanged in the urine in 24 hours. The terminal elimination half-life is about 3 hours. It is distributed to the CSF.

Less than 1% of a dose is absorbed after topical application.

$C_{29}H_{40}N_2O_4$,2HCl,$7H_2O$=679.7

CAS — 483-18-1 (emetine); 316-42-7 (anhydrous emetine hydrochloride); 7083-71-8 (emetine hydrochloride, hydrate); 79300-08-6 (emetine hydrochloride, heptahydrate).

ATC — P01AX02.

UNII — U52OG12P96 (anhydrous emetine hydrochloride); J636CC0C64 (emetine hydrochloride heptahydrate); 07DUYSKQBX (emetine hydrochloride pentahydrate).

Pharmacopoeias. In *Chin.* and *Viet.*

Eur. has a monograph for Emetine Hydrochloride Pentahydrate;

Int. permits the heptahydrate or pentahydrate in the same monograph. *US* has a monograph for the anhydrous salt.

Ph. Eur. 8: (Emetine Hydrochloride Pentahydrate). A white or slightly yellow crystalline powder. Freely soluble in water and in alcohol. A 2% solution in water has a pH of 4.0 to 6.0. Protect from light.

USP 36: (Emetine Hydrochloride). The hydrochloride of an alkaloid obtained from ipecacuanha, or prepared by methylation of cephaëline, or prepared synthetically. Anhydrous emetine hydrochloride is a white or slightly yellowish, odourless, crystalline powder. Freely soluble in

water and in alcohol. Store in airtight containers at a temperature of 25 degrees, excursions permitted between 15 degrees and 30 degrees. Protect from light.

Uses and Administration

Emetine, an alkaloid of ipecacuanha (p. 1667.2), is a tissue amoebicide acting mainly in the bowel wall and in the liver. It has been given by deep subcutaneous or intramuscular injection in the treatment of severe invasive amoebiasis (p. 919.1), including hepatic amoebiasis in patients who do not respond to metronidazole, but safer drugs have generally replaced it. Emetine was formerly given orally as emetine and bismuth iodide.

Emetine has also been included in combination preparations for the symptomatic relief of cough.

Adverse Effects

Emetine hydrochloride is commonly associated with muscle pain and weakness around the injection site; there may be necrosis and abscess formation. After injection, diarrhoea and nausea and vomiting, sometimes with dizziness and headache, are common. There may be more generalised myalgia and weakness, and, more rarely, mild sensory disturbances. Eczematous, urticarial, and purpuric skin lesions have been reported.

Cardiotoxicity may be marked by precordial pain, dyspnoea, tachycardia, and hypotension. ECG changes, particularly flattening or inversion of the T-wave and prolongation of the QT interval, occur in many patients. Accumulation after large doses or prolonged use may cause lesions of the heart, gastrointestinal tract, kidneys, liver, and skeletal muscle. Severe acute degenerative myocarditis may occur and give rise to sudden cardiac failure and death. In some patients cardiotoxic effects have appeared after the completion of treatment with therapeutic doses.

Emetine hydrochloride is very irritant and contact with mucous membranes should be avoided.

Precautions

Emetine is contra-indicated in cardiac, renal, or neuromuscular disease, in pregnancy, and in children except in severe amoebic dysentery unresponsive to other drugs. It should be used with great caution in old or debilitated patients. Patients given emetine should be closely supervised; ECG monitoring is advisable during treatment.

Pharmacokinetics

After injection emetine hydrochloride is concentrated in the liver, and to some extent in kidney, lung, and spleen. Excretion is slow and detectable amounts may persist in urine 40 to 60 days after treatment has been stopped.

ATC — P01AX10.
ATC Vet — QP51AX23.
UNII — 7OW73204U1.

Profile

Fumagillin is an alicyclic antibiotic produced by certain strains of *Aspergillus fumigatus*. It has activity against microsporidia and is used in veterinary practice to control *Nosema apis* infection in honeybees.

Fumagillin is given in an oral dose of 20 mg three times daily for 14 days in the treatment of diarrhoea due to intestinal microsporidial infection (see below) with *Enterocytozoon bieneusi* in patients with HIV infection. It has also been tried in humans in the topical treatment of microsporidial keratoconjunctivitis. It was formerly given orally in the treatment of intestinal amoebiasis, but produced an unacceptably high frequency of adverse effects. Analogues of fumagillin have been studied for effects on angiogenesis in solid tumours.

Microsporidiosis. As discussed on p. 924.1, topical treatment of microsporidial keratoconjunctivitis has been disappointing. There have been several reports of successful treatment in individual patients using fumagillin topically,[1-3] usually as a solution of bicyclohexylammonium fumagillin containing the equivalent of fumagillin 70 micrograms/mL.

Oral fumagillin has been effective in the treatment of diarrhoea due to intestinal microsporidial infection with *Enterocytozoon bieneusi* in immunocompromised patients, including those with HIV infection[4-6] and solid organ transplant recipients.[6-8] US guidelines for prevention and treatment of opportunistic infections in HIV-infected adults and adolescents[9] recommend the use of topical fumagillin plus oral albendazole for microsporidial eye infections.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Fr.*: Flisint.

Furazolidone *(BAN, rINN)*

Furatsolidoni; Furazolidon; Furazolidona; Furazolidonum; Nifurazolidonum; Фуразолидон.
3-(5-Nitrofurfurylideneamino)-2-oxazolidone.
$C_8H_7N_3O_5$=225.2
CAS — 67-45-8.
ATC — G01AX06.
ATC Vet — QG01AX06; QJ01XE90.
UNII — SJ9CPU3RE0.

Pharmacopoeias. In *Br.*, *Fr.*, and *US*.

BP 2014: (Furazolidone). A yellow odourless or almost odourless crystalline powder. Very slightly soluble in water and in alcohol; slightly soluble in chloroform; practically insoluble in ether. The filtrate from a 1% suspension in water has a pH of 4.5 to 7.0. Protect from light.

USP 36: (Furazolidone). A yellow, odourless, crystalline powder. Practically insoluble in water, in alcohol, and in carbon tetrachloride. Store in airtight containers. Protect from light and avoid exposure to direct sunlight.

Uses and Administration

Furazolidone is a nitrofuran derivative with antiprotozoal and antibacterial activity. It is active against the protozoan *Giardia intestinalis* (*Giardia lamblia*) and against a range of enteric bacteria *in vitro*, including staphylococci, enterococci, *Escherichia coli*, *Salmonella* spp., *Shigella* spp., and *Vibrio cholerae*. Furazolidone is bactericidal and appears to act by interfering with bacterial enzyme systems. Resistance is reported to be limited. It is used in the treatment of giardiasis (p. 921.3) and cholera (p. 184.2). It has been suggested for other bacterial gastrointestinal infections, but antibacterial therapy is regarded as unnecessary in mild and self-limiting gastro-enteritis (see p. 182.2).

Furazolidone is given orally in a dose of 100 mg four times daily. It is usually given for 2 to 5 days, but may be given for up to 7 days in some patients, or for up to 10 days for giardiasis.

For details of doses in children see below.

Administration in children. For the treatment of giardiasis, cholera, and other diarrhoeal diseases caused by susceptible organisms, children and infants from 1 month of age may be given oral furazolidone at a dose of 1.25 to 1.5 mg/kg four times daily for 2 to 5 days. Some patients may need 7 days of treatment, or up to 10 days for giardiasis.

Peptic ulcer disease. Furazolidone is not one of the main antibacterials used in *Helicobacter pylori* eradication regimens for peptic ulceration (p. 1816.2), but there are some studies suggesting its efficacy in adults,[1-7] children,[8,9] and in patients unresponsive to standard first- or second-line eradication regimens.[10-14]

Adverse Effects

Adverse effects of furazolidone are usually mild and transient. The most common involve the gastrointestinal tract and include nausea and vomiting. Dizziness, drowsiness, headache, and a general malaise have also been reported.

Allergic reactions, most commonly skin reactions such as rashes or angioedema, may occur. There have been instances of acute pulmonary reactions, similar to those seen with the structurally related drug nitrofurantoin, and of hepatotoxicity. Agranulocytosis has been reported rarely. Haemolytic anaemia may occur in patients with G6PD deficiency given furazolidone.

Darkening of the urine has been attributed to the presence of metabolites.

Precautions

Furazolidone should be used with caution in those with G6PD deficiency because of the risk of haemolytic anaemia. It should not be given to infants under 1 month of age since their enzyme systems are immature.

Interactions

A disulfiram-like reaction has been reported in patients taking alcohol while on furazolidone therapy; alcohol should be avoided during, and for a short period after, treatment with furazolidone.

A metabolite of furazolidone is an MAOI and the cautions advised for these drugs regarding use with other drugs, especially indirect-acting sympathomimetic amines, and the consumption of food and drink containing tyramine, should be followed (see Phenelzine Sulfate, p. 444.3 and p. 445.1). However, there appear to be no reports of hypertensive crises in patients receiving furazolidone and it has been suggested that, since furazolidone inhibits monoamine oxidase gradually over several days, the risks are small if treatment is limited to a 5-day course. Toxic psychosis has been reported in a patient receiving furazolidone and amitriptyline (see Antiprotozoals, under Interactions of Amitriptyline, p. 406.3). Omeprazole modestly decreases serum concentrations of furazolidone; other proton pump inhibitors could interact similarly.

Pharmacokinetics

Although furazolidone has been considered to be largely unabsorbed when given orally, the occurrence of systemic adverse effects and coloured metabolites in the urine suggest that this may not be the case. Rapid and extensive metabolism, possibly in the intestine, has been proposed.

$C_{34}H_{53}NaO_8$=612.8

CAS — 25999-20-6.

ATC Vet — QP51AH02.

UNII — W2S5C71Y3G.

Profile

Lasalocid, an antibiotic produced by *Streptomyces lasaliensis*, is an antiprotozoal used as the sodium salt in veterinary practice for the prevention of coccidiosis in birds.

Maduramicin *(BAN, USAN, rINN)*

CL-273703; Maduramicin Ammonium; Maduramicina; Maduramicine; Maduramicinum; Мадурамицин.

Ammonium (2*R*,3*S*,4*S*,5*R*,6*S*)-tetrahydro-2-hydroxy-6-{(*R*)-1-[(2*S*,5*R*,7*S*,8*R*,9*S*)-9-hydroxy-2,8-dimethyl-2-{(2*S*,2'*R*,3'*S*,5*R*,5'*R*)-octahydro-2-methyl-3'-[(2*R*,4*S*,5*S*,6*S*)-tetrahydro-4,5-dimethoxy-6-methyl-2*H*-pyran-2-yl]oxy}-5'-[(2*S*,3*S*,5*R*,6*S*)-tetrahydro-6-hydroxy-3,5,6-trimethyl-2*H*-pyran-2-yl](2,2'-bifuran-5-yl)-1,6-dioxaspiro[4.5]dec-7-yl ethyl}-4,5-dimethoxy-3-methyl-2*H*-pyran-2-acetate.

$C_{47}H_{80}O_{17},NH_3$=934.2

CAS — 84878-61-5.

ATC Vet — QP51AX10.

UNII — 5U912U22T2.

NOTE. The name maduramicin has also been used to denote the acid.

Profile

Maduramicin is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in poultry. Accidental ingestion by humans has resulted in muscle weakness, polyneuropathy, myonecrosis and rhabdomyolysis, and acute renal failure; fatalities have been reported.

Melarsoprol *(BAN, rINN)*

Mel B; Melarsen Oxide-BAL; Mélarsoprol; Melarsoprolum; RP-3854; Меларсопрол.

2-[4-(4,6-Diamino-1,3,5-triazin-2-ylamino)phenyl]-1,3,2-dithiarsolan-4-ylmethanol.

$C_{12}H_{15}AsN_6OS_2$=398.3

CAS — 494-79-1.

ATC — P01CD01.

ATC Vet — QP51AD04.

UNII — ZF3786Q2E8.

Uses and Administration

Melarsoprol, a trivalent arsenical derivative, is a trypanocide that appears to act by inhibiting trypanosomal pyruvate kinase. It is effective in the treatment of all stages of African trypanosomiasis due to *Trypanosoma brucei gambiense* or *T brucei rhodesiense* (see below), but because of its toxicity its use is usually reserved for stages of the disease involving the CNS. Resistance has been reported to develop.

Patients undergoing therapy with melarsoprol should be treated in hospital. Melarsoprol is given by intravenous injection as a 3.6% solution in propylene glycol. The injection should be given slowly, care being taken to prevent leakage into the surrounding tissues, and the patient should remain supine and fasting for several hours after the injection.

Treatment protocols vary, but in general melarsoprol is given in low doses initially (0.36 to 1.8 mg/kg daily), especially in children and debilitated patients, increased gradually to the maximum daily dose of 3.6 mg/kg. For **intermittent** cyclic therapy, doses are given daily for 3 or 4 days and the course repeated 2 or 3 times with an interval of 7 to 10 days between courses. Since massive destruction of parasites resulting in a Jarisch-Herxheimer reaction is particularly dangerous during treatment with melarsoprol, several doses of suramin or pentamidine may be given to induce the reaction before melarsoprol is started.

An alternative 10-day **consecutive** treatment course of intravenous melarsoprol 2.2 mg/kg daily, for the treatment of *T. b. gambiense*, has been endorsed by many authorities, since it shortens patients' time in hospital and reduces the total amount of drug given. See also below.

Melarsonyl potassium is a water-soluble derivative of melarsoprol which was formerly used as an alternative to melarsoprol but was probably more toxic and less effective.

African trypanosomiasis. Melarsoprol, which is effective against both *Trypanosoma brucei gambiense* and *T. b. rhodesiense*, is usually only given to treat the meningoencephalitic stage of African trypanosomiasis (p. 925.2) because it may produce potentially fatal encephalopathy. However, protection against this toxicity may be provided by prophylaxis with prednisolone.[1,2] Therapy with melarsoprol and eflornithine was reported to be effective in a patient who had not responded to either drug alone.[3] A study[4] to evaluate the efficacy and toxicity of a combination of eflornithine for 4 days followed by 3 daily injections of melarsoprol in 42 patients with melarsoprol-resistant Gambian trypanosomiasis, was associated with cure in 93% of patients. Efficacy and toxicity were considered to be similar to a 7-day course of eflornithine monotherapy. A comparative study[5] in 500 patients with second-stage infection with *T. b. gambiense* found that an alternative dosage regimen of melarsoprol 2.2 mg/kg daily, as a single course over 10 consecutive days, was similar in efficacy to intermittent cyclic regimens of 1.2 to 3.6 mg/kg daily for 3 or 4 days repeated twice over a 26-day period with 7-day intervals between series, although there was no difference between the regimens in the incidence of associated encephalopathy. Follow-up involving 442 of these patients indicated that results of the 2 regimens continued to be comparable; relapse after 1 year occurred in 3% of those given standard treatment and in 2% given alternative treatment; relapse rates after 2 years were

reported to be 5% and 6% respectively.[6] A further uncontrolled, multinational drug-utilisation study[7] in 2020 patients with late-stage African trypanosomiasis treated with the 10-day consecutive melarsoprol regimen reported a 93.9% cure rate 24 hours after completing treatment and an 86.2% cure rate after 2 years, however, nearly half of the patients were lost to follow-up. The overall reported fatality rate was 5.9%; encephalopathic syndrome was reported for 8.7% of patients and it was fatal in about half of all cases.

Adverse Effects and Treatment

Adverse effects are common and may be severe during the treatment of African trypanosomiasis with melarsoprol. It may be difficult to distinguish between effects of the disease, Jarisch-Herxheimer reactions resulting from the release of antigens from trypanosomes killed by melarsoprol, and adverse effects due to the drug's arsenic content or to hypersensitivity. For the adverse effects of arsenic and their treatment, see Arsenic Trioxide, p. 2448.3.

A severe febrile reaction may occur after the first injection of melarsoprol, especially in patients with large numbers of trypanosomes in their blood. For those patients receiving intermittent cyclic treatment it is common practice to give 2 or 3 injections of suramin or pentamidine before starting melarsoprol therapy.

The most serious adverse effect is reactive encephalopathy, which occurs in about 3 to 10% of patients treated with melarsoprol and is usually seen between the end of the first 3- or 4-day course of injections and the start of the second course in those patients receiving intermittent cyclic treatment and from day 8 to 10 in those receiving the 10-day consecutive schedule. (For further information on treatment schedules see Uses and Administration, p. 934.3.) Encephalopathy may be sudden in onset or develop slowly. Symptoms include fever, headache, tremor, slurring of speech, convulsions, and coma; death has occurred in up to 5% of patients treated with melarsoprol. Less commonly, haemorrhagic encephalopathy may occur. The prophylactic use of corticosteroids has been suggested during treatment courses of melarsoprol (see African Trypanosomiasis, p. 934.3). Treatment of reactive encephalopathy has included the use of corticosteroids, hypertonic solutions to combat cerebral oedema, anticonvulsants such as diazepam, and subcutaneous adrenaline; dimercaprol has been given on the assumption that encephalopathy resulted from arsenic poisoning, but has not generally been of benefit.

Hypersensitivity reactions to melarsoprol may occur during the second and subsequent courses of treatment. Desensitisation with gradually increasing doses of melarsoprol has been attempted; corticosteroids may help to control symptoms during this procedure. Some authorities consider that the use of small doses of melarsoprol may increase the risk of resistance.

Melarsoprol injection is very irritant and extravasation during intravenous use should be avoided. Vomiting and abdominal colic may occur if it is injected too rapidly. Other adverse effects reported include agranulocytosis, hypertension, peripheral neuropathy, proteinuria, severe diarrhoea, myocardial damage, exfoliative dermatitis, and renal and hepatic disturbances.

Precautions

Use of melarsoprol in febrile patients has been associated with an increased incidence of reactive encephalopathy, and therefore it should not be given during epidemics of influenza. Intercurrent infections such as malaria and pneumonia should be treated before melarsoprol is used. Severe haemolytic reactions have been reported in patients with G6PD deficiency. It may precipitate erythema nodosum when given to patients with leprosy.

Patients should be in hospital when they are treated with melarsoprol and dosage decided after taking into account their general condition.

Treatment of pregnant women with trypanosomiasis should be deferred until after delivery. Pregnant women with meningoencephalitis may be treated with pentamidine (*Trypanosoma brucei gambiense*) or suramin (*T. b. rhodesiense*).

Pharmacokinetics

Melarsoprol is reported to be unreliably absorbed if given orally and is usually given by intravenous injection. A small amount penetrates into the CSF where it has a local trypanocidal action. It is a prodrug and is rapidly metabolised to the active form, melarsen oxide. Melarsoprol itself has a plasma half-life of 30 minutes and is excreted in the faeces and urine.

The pharmacokinetics of melarsoprol have not been fully evaluated. Using biological assay and atomic absorption spectrometry, the terminal half-life of melarsoprol was originally calculated to be 35 hours and low trypanocidal activity was detected in the CSF. These methods, however, cannot distinguish melarsoprol from other substances such as melarsoprol metabolites that also have trypanocidal activity. When the terminal half-life was calculated by high-performance liquid chromatography (HPLC), melarsoprol was found to be eliminated from the plasma within 1 hour.[1,2] Based on these findings it is thought that melarsoprol is rapidly eliminated from the plasma and transformed into metabolites with trypanocidal activity.[1] Melarsen oxide has been identified by HPLC as a metabolite; the peak plasma concentration was reached 15 minutes after a dose and the half-life of free melarsen oxide was 3.9 hours.[2]

Acrichinum; Acrinamine; Antimalarinae Chlorhydras; Chinacrina; Hidrocloruro de atatabrina; Hidrocloruro de mepacrina; Hidrocloruro de quinacrina; Mepacrina, hidrocloruro de; Mépacrine, Chlorhydrate de; Mepacrini Hydrochloridum; Mepakrin Hidroklorür; Quinacrine Hydrochloride; Менакрина Гидрохлорид.

6-Chloro-9-(4-diethylamino-1-methylbutylamino)-2-methoxyacridine dihydrochloride dihydrate.

$C_{23}H_{30}ClN_3O,2HCl,2H_2O$=508.9

CAS — 83-89-6 (mepacrine); 69-05-6 (anhydrous mepacrine dihydrochloride); 6151-30-0 (mepacrine dihydrochloride dihydrate).

ATC — P01AX05.

UNII — G6242H2NAA (mepacrine hydrochloride dihydrate); 81A613ZZ6X (anhydrous mepacrine hydrochloride).

Uses and Administration

Mepacrine is a 9-aminoacridine antiprotozoal used as the hydrochloride mainly as an alternative to the nitroimidazoles in the treatment of giardiasis (p. 921.3).

In giardiasis, mepacrine hydrochloride is given orally in doses of 100 mg three times daily after food for 5 to 7 days.

For details of doses in children, see below.

Mepacrine hydrochloride may also be used for the treatment of some cutaneous forms of lupus erythematosus and for SLE (see below). It has also been used locally in the treatment of some forms of cutaneous leishmaniasis, as a sterilisation technique for contraception, and in the management of malignant pleural effusions. For further information on such uses see below. It was formerly used to treat malaria.

The mesilate was also formerly used.

Mepacrine is under investigation for the treatment of variant Creutzfeldt-Jakob Disease.

Administration in children. As an alternative drug for the treatment of giardiasis, mepacrine hydrochloride may be given orally to children at a dose of 2 mg/kg three times daily after food (to a maximum 300 mg daily) for 5 days.

Contraception. Sterilisation with intra-uterine mepacrine has been attempted as an irreversible method of contraception (p. 2232.3). It produces occlusion of the fallopian tube and has been reported to be an effective non-surgical means of female sterilisation,[1] although it may be less effective than other methods.[2] There has been speculation about the risk of cancer from this technique but there appeared to be no evidence to confirm such a risk.[3-5] However, the method remains controversial and a full evaluation of its safety and efficacy has been recommended.[6] The Indian government has banned the use of mepacrine for sterilisation.[7]

Leishmaniasis. Mepacrine has historically been suggested for intralesional injection in the treatment of early noninflamed nodular lesions of cutaneous leishmaniasis (p. 922.1) due to *Leishmania tropica, L. major, L. mexicana, L. panamensis,* or *L. peruviana.*[1] The suggested course of treatment was 3 intralesional injections of a 5% solution of mepacrine given at intervals of 3 to 5 days. However, local infiltration of drugs can be difficult and painful.

Lupus erythematosus. Mepacrine may be added to the treatment regimen of patients with some forms of cutaneous lupus erythematosus. Treatment is usually started with hydroxychloroquine and if no improvement occurs after about 2 months mepacrine is added at an initial dosage of 100 mg daily. If this combination treatment is effective the dose of both drugs may be decreased after 1 month to reduce any adverse effects. Chloroquine may be used as an alternative to hydroxychloroquine and can also be combined with mepacrine.[1,2] Mepacrine has also been used as monotherapy, in a similar dose, in patients with visual disorders in whom treatment with hydroxychloroquine or chloroquine was considered unsuitable.[2]

Mepacrine has also been used as an alternative to standard treatments in SLE (p. 1613.3). A small study[3] reported that 5 of 6 patients with SLE unresponsive to treatment with hydroxychloroquine plus prednisone and either azathioprine or methotrexate, had complete remission of their disease when mepacrine (100 mg daily) was added to their existing treatment. Other small studies[4,5] in patients with stable SLE disease found that the addition of mepacrine to their current treatment reduced the SLE disease activity index and lowered serum levels of B lymphocyte activating factor and anticardiolipin antibody titres in some patients.

Sclerotherapy. Intrapleural instillations of mepacrine hydrochloride or mesilate have been used as sclerosants in the management of malignant pleural effusions (p. 700.1) and recurrent pneumothorax but the treatment is associated with pain and a high frequency of toxic effects.

Adverse Effects

The most common adverse effects associated with mepacrine are dizziness, headache, and gastrointestinal disturbances such as nausea and vomiting. Reversible yellow discoloration of the skin, conjunctiva, and urine may occur during long-term use or after large doses; blue/black discoloration of the palate and discoloration of the nails have also been reported. Doses such as those used in the treatment of giardiasis may occasionally cause transient acute toxic psychosis. CNS stimulation and convulsions have been reported at high parenteral doses. Retinopathy similar to that seen with chloroquine (p. 651.2) and chronic dermatoses, including severe exfoliative dermatitis and lichenoid eruptions, have also occurred after prolonged use of mepacrine. Aplastic anaemia has also been reported after long term use, often preceded by such dermatoses. Hepatitis and hepatic necrosis occur rarely.

Effects on the nervous system. Two patients had convulsions a few hours after mepacrine hydrochloride 400 mg was given intrapleurally for malignant effusions.

One developed status epilepticus and died and the other was successfully treated with anticonvulsants.[1]

1. Borda I, Krant M. Convulsions following intrapleural administration of quinacrine hydrochloride. *JAMA* 1967; 201: 1049–50.

Precautions

Mepacrine should be used with caution in elderly patients or patients with a history of psychosis, or in the presence of hepatic disease. Mepacrine can cause exacerbation of psoriasis and should be avoided in psoriatic patients.

Interactions

Mepacrine has been reported to produce a mild disulfiram-like reaction (see p. 2496.1) when taken with alcohol.

Theoretically, mepacrine may increase the plasma concentrations of primaquine resulting in a higher risk of toxicity, and it has been recommended that these drugs should not be used together.

Pharmacokinetics

Mepacrine is readily absorbed from the gastrointestinal tract and peak plasma concentrations occur in 1 to 3 hours. It is widely distributed throughout the body. It accumulates in body tissues, particularly the liver, and is liberated slowly. Protein binding is 85%. It is excreted slowly mainly in the urine, with an elimination half-life of 5 days, and is still detectable in the urine after 2 months. Mepacrine crosses the placenta.

Intrapleural administration. Peak plasma concentrations of mepacrine far above those associated with CNS effects were rapidly attained in 3 of 4 patients after intrapleural instillation of a solution of mepacrine hydrochloride and remained at these levels for several hours.[1]

$C_6H_9N_3O_3$.HCl=207.6

CAS — 69198-10-3.

ATC — A01AB17; D06BX01; G01AF01; J01XD01; P01AB01.

ATC Vet — QA01AB17; QD06BX01; QG01AF01; QJ01XD01; QP51AA01.

UNII — 76JC1633UF.

Incompatibility. Solutions of metronidazole hydrochloride have a low pH, usually of less than 2.0, before dilution and neutralisation for intravenous use. These undiluted solutions react with aluminium in equipment such as needles and produce reddish-brown discoloration, and a precipitate has been reported with ready-to-use preparations of metronidazole hydrochloride, although this occurred after contact for 6 hours or more.[1,2]

Several studies have assessed the compatibility of antibacterial injections and other drugs when added to metronidazole solution for intravenous infusion.[3-7] Results have varied according to the criteria applied and the preparations and conditions used. Physical incompatibilities due to the low pH of metronidazole injections appear to be more of a problem than chemical incompatibility. Regardless of these studies, it is generally recommended that other drugs should not be added to intravenous solutions of metronidazole or its hydrochloride. Specific information on the compatibility of individual formulations may be found in the manufacturers' literature.

Uses and Administration

Metronidazole is a 5-nitroimidazole derivative with activity against anaerobic bacteria and protozoa (see Antimicrobial Action, p. 939.3); it also has a radiosensitising effect and has been tried in the treatment of malignant neoplasms. Its mechanism of action is thought to involve interference with DNA by a metabolite in which the nitro group of metronidazole has been reduced.

Metronidazole is used in the treatment of susceptible protozoal infections such as amoebiasis, balantidiasis, *Blastocystis hominis* infections, giardiasis, and trichomoniasis; it has also been tried in leishmaniasis and microsporidiosis. For details of these infections and their treatment see under Choice of Antiprotozoal, p. 919.1. Metronidazole is also used in the treatment and prophylaxis of anaerobic bacterial infections. Specific bacterial infections treated with metronidazole include acute necrotising ulcerative gingivitis, bacterial vaginosis, pelvic inflammatory disease, urethritis (nongonococcal), tetanus, and antibiotic-associated colitis. For details of these infections and their treatment see under Choice of Antibacterial, p. 172.2.

Metronidazole is used to eradicate *Helicobacter pylori* in peptic ulcer disease (with other antimicrobials, and either bismuth compounds or proton pump inhibitors) and in the management of malodorous tumours and ulcers where there is anaerobic infection. It is also used in the treatment of rosacea and of dracunculiasis (guinea-worm infection) and has been given orally in the treatment of hepatic encephalopathy and perianal Crohn's disease; a topical ointment containing 10% metronidazole is also used in investigation for the treatment of perianal Crohn's disease. See also below for these miscellaneous uses.

ADMINISTRATION AND DOSAGE. Metronidazole is given orally in tablets, capsules, or extended release tablets or, as metronidazole benzoate, in oral suspension; the tablets are taken with or after food and the suspension at least 1 hour before food. Extended-release tablets should be given at least 1 hour before or 2 hours after meals. Metronidazole is also given rectally in suppositories, intravaginally as a gel or cream, applied topically as a cream or gel, or given by intravenous infusion of metronidazole or metronidazole hydrochloride. Doses are expressed in terms of metronidazole base.

In **amoebiasis**, metronidazole acts as an amoebicide at all sites of infection with *Entamoeba histolytica*. Because of its rapid absorption it is probably less effective against parasites in the bowel lumen and is therefore used with a luminal amoebicide such as diloxanide furoate or diiodohydroxyquinoline in the treatment of symptomatic (invasive) amoebiasis. For the treatment of invasive intestinal amoebiasis, metronidazole is given in oral doses of 800 mg every 8 hours for 5 days; for extra-intestinal amoebiasis (including liver abscess) a dose of 400 to 800 mg every 8 hours for 5 to 10 days is given.

In **balantidiasis** and ***Blastocystis hominis* infection**, metronidazole has been given orally in a dose of 750 mg three times daily for 5 and 10 days, respectively.

In **giardiasis**, the usual oral dose of metronidazole is 2 g once daily for 3 successive days, or 400 mg three times daily for 5 days, or 500 mg twice daily for 7 to 10 days.

In **trichomoniasis**, metronidazole is given orally either as a single 2-g dose, as a 7-day course of 200 mg every 8 hours, or at a dose of 400 to 500 mg every 12 hours for 5 to 7 days. Sexual partners should also be treated. If treatment needs to be repeated, an interval of 4 to 6 weeks between courses has been recommended. Vaginal preparations containing metronidazole are available for the treatment of vaginal trichomoniasis in some countries.

Bacterial vaginosis is treated similarly to vaginal trichomoniasis with which it may co-exist; metronidazole is usually given orally as a single 2-g dose or as a 5 to 7-day course of 400 or 500 mg twice daily. Alternatively it may be applied locally as 5 g of a 0.75% gel once or twice daily for 5 days.

In **acute necrotising ulcerative gingivitis**, metronidazole 200 to 250 mg three times daily is given orally for 3 days; similar doses are used in acute oral infections. A 25% dental gel has also been used as an adjunct to the treatment of chronic periodontal infections.

For the treatment of most **anaerobic bacterial infections**, metronidazole is given orally in an initial dose of 800 mg followed by 400 mg every 8 hours, usually for about 7 days. A regimen of 500 mg every 8 hours is an alternative. When oral therapy is precluded metronidazole may be given intravenously, 500 mg being infused as 100 mL of a 5 mg/mL solution at a rate of 5 mL/minute every 8 hours, or rectally as a 1-g suppository every 8 hours for 3 days; if rectal use needs to be continued for more than 3 days, the dose should be reduced to 1 g 12 hourly. Alternative adult doses of metronidazole are 7.5 mg/kg every 6 to 8 hours orally or 15 mg/kg by intravenous infusion followed by 7.5 mg/kg every 6 hours, doses being infused over 1 hour; by either route a total dose of 4 g in 24 hours should not be exceeded. In mixed anaerobic and aerobic infections metronidazole is given with the appropriate antibacterials.

For details of doses in children, see p. 937.1.

For the **prevention of postoperative anaerobic bacterial infections**, especially in patients undergoing abdominal or gynaecological surgery, metronidazole is given orally, intravenously, or rectally in doses similar to those used for treatment, usually with a beta-lactam or an aminoglycoside antibacterial. Various schedules have been employed. In the UK, licensed doses for adults are:

- orally 400 mg every 8 hours in the 24 hours before surgery followed postoperatively by intravenous or rectal dosage until oral therapy is possible
- by intravenous infusion, 500 mg shortly before operation and repeated every 8 hours, oral doses of 200 or 400 mg every 8 hours being substituted as soon as possible
- by rectum, 1 g every 8 hours starting 2 hours before surgery.

The *BNF*, however, recommends that oral doses should be started only 2 hours before the operation and that the

number of doses for all dose routes be limited to a total of four. In the USA the recommended schedule for adults undergoing colorectal surgery is metronidazole 15 mg/kg by intravenous infusion over 30 to 60 minutes, completed about 1 hour before surgery, followed by two further intravenous doses of 7.5 mg/kg infused at 6 and 12 hours after the initial dose.

In **peptic ulcer disease**, metronidazole is used in combination therapy to eradicate *Helicobacter pylori*. Typical regimens include metronidazole plus another antibacterial (clarithromycin or amoxicillin) and a proton pump inhibitor. The usual dose of metronidazole is 400 mg twice daily except when given with omeprazole and amoxicillin, when metronidazole 400 mg three times daily is used. Initial treatment is given for 1 week.

For **leg ulcers** and **pressure sores** infected with anaerobic bacteria, oral metronidazole 400 mg may be given three times daily for 7 days. Metronidazole is also applied topically as a 0.75% or 0.8% gel to reduce the odour associated with anaerobic infection in **fungating tumours**.

In the treatment of **rosacea** metronidazole is given orally or applied topically.

General references.

Administration in children. Metronidazole may be given to children for the treatment of susceptible protozoal infections and also in the treatment and prophylaxis of anaerobic bacterial infections.

In **invasive intestinal amoebiasis** and **extra-intestinal amoebiasis**, the *BNFC* recommends oral metronidazole, for 5 days for intestinal infection or 5 to 10 days for extra-intestinal infection, in the following doses:

- children aged 1 to 3 years: 200 mg 3 times daily
- those aged 3 to 7 years: 200 mg 4 times daily
- those aged 7 to 10 years: 400 mg 3 times daily
- those more than 10 years: 800 mg 3 times daily

Alternatively experts in the USA[1] recommend oral metronidazole 35 to 50 mg/kg daily in 3 divided doses for 7 to 10 days.

In **giardiasis**, the *BNFC* recommends oral metronidazole in the following doses:

- children aged 1 to 3 years: 500 mg once daily for 3 days
- those aged 3 to 7 years: 600 to 800 mg once daily for 3 days
- those aged 7 to 10 years: 1 g once daily for 3 days
- those aged more than 10 years: 2 g once daily for 3 days, or 400 mg 3 times daily for 5 days, or 500 mg twice daily for 7 to 10 days

Alternatively experts in the USA[1] recommend oral metronidazole 15 mg/kg daily in 3 divided doses for 5 to 7 days.

In **trichomoniasis**, the *BNFC* recommends oral metronidazole in the following doses:

- children aged 1 to 3 years: 50 mg 3 times daily for 7 days
- those aged 3 to 7 years: 100 mg twice daily for 7 days
- those aged 7 to 10 years: 100 mg 3 times daily for 7 days
- those more than 10 years: 200 mg 3 times daily for 7 days or 400 to 500 mg twice daily for 5 to 7 days, or 2 g as a single dose

Alternatively experts in the USA[1] recommend oral metronidazole 15 mg/kg daily in 3 divided doses for 7 days.

For the treatment of most **anaerobic bacterial infections**, the *BNFC* recommends metronidazole is given (usually for 7 days but for 10 to 14 days in antibiotic-associated colitis) in the following doses:

- neonates: 7.5 mg/kg by intravenous infusion every 12 hours
- children 1 to 2 months of age: 7.5 mg/kg orally every 12 hours, *or* 7.5 mg/kg by intravenous infusion every 12 hours
- children aged 2 months and older: 7.5 mg/kg orally (to a maximum of 400 mg) every 8 hours, *or* 7.5 mg/kg by intravenous infusion (to a maximum of 500 mg) every 8 hours

or alternatively

- rectal doses may be given 3 times daily for 3 days, then twice daily thereafter in the following doses: children aged 1 month to 1 year may be given 125 mg, those 1 to 5 years, 250 mg, those 5 to 10 years, 500 mg, and those more than 10 years may be given 1 g

Alternative doses recommended by the American Academy of Pediatrics[2] are:

- for neonates aged ≤7 days and weighing ≤2 kg: a loading dose of 15 mg/kg followed by 7.5 mg/kg given intravenously every 24 to 48 hours; a dosing interval of 48 hours is suggested for extremely low birth-weight neonates (weighing less than 1 kg)
- for neonates aged ≤7 days and weighing >2 kg: 15 mg/kg given intravenously every 24 hours
- for neonates aged 8 to 28 days and weighing ≤2 kg: 15 mg/kg given intravenously every 24 hours; a dosing interval of 48 hours may be used until 2 weeks of life in extremely low birth-weight neonates (weighing less than 1 kg)
- for neonates aged 8 to 28 days and weighing >2 kg: 15 mg/kg given intravenously every 12 hours
- children 1 month and older: 30 to 50 mg/kg given orally in 3 divided doses (to a maximum daily dose of 0.75 to 2.25 g) *or* 22.5 to 40 mg/kg given intravenously in 3 divided doses (to a maximum daily dose of 1.5 g)

Administration in hepatic impairment. Since metronidazole is mainly metabolised by hepatic oxidation, accumulation of metronidazole and its metabolites is likely in patients with severely impaired hepatic function. Metronidazole should therefore be given with caution and at reduced doses to patients with severe hepatic impairment, and especially hepatic encephalopathy when adverse affects of metronidazole can add to the symptoms of the disease. One-third of the usual daily dose may be given once daily in these patients. For patients with lesser degrees of hepatic impairment, pharmacokinetic studies have not produced consistent results (see under Pharmacokinetics, p. 940.2) and no recommendations about dosage reduction have been made in either the UK or US licensed product information.

Administration in renal impairment. The elimination of metronidazole is largely unchanged in patients with renal impairment, although metabolites may accumulate in patients with end-stage renal disease on dialysis (see under Pharmacokinetics, p. 940.2). Dosage reductions are therefore not usually recommended for patients with renal impairment or for those undergoing peritoneal dialysis. However, both metronidazole and its metabolites are removed by haemodialysis, doses need to be given immediately after haemodialysis.

Dracunculiasis. Metronidazole may be beneficial in the management of dracunculiasis (p. 145.1). It provides symptomatic relief and is also thought to weaken the anchorage of the worms within subcutaneous tissue, thus allowing them to be removed more quickly.

Metronidazole has been given in a variety of regimens, including doses of 400 mg three times daily for 5 days,[1] 40 mg/kg daily in three divided doses (to a maximum daily dose of 2.4 g) for 3 days,[2] and 400 mg daily for 10 to 20 days.[3] WHO recommends 25 mg/kg daily for 10 days;[4] a dose of 250 mg three times daily for 10 days has also been recommended.

Hepatic encephalopathy. The treatment of hepatic encephalopathy is discussed on p. 1811.2. It includes the use of an antimicrobial such as metronidazole to reduce the intestinal flora.

Inflammatory bowel disease. Oral metronidazole is used in the treatment of perineal Crohn's disease (see Inflammatory Bowel Disease, p. 1811.3) and may also be used in colonic Crohn's disease, when it has been tried with ciprofloxacin. It has also proved effective for the prevention of postsurgical recurrence. Duration of therapy is usually limited to 3 months.

Metronidazole ointment is being investigated in the management of perianal Crohn's disease.[1]

1. Maeda Y, *et al.* Randomized clinical trial of metronidazole ointment versus placebo in perianal Crohn's disease. *Br J Surg* 2010; **97**: 1340–7.

Metabolic disorders. Children with excesses of methylmalonic[1-3] and propionic[3,4] acid in their blood or urine have shown clinical improvement when given metronidazole, which reduced the excretion of faecal propionate and urinary methylmalonate. Metronidazole is considered to act through its antimicrobial effect on gut anaerobes that are involved in propionate production; such propionate cannot be handled by these children who are deficient in the relevant enzyme.

2. Cecchin E, *et al.* Treatment of cyclosporine-induced gingival hypertrophy. *Ann Intern Med* 1997; **126**: 409–10.

Peptic ulcer disease. The use of metronidazole is well established in regimens for eradicating *Helicobacter pylori* (see Peptic Ulcer Disease, p. 1816.2). However, the emergence of metronidazole-resistant strains of *H. pylori* has been associated with an increased rate of treatment failures with some regimens.[1-4] The *Helicobacter pylori* Antimicrobial Resistance Monitoring Program (HARP) in the USA[5] reported about a 25% metronidazole resistance rate in clinical *H. pylori* isolates collected from December 1998 through 2002. Difficulties arise in assessing metronidazole resistance and in correlating *in-vitro* results with clinical response.[6] In populations in which the incidence of resistance is high, it may become necessary to use alternative regimens,[7] but in other areas, such as the UK, regimens including metronidazole continue to be among the standard alternatives (although the *BNF* recommends that they should not be used for initial treatment in patients who have been given metronidazole for other infections).

Skin disorders. Metronidazole may be effective in the management of malodorous anaerobic skin infections associated with ulceration (p. 207.1), including *pressure sores* and *fungating tumours*. Both the oral and topical routes have been employed but the evidence in favour of its use is largely anecdotal as few randomised controlled studies have yet been performed.[1,2]

Metronidazole has also been used[3] in the treatment of *rosacea* (p. 1688.3). Oral metronidazole 200 mg twice daily was more effective than placebo[4] and as effective as oral oxytetracycline.[5] Similarly, topical preparations (for example, 0.75% cream, gel, or lotion or 1% cream) have been found to be better than placebo and as effective as oral oxytetracycline.[6,7]

Oral metronidazole has been tried in the management of *lichen planus*.[8]

Surgical infection. Metronidazole and related nitroimidazoles are used in surgical infection prophylaxis (p. 209.1) to reduce the rate of wound infection.

HAEMORRHOIDECTOMY. Prophylactic metronidazole reduced pain after haemorrhoidectomy in a small study.[1]

1. Carapeti EA, *et al.* Double-blind randomised controlled trial of effect of metronidazole on pain after day-case haemorrhoidectomy. *Lancet* 1998; **351**: 169–72.

Adverse Effects

The adverse effects of metronidazole are generally dose-related. The most common are gastrointestinal disturbances, especially nausea and an unpleasant metallic taste. Abdominal pain, anorexia, vomiting, and diarrhoea or constipation may also occur. A furred tongue, glossitis, and
