Sarcoidosis. Chloroquine and hydroxychloroquine have been tried in the management of sarcoidosis (p. 1612.2) as alternatives or adjuncts to corticosteroid therapy. For references to the use of hydroxychloroquine, see under Chloroquine, p. 651.1.

Skin disorders. For reference to the use of hydroxychloroquine in a variety of skin disorders, see under Chloroquine, p. 651.2.

Systemic lupus erythematosus. Antimalarials have been widely used in the treatment of lupus erythematosus (p. 1613.3), particularly its cutaneous manifestations, although much of the evidence is based on case series and reports.[1] Hydroxychloroquine is most widely used,[1,2] as it is thought to have fewer adverse effects than chloroquine, although any benefit with chloroquine generally starts to become evident within several weeks of starting treatment, whereas it may take up to 2 months for any effect of hydroxychloroquine to be seen. For extracutaneous disease, antimalarials are often combined with other drugs; treatment may be continued for many years. For reference to precautions to reduce the risk of retinopathy see Effects on the Eyes, under Adverse Effects of Chloroquine, p. 651.2. There is evidence from a case-control study[3] that long-term hydroxychloroquine treatment is associated with improved survival in patients with SLE, and some consider it to be underused.[2] It has been suggested that hydroxychloroquine may also have a role in reducing the thrombotic symptoms of SLE, including in patients with antiphospholipid syndrome.[4]

4. Petri M. Use of hydroxychloroquine to prevent thrombosis in systemic lupus erythematosus and in antiphospholipid antibody-positive patients. *Curr Rheumatol Rep* 2011; 13: 77–80.

Venous thromboembolism. Standard prophylaxis for surgical patients at high risk of venous thromboembolism (p. 1274.1) is usually with an anticoagulant. Hydroxychloroquine has been described by some as an antiplatelet agent[1] and although its mechanism of action is uncertain the incidence of fatal pulmonary embolism has been reduced in patients given hydroxychloroquine prophylactically after total hip replacement;[2] the usual daily divided oral dose was about 800 mg from the day before surgery until discharge; larger doses had been used.

Adverse Effects, Treatment, and Precautions

As for Chloroquine, p. 651.2.

Breast feeding. Hydroxychloroquine has been detected in human breast milk[1,2] but no adverse effects have been seen in breast-fed infants and the American Academy of Pediatrics considers[3] that it is therefore usually compatible with breast feeding.

Effects on the eyes. The main adverse effects of chloroquine and hydroxychloroquine on the eye are keratopathy and retinopathy. With respect to retinopathy, precautions should be taken in patients undergoing long-term treatment, as described under Chloroquine on p. 651.2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies hydroxychloroquine as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

For a discussion of the use of other antimalarials in patients with porphyria, see under Precautions for Chloroquine, p. 653.1.

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 10/10/11)

Pregnancy. In a study[1] of 133 pregnancies in 90 women treated with hydroxychloroquine, no statistical difference in pregnancy outcome was found compared with a control group consisting of 70 pregnancies in 53 women. It was concluded that the findings supported preliminary evidence for the safety of hydroxychloroquine treatment in pregnancy, and that treatment should probably therefore be maintained during pregnancy in patients with SLE. A later systematic review[2] also concluded that there was no increased risk of congenital defects, spontaneous abortion, fetal death or prematurity associated with use of hydroxychloroquine for auto-immune diseases during pregnancy.

Pharmacopoeias. In *Chin.*

Uses and Administration

Lumefantrine is a dichlorobenzylidine derivative given orally with artemether (p. 648.1) for the treatment of uncomplicated falciparum malaria (p. 644.1). In some countries, the combination is also used for the treatment of chloroquine-resistant non-falciparum malaria. Lumefantrine is a blood schizontocide with a relatively slow onset of action but it has a longer duration of action than artemether. The combination is given as a six-dose regimen, with each dose containing lumefantrine 480 mg and artemether 80 mg. The first dose is given at initial diagnosis, with subsequent doses given after 8, 24, 36, 48, and 60 hours; it has been suggested that doses be given after a milky drink or fat-containing food to ensure adequate absorption.

For details of dosing in children, see below.

3. Kokwaro G, *et al.* Artemether/lumefantrine in the treatment of uncomplicated falciparum malaria. *Expert Opin Pharmacother* 2007; 8: 75–94.
4. Adjei GO, *et al.* Artemether-lumefantrine: an oral antimalarial for uncomplicated malaria in children. *Expert Rev Anti Infect Ther* 2009; 7: 669–81.
5. Ngasala BE, *et al.* Efficacy and effectiveness of artemether-lumefantrine after initial and repeated treatment in children < 5 years of age with acute uncomplicated *Plasmodium falciparum* malaria in rural Tanzania: a randomized trial. *Clin Infect Dis* 2011; 52: 873–82.

Administration in children. Lumefantrine may be given orally to infants and children, with artemether, for the treatment of **uncomplicated falciparum malaria**. In some countries, the combination is also used for the treatment of **chloroquine-resistant non-falciparum malaria**. A total of 6 doses are given, starting at diagnosis and repeated after 8, 24, 36, 48, and 60 hours; recommended doses according to body-weight are as follows:

- 5 to 14 kg: lumefantrine 120 mg with artemether 20 mg
- 15 to 24 kg: lumefantrine 240 mg with artemether 40 mg
- 25 to 34 kg: lumefantrine 360 mg with artemether 60 mg
- over 35 kg: as for adults (see above)

It has been suggested that doses be given after a milky drink or fat-containing food to ensure adequate absorption.

Adverse Effects and Precautions

Adverse effects associated with the combination of lumefantrine with artemether commonly include headache, dizziness, sleep disturbance, palpitations, gastrointestinal disturbances, anorexia, pruritus, rash, cough, arthralgia, myalgia, and fatigue.

Lumefantrine-artemether may cause prolongation of the QT interval, and therefore should be avoided in patients with serum-potassium or magnesium disturbances, any clinical condition known to prolong the QT interval (such as congenital long QT syndrome, symptomatic cardiac arrhythmia, or severe heart failure), or a family history of sudden cardiac death.

Lumefantrine-artemether should be given with caution in severe hepatic or renal impairment and ECG and blood potassium monitored.

Effects on the blood. Severe haemolytic anaemia necessitating corticosteroid treatment, blood transfusion, and haemodialysis occurred in a patient after taking 8 lumefantrine-artemether tablets after a malarial attack.[1] It was considered that, given its molecular similarity to other antimalarials known to cause haemolysis, the causative drug was probably lumefantrine.

1. Mérat S, *et al.* Case report: combination artemether-lumefantrine and haemolytic anaemia following a malarial attack. *Trans R Soc Trop Med Hyg* 2003; 97: 433–4.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies the combination of lumefantrine plus artemether as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

For a discussion of the use of other antimalarials in patients with porphyria, see under Precautions for Chloroquine, p. 653.1.

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 12/10/11)

Interactions

Use of lumefantrine-artemether should be avoided in patients who are using other drugs known to prolong the QT interval (such as halofantrine, quinine, and mefloquine). For patients previously treated with halofantrine, licensed product information recommends that at least a month should pass before starting lumefantrine-artemether. The combination is also considered contra-indicated in patients taking any drugs that are metabolised by the cytochrome enzyme CYP2D6, particularly those with cardiac effects (including amitriptyline, clomipramine, flecainide, imipramine, and metoprolol). Given the long elimination half-life of lumefantrine (see Pharmacokinetics, below), care must also be taken when starting potentially interacting medications soon after lumefantrine has been stopped.

Pharmacokinetics

The bioavailability of lumefantrine after oral doses is variable; absorption begins after a lag-time of up to 2 hours and bioavailability is substantially increased when given with food, particularly meals high in fat. Peak plasma concentrations occur after about 6 to 8 hours. Lumefantrine is almost completely protein bound. It is considered to be metabolised mainly in the liver and is excreted in the faeces. The elimination half-life is reported to be between 4 to 6 days in patients with malaria.

Uses and Administration

Mefloquine is a 4-methanolquinoline antimalarial related to quinine. It is a blood schizontocide effective against all forms of malaria including chloroquine- or multidrug-resistant strains of *Plasmodium falciparum*, although some strains are naturally resistant to mefloquine. It is used for the treatment of uncomplicated falciparum malaria and chloroquine-resistant vivax malaria, and also for malaria prophylaxis (see below). Mefloquine is also used after treatment with an artemisinin derivative for acute uncomplicated malaria, to reduce the risk of recrudescence.

Mefloquine is given orally as the hydrochloride but variation in the way doses are expressed could lead to confusion. In the UK and elsewhere, doses are expressed in terms of the base and a dose of 250 mg base is equivalent to about 274 mg of mefloquine hydrochloride. In the USA, doses are expressed in terms of the hydrochloride and a dose of 250 mg is therefore equivalent to only about 228 mg of mefloquine base. Doses in the USA could therefore be about 10% less than elsewhere.

For the *treatment of uncomplicated malaria in non-immune travellers*, WHO recommends 25 mg/kg of mefloquine base given in a split-dose regimen of 15 mg/kg initially, followed by 10 mg/kg 6 to 24 hours later. However, the *BNF* notes that mefloquine is rarely used for treatment of falciparum malaria or chloroquine-resistant non-falciparum malarias due to concern about resistance and, in the case of the non-falciparum malarias, the availability of better tolerated treatments.

For the *treatment of uncomplicated falciparum malaria in endemic areas*, WHO recommends that mefloquine 25 mg/kg be given with a 3-day course of artesunate (see p. 648.2); the mefloquine dose may be given as the split-dose regimen above, or as 8.3 mg/kg once daily for 3 days.

For the *prophylaxis* of malaria, a once-weekly dose of 250 mg mefloquine base has been recommended; prophylaxis should start at least 1 week, but preferably 2 to 3 weeks before entering the malarious area and continue for 4 weeks after leaving.

For further information, and for details of dosing in children, see below.

Administration in children. Mefloquine may be given orally to infants and children for malaria prophylaxis, as well as for the treatment of uncomplicated falciparum malaria and chloroquine-resistant vivax malaria, although it is not licensed for use in children under 3 months of age or weighing less than 5 kg.

For the **treatment of uncomplicated malaria in non-immune travellers**, WHO[1] recommends 25 mg/kg of mefloquine base given in a split-dose regimen of 15 mg/kg initially, followed by 10 mg/kg 6 to 24 hours later.

For the **treatment of uncomplicated falciparum malaria in endemic areas**, WHO[2] recommends that mefloquine 25 mg/kg be given with a 3-day course of artesunate (see p. 648.2); the mefloquine dose may be given as the split-dose regimen above, or as 8.3 mg/kg once daily for 3 days.

Recommended doses for **prophylaxis** are generally based on 5 mg/kg of mefloquine base as a single weekly dose in children weighing over 5 kg.[1] Typical once-weekly doses used in the UK[3] for infants and children from 5 kg bodyweight and over 3 months of age are as follows:

- 5 to 15.9 kg (3 months to 3 years 11 months): 62.5 mg
- 16 to 24.9 kg (4 years to 7 years 11 months): 125 mg
- 25 to 44.9 kg (8 years to 12 years 11 months): 187.5 mg
- 45 kg and over: the adult dose (see above)

Malaria. The overall treatment and prophylaxis of malaria and the place of mefloquine in current recommendations are discussed on p. 644.1.

TREATMENT. Clinical studies have shown mefloquine to be effective in the treatment of chloroquine- or multidrug-resistant falciparum malaria. It is also effective in non-falciparum malarias, but is not normally required since they usually respond to chloroquine.

Mefloquine has been widely used as an alternative to regimens using quinine for the treatment of chloroquine-resistant or multidrug-resistant strains of *Plasmodium falciparum*. It is now also used with an artemisinin derivative in multidrug resistance (see p. 649.1).

As there is no parenteral formulation of mefloquine currently available it can only be used in patients who can take oral medication and is therefore unsuitable for sole treatment in severe infections. Mefloquine has produced adequate blood concentrations by the nasogastric route, but this route cannot be relied upon in seriously ill patients.[1] If mefloquine is given to patients after parenteral doses of quinine, it is recommended that a period of 12 hours should be allowed after the last dose of quinine to avoid toxicity.

WHO[2] considers that drugs used for the treatment of uncomplicated falciparum malaria may in principle be carried as a *standby* for use in similar doses for the emergency self-treatment of malaria, although mefloquine is not recommended by WHO as a first-line regimen.

PROPHYLAXIS. It had been hoped that mefloquine could be reserved for the treatment of malaria, but increasing drug resistance to chemoprophylactic regimens has led to it being widely used for malaria prophylaxis.[3] WHO recommends[2] that mefloquine should be used where there is a high risk of falciparum malaria and drug resistance or a moderate to low risk but with high drug resistance. The equivalent of 250 mg of mefloquine base is given every week, starting 1 to 3 weeks before departure, and continuing throughout the period of exposure and for 4 weeks after leaving the malarious area. Starting mefloquine prophylaxis 2 to 3 weeks before exposure allows for detection of possible adverse effects before travelling (see Effects on the Nervous System, p. 658.1, for concerns about neurotoxicity). It is now considered that mefloquine prophylaxis can be given for periods of up to one year instead of the previous limit of 3 months.

In the event of breakthrough malaria during malaria prophylaxis there may be a delay of up to several months before the onset of symptoms in contrast to that seen with other forms of prophylaxis.[4] Mefloquine should not be used for treatment if it has been used for prophylaxis.

4. Day JH, Behrens RH. Delay in onset of malaria with mefloquine prophylaxis. *Lancet* 1995; 345: 398.

Schistosomiasis. A combination of mefloquine plus artesunate (p. 648.2) has been investigated for use in the treatment of schistosomiasis (p. 148.1). In a randomised, open-label study,[1] mefloquine 250 mg plus artesunate 100 mg both given orally once daily for 3 days resulted in a cure rate of 61% among schoolchildren infected with *Schistosoma haematobium*; high cure rates and egg reduction rates were also seen in children coinfected with *S. mansoni*.

1. Keiser J, *et al.* Efficacy and safety of mefloquine, artesunate, mefloquine-artesunate, and praziquantel against *Schistosoma haematobium*: randomized, exploratory open-label trial. *Clin Infect Dis* 2010; 50: 1205–13.

Adverse Effects

Since mefloquine has a long elimination half-life, adverse effects may occur or persist up to several weeks after the last dose.

The most frequent adverse effects of mefloquine are nausea, diarrhoea, vomiting, abdominal pain, anorexia, headache, somnolence, and sleep disorders, notably insomnia and abnormal dreams. Dizziness, vertigo, and loss of balance may also occur, and in rare cases have continued for months after the drug was stopped.

Neurological or psychiatric disturbances have also been reported with mefloquine and include sensory and motor neuropathies, tremor, ataxia, visual disturbances, tinnitus and hearing impairment, convulsions, anxiety, depression, confusion, hallucinations, panic attacks, emotional instability, aggression and agitation, and acute psychosis. There have been rare reports of suicidal ideation.

Other adverse effects include rashes, pruritus and urticaria, hair loss, muscle weakness, myalgia, liver function disturbances, and very rarely thrombocytopenia and leucopenia. There have been rare occurrences of erythema multiforme and Stevens-Johnson syndrome. Anaphylaxis has occurred rarely. Cardiovascular effects have included hypotension, hypertension, tachycardia or palpitations, bradycardia, QT prolongation, and other minor ECG changes. There have been isolated cases of atrioventricular block.

Incidence of adverse effects. The frequencies of adverse effects reported[1] in 134 soldiers given mefloquine hydrochloride 250 mg weekly for malaria chemoprophylaxis were: diarrhoea (48%), nausea (13%), vomiting (2%), headache (13%), and dizziness (7%). All of 7 healthy sub-

jects who received a dose of mefloquine hydrochloride 15 mg/kg had symptoms that included vertigo, nausea, dizziness, and lightheadedness.[2] The manufacturers reported that dizziness occurred in 24% of patients with malaria treated with 750 mg of mefloquine, in 38% treated with 1 g, and in 96% treated with 1.5 g; splitting a dose into two doses given 8 hours apart can reduce the incidence of dizziness.[3] A prospective study involving 3673 patients found that anorexia, nausea, vomiting, dizziness, and sleep disorders were 1.1 to 1.4 times more frequent in patients receiving mefloquine 25 mg/kg for treatment of malaria than in those receiving 15 mg/kg, and that vomiting could be reduced by 40% if the higher dose was split and given as 15 mg/kg followed by a further 10 mg/kg after 16 to 24 hours.[4] The frequency of adverse effects is reported to be higher in subjects who become dehydrated.[5]

There has been concern that the adverse effects of mefloquine, especially neuropsychiatric reactions, might limit its use for the prophylaxis of malaria but, as discussed under Effects on the Nervous System, below, the incidence of adverse effects does not appear to be greater than with other prophylactic schedules.

Effects on the blood. Agranulocytosis was reported[1] in a patient with malaria 48 hours after treatment with a 1250-mg course of mefloquine. The patient had previously taken 250 mg of mefloquine weekly for 7 weeks without adverse effects. Thrombotic thrombocytopenic purpura has been reported[2] in a patient after taking two standard weekly doses of mefloquine for malaria prophylaxis. Symptoms improved after plasmapheresis.

2. Placcadori E, *et al.* Thrombotic-thrombocytopenic purpura following malaria prophylaxis with mefloquine. *J Antimicrob Chemother* 2006; 57: 160–1.

Effects on the liver. Acute fatty liver was reported[1] in a patient who had recently received mefloquine 250 mg weekly for 5 weeks for malaria prophylaxis. Symptoms resolved with fluid, electrolyte, and albumin replacement, after stopping mefloquine. In another report,[2] acute elevation of liver transaminases, associated with severe acute hepatitis, occurred in a patient with pre-existing mild hepatic impairment after a 6-week course of mefloquine 250 mg weekly.

1. Grieco A, *et al.* Acute fatty liver after malaria prophylaxis with mefloquine. *Lancet* 1999; 353: 295–6.
2. Gotsman I, *et al.* Mefloquine-induced acute hepatitis. *Pharmacotherapy* 2000; 20: 1517–19.

Effects on the lungs. Acute pneumonitis requiring hospitalisation[1] was reported in a patient after a single dose of oral mefloquine 250 mg for malaria prophylaxis. The condition slowly resolved after the drug was stopped but recurred with mefloquine rechallenge 4 months later, leading to intensive care unit admission. A subsequent case of eosinophilic pneumonia associated with mefloquine prophylaxis has also been reported.[2]

Between May 1989 and January 2008, the US FDA received 13 reports of pneumonitis associated with mefloquine use at either treatment or prophylactic doses.[3] Although most of these patients recovered fully after the drug was stopped, one death, in a 4-year old, occurred. Antibacterial treatment was not of benefit in many cases, although one-third of patients improved after treatment with corticosteroids, suggesting a possible allergic aetiology.

Effects on the nervous system. Neuropsychiatric reactions have been associated with the use of mefloquine[1] although various figures have been reported for their frequency. The UK CSM has quoted[2] figures of 1 in 10 000 to 1 in 20 000 for severe reactions to *prophylactic* doses and similarly the manufacturers report that 1 in 10 000 patients given mefloquine prophylaxis will have serious problems. Others consider that the incidence of serious reactions is extremely low,[3] with a frequency of about 1 in 80 000. The manufacturers have also reported that most reactions in patients taking mefloquine for prophylaxis appear to occur after the first dose and have suggested that monitoring after the first dose could identify 40% of those at risk of neuropsychiatric effects.[4] Some authorities consider that over 75% of such reactions to mefloquine are apparent by the third dose.[5] This may allow for tolerability problems with mefloquine prophylaxis to be identified before travel. There has been much discussion on the comparative tolerability of antimalarials used for chemoprophylaxis. The incidence of adverse events, including neuropsychiatric events, was comparable for mefloquine and chloroquine in 2 uncontrolled questionnaire studies, one in tourists[6] and one in US Peace Corps volunteers.[7] However, in a more recent questionnaire in travellers,[8] although the incidence of reported adverse events was similar for mefloquine and chloroquine plus proguanil, neuropsychiatric adverse events were significantly more common in mefloquine recipients. In two randomised controlled studies,[9,10] both in military personnel, there was no difference between CNS symptoms in those given weekly mefloquine and those receiving chloroquine (with or without proguanil). In one of these studies,[10] a subgroup receiving a loading dose of mefloquine daily for 3 days initially had a higher incidence of CNS events. A review[11] of 10 controlled studies found no significant difference in the rates of withdrawal and overall incidence of adverse effects for mefloquine and alternative prophylactic regimens, but mefloquine was more likely than other drugs to cause insomnia and fatigue. Women (particularly first-time users of mefloquine, or those with a low BMI)[12] may be at greater risk of adverse effects than men, and WHO has commented that the occurrence of such adverse effects may mean that only highly motivated occupational subgroups or individuals at high risk of infection with chloroquine-resistant malaria will be willing to continue with mefloquine prophylaxis.[13]

Neuropsychiatric reactions are more frequent after the higher doses of mefloquine used for *treatment* than those used for prophylaxis. Some workers have estimated that overall 1 in 8000 mefloquine users have such reactions, with the incidence 60 times higher after treatment than after prophylaxis.[14] Other workers who have used mefloquine in nearly 14 000 treatments calculated that the overall frequency of serious neuropsychiatric reactions was 1 per 1754 treatments; it therefore appeared that serious neuropsychiatric reactions were 10 times more probable after treatment than with prophylactic use of mefloquine.[15]

A severe neurological syndrome associated with mefloquine treatment, with agitation, delirium, stupor, hyperpyrexia, mydriasis, and generalised rigors responded rapidly to treatment with physostigmine, suggesting a central anticholinergic aetiology.[16]

A discrete post-malaria neurological syndrome (including an acute confusional state or acute psychosis, convulsions, and tremor) has been seen on recovery from falciparum malaria and there appeared to be a strong association with mefloquine although it was not the only risk factor.[17] Nevertheless the risk was considered unacceptable and the recommendation made[17] that, where there was an effective alternative drug, mefloquine should not be used after initial treatment of severe malaria.

Emergence delirium during recovery from general anaesthesia after mefloquine prophylaxis has been reported in 3 cases.[18]

There is evidence from a small study[19] in healthy subjects, and from similar results in *animals*, that mefloquine may induce deficits in motor learning skills.

Effects on the oesophagus. Oesophageal ulceration in one patient and discomfort in another 4 was attributed to swallowing mefloquine tablets with insufficient fluid.[1]

1. Phillips M. Antimalarial mefloquine. *Med J Aust* 1994; 161: 227–8.

Effects on the skin. Isolated cases of Stevens-Johnson syndrome,[1] severe facial lesions,[2,3] exfoliative dermatitis,[3] toxic epidermal necrolysis,[5] psoriasis exacerbation,[6] and cutaneous vasculitis[7] have been associated with use of mefloquine for malaria prophylaxis.

For a comparison of the incidence of pruritus induced by various antimalarials, including mefloquine, see under Chloroquine, p. 652.2.

Overdosage. Cardiac, hepatic, and neurological symptoms have been reported in a patient who inadvertently received 5.25 g of mefloquine over 6 days.[1] All symptoms disappeared rapidly when mefloquine was stopped.

1. Bourgeade A, *et al.* Intoxication accidentelle à la méfloquine. *Presse Med* 1990; 19: 1903.

Precautions

Tasks requiring fine coordination such as driving should not be undertaken during treatment with mefloquine or for at least 3 weeks afterwards; in the case of prophylactic use, care should be exercised while taking mefloquine and for at least 3 weeks after stopping it. The use of mefloquine for malaria prophylaxis is contra-indicated in patients with a history of psychiatric (including depression) or convulsive disorders. Increased plasma concentrations may occur in patients with hepatic impairment. Mefloquine should be stopped should symptoms suggestive of psychiatric disturbance occur during prophylaxis, and an alternative antimalarial substituted.

Mefloquine is teratogenic in *animals* and its use during pregnancy is best avoided; however, in areas of chloroquine-resistant *Plasmodium falciparum*, WHO states that mefloquine may normally be taken for malaria prophylaxis during the second and third trimesters of pregnancy. It is recommended that women should also avoid becoming pregnant during, and for 3 months after, mefloquine use and that mothers should not breast feed while taking mefloquine.

Mefloquine should be used with caution in patients with renal impairment and in those with cardiac conduction disorders.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies mefloquine as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

For a discussion of the use of other antimalarials in patients with porphyria, see under Precautions for Chloroquine, p. 653.1.

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 10/10/11)

Pregnancy. Licensed product information for mefloquine reports that it is teratogenic in *rodents*. There is limited information on its effects in humans. One study in Thailand cited by WHO[1] found no difference between mefloquine and quinine in pregnancy outcome, but the numbers of treated patients who were in their first trimester were very small and its use should be kept to a minimum in that stage of pregnancy. Further spontaneous reports of exposure to mefloquine during the first trimester of pregnancy collected by the manufacturer revealed 24 fetal abnormalities and 17 spontaneous or missed abortions in 358 pregnancies, although a causal relationship was not established,[2] and a later study by the manufacturer involving 1627 reports of exposure during pregnancy appeared to show a similar incidence of congenital malformation to

that in offspring of unexposed women.[3] In 53 army service women who inadvertently used mefloquine in pregnancy, and for whom pregnancy outcome was known, there were 17 elective abortions, 12 spontaneous abortions, one molar pregnancy, and 23 healthy live births, with no major congenital malformations.[4] The rate of spontaneous abortions was considered high.[4] A prospective cohort study involving 236 pregnant women who received an antimalarial in the first trimester did not find an increased risk of spontaneous abortion or anomaly in women who took mefloquine compared with other antimalarials, and the rate of spontaneous abortion was comparable with background rates.[5]

Confidence in the safety of mefloquine has increased, and WHO now considers mefloquine suitable for malaria prophylaxis in the second and third trimesters;[6] WHO has stated its use is not recommended in the first trimester because of limited information on its safety. Authorities in the UK consider that use may sometimes be justified in the first trimester in areas of high risk of acquiring falciparum malaria; inadvertent use is not an indication to terminate pregnancy.[7]

Pregnancy should be avoided during and for 3 months after prophylactic use.

Interactions

Halofantrine should not be given with, or within 15 weeks of the last dose of, mefloquine because of the increased potential to induce hazardous and potentially fatal cardiac arrhythmias, as discussed under Effects on the Heart on p. 654.3. Similarly, ketoconazole given with or after mefloquine may increase serum concentrations and the elimination half-life of mefloquine, potentially increasing the risk of QT-interval prolongation and arrhythmia. There is an increased risk of convulsions when mefloquine is used with chloroquine, quinidine, or quinine.

Alcohol. There has been a case report[1] of a patient who had neuropsychiatric disturbances after consuming a large quantity of alcohol with mefloquine; subsequent abstinence from alcohol led to complete reversal of the reactions.

1. Wittes RC, Saginur R. Adverse reaction to mefloquine associated with ethanol ingestion. *Can Med Assoc J* 1995; **152**: 515–17.

Antibacterials. Studies in healthy subjects have indicated that *ampicillin*[1] or *tetracycline*[2] could increase blood concentrations of mefloquine. Alternatively, concurrent use with *rifampicin* may decrease blood concentrations and reduce the elimination half-life of mefloquine.[3] Convulsions have been precipitated in 3 non-epileptic patients who were given mefloquine and the quinolone antibacterials *ciprofloxacin*, *ofloxacin*, or *sparfloxacin*.[4]

1. Karbwang J, *et al.* Effect of ampicillin on mefloquine pharmacokinetics in Thai males. *Eur J Clin Pharmacol* 1991; **40**: 631–3.
2. Karbwang J, *et al.* Effect of tetracycline on mefloquine pharmacokinetics in Thai males. *Eur J Clin Pharmacol* 1992; **43**: 567–9.
3. Riddiid W, *et al.* Effect of rifampin on plasma concentrations of mefloquine in healthy volunteers. *J Pharm Pharmacol* 2000; **52**: 1265–9.
4. Mangalvedhekar SS, *et al.* Convulsions in non-epileptics due to mefloquine-fluoroquinolone co-administration. *Natl Med J India* 2000; **13**: 47.

Antidepressants. Licensed product information for mefloquine states that in patients taking tricyclic antidepressants use of mefloquine may theoretically contribute to prolongation of the QT interval.

Antiepileptics. Licensed product information states that mefloquine may reduce seizure control by lowering the plasma concentration of antiepileptics, including carbamazepine, phenobarbital, and phenytoin. For the effect of mefloquine on *valproate*, see p. 557.3. For its effect on *carbamazepine*, see p. 517.2.

Antihistamines. Giving mefloquine with antihistamines may theoretically contribute to the prolongation of QT intervals; however, this is not considered to be an absolute contra-indication.

Antimalarials. It is well established that the use of *halofantrine* with or after mefloquine is contra-indicated because of the risk of hazardous cardiac arrhythmias. Mefloquine and other related compounds such as *quinine*, *quinidine*, and *chloroquine* may be given together only under close medical supervision because of possible additive cardiotoxicity; there is also an increased risk of convulsions.

A study in healthy subjects indicated that use of *primaquine* could increase blood concentrations of mefloquine and might increase the incidence of adverse effects due to mefloquine,[1] but others reported no such interaction.[2]

1. MacLeod CM, *et al.* Interaction of primaquine with mefloquine in healthy males. *J Clin Pharmacol* 1990; **30**: 841.
2. Karbwang J, *et al.* Pharmacokinetics of mefloquine in the presence of primaquine. *Eur J Clin Pharmacol* 1992; **42**: 559–60.

Antipsychotics. The use of mefloquine with *phenothiazines* or *pimozide* may theoretically contribute to prolonged QT intervals, although this is not considered to be an absolute contra-indication.

Cardiovascular drugs. It has been recommended that mefloquine should be used with extreme caution in patients also taking *antiarrhythmics, beta blockers, calcium-channel blockers*, or *digitalis*, until more was known about the risks of cardiotoxicity, since theoretically these drugs might contribute to prolongation of the QT interval. An increased risk of ventricular arrhythmias has been reported when mefloquine is given with *amiodarone*.

Cardiopulmonary arrest has occurred after a single dose of mefloquine in a patient who was taking *propranolol*.[1]

1. Anonymous. Mefloquine for malaria. *Med Lett Drugs Ther* 1990; **32**: 13–14.

Gastrointestinal drugs. Use with *metoclopramide* may increase plasma concentrations of mefloquine.[1]

1. Na Bangchang K, *et al.* The effect of metoclopramide on mefloquine pharmacokinetics. *Br J Clin Pharmacol* 1991; **32**: 640–1.

Vaccines. Unfortunately, conflicting advice has been issued concerning the use of mefloquine after typhoid vaccination, for details see p. 2423.1.

Pharmacokinetics

The pharmacokinetics of mefloquine may be altered by malaria infection in a manner similar to those of quinine, the main effects being reductions in both its volume of distribution and its overall clearance.

Mefloquine is well absorbed from the gastrointestinal tract but there is marked interindividual variation in the time required to achieve peak plasma concentrations. Mefloquine is about 98% bound to plasma proteins and high concentrations have been reported in red blood cells. It is widely distributed throughout the body. Mefloquine has a long elimination half-life; mean values of about 21 days have been reported for some patients, although like other pharmacokinetic data on mefloquine there is considerable variation in reported figures. Subtherapeutic concentrations of mefloquine may persist in the blood for several months. Mefloquine is metabolised in the liver. Little of a dose is excreted in the urine and *animal* studies suggest excretion of mefloquine and its metabolites is mainly in the bile and faeces.

Mefloquine is distributed into breast milk in small amounts.

Reviews of pharmacokinetic studies of mefloquine reveal considerable interindividual variation for several pharmacokinetic parameters and some evidence that there might be pharmacokinetic differences between ethnic groups.[1,2] Mefloquine is well absorbed by healthy subjects and by patients with uncomplicated malaria after oral doses.[3,4] In patients with complicated malaria adequate blood concentrations have been obtained by the nasogastric route but this route cannot be relied upon for seriously ill patients[5] as absorption may be incomplete.[1] Mefloquine has a large apparent volume of distribution but this is reduced in the presence of malaria.[6,7] In children given mefloquine with sulfadoxine and pyrimethamine as tablets crushed and mixed with a glucose syrup, maximum blood-mefloquine concentrations were higher and reached in a shorter time compared with equivalent doses in adults.[8] In pregnant women with uncomplicated malaria, blood concentrations were lower than in non-pregnant women and the apparent volume of distribution was larger.[9] Once-weekly prophylactic doses of mefloquine resulted in steady-state conditions at about 10 doses with no evidence of subsequent accumulation.[10]

Mefloquine is metabolised in the liver[11] largely into 2,8-bis(trifluoromethyl)-4-quinoline carboxylic acid [Ro-21-5104][12] but this metabolite appears to be inactive against *Plasmodium falciparum*.[13] Only a small percentage of a dose is excreted in the urine[14] and *animal* studies suggest excretion of mefloquine and its metabolites is mainly in the bile and faeces.[1] Mefloquine has an extremely long plasma elimination half-life; again there is considerable interindividual variation and mean values ranging from 13.9 to 27.5 days have been quoted, the lower end of the range referring to a formulation that was less well absorbed than the preparation now in use.[1]

Mefloquine is distributed into breast milk, but a single dose study in 2 women[15] indicated that the concentration of mefloquine in milk was only a small proportion of that seen in plasma.

Uses and Administration

Piperaquine phosphate is a bisquinoline antimalarial that has traditionally been used in China for the treatment and prophylaxis of falciparum malaria (p. 644.1). It is a structural analogue of chloroquine (p. 650.2) and is thought to have a similar mechanism of action.

A fixed-dose combination product of piperaquine phosphate and artenimol (see Artemisinin Derivatives, p. 648.1) has been developed to improve patient adherence and avoid monotherapy, and thereby decrease the risk of acquired drug resistance. This combination product is used for the treatment of acute uncomplicated malaria caused by *Plasmodium falciparum*; it should not be used to treat severe malaria. The ratio of piperaquine phosphate to artenimol of 8 to 1 has been selected to provide a target daily dose of 18 mg/kg for piperaquine. The combination may be given to patients from 6 months of age and weighing 5 kg or more. It

is given orally once daily for 3 days; no food should be taken within 3 hours of each dose. For those who have difficulties swallowing, the tablets may be crushed and mixed with water. Recommended doses according to body-weight are as follows:

- 5 to less than 7 kg: 80 mg piperaquine phosphate with 10 mg artenimol
- 7 to less than 13 kg: 160 mg piperaquine phosphate with 20 mg artenimol
- 13 to less than 24 kg: 320 mg piperaquine phosphate with 40 mg artenimol
- 24 to less than 36 kg: 640 mg piperaquine phosphate with 80 mg artenimol
- 36 to less than 75 kg: 960 mg piperaquine phosphate with 120 mg artenimol
- 75 to 100 kg: 1280 mg piperaquine phosphate with 160 mg artenimol
- 100 kg or more: no data available on which to make a dose recommendation

Due to the long elimination half-life of piperaquine phosphate a second, 3-day course should not be given within 2 months of the first course; no more than 2 courses should be given within a 12 month period.

Combinations of piperaquine, artenimol, and trimethoprim (*Artecom*) and piperaquine with artemisinin and primaquine (*Artequick*) are available in some countries. Piperaquine is also under investigation for use with a synthetic artemisinin derivative artelolane maleate.

Administration in children. The fixed-dose combination product of piperaquine phosphate and artenimol may be given to children from 6 months of age and weighing 5 kg or more for the treatment of acute uncomplicated infections caused by *Plasmodium falciparum*. For dose recommendations in these children, see p. 659.3.

Adverse Effects and Precautions

Piperaquine phosphate given as monotherapy or with artenimol is generally well tolerated. The most commonly reported adverse effects with piperaquine phosphate alone are dizziness, headache, and gastrointestinal effects such as nausea, vomiting, and abdominal pain.

Commonly reported adverse effects reported with the use of the fixed-dose combination product of piperaquine phosphate and artenimol are anaemia, asthenia, headache, and pyrexia. Prolongation of the QTc interval and tachycardia are also frequent and the combination is contra-indicated in those with a family history of sudden death or cardiovascular disorders such as congenital prolongation of the QTc interval, symptomatic cardiac arrhythmias, severe hypertension, left ventricular hypertrophy, congestive heart failure, and in those with electrolyte disturbances. It is also contra-indicated in those who have recently taken or are taking other drugs known to prolong the QTc interval. ECG and blood potassium monitoring are recommended. Caution is advised when giving the combination product to those with jaundice, and/or moderate or severe renal or hepatic impairment.

Interactions

Piperaquine is metabolised by the cytochrome P450 isoenzyme CYP3A4 and to a lesser extent by CYP2C19 and CYP2C9. It is an inhibitor of the CYP3A4 and CYP2C19 isoenzymes and may inhibit the metabolism of other drugs that are metabolised by this route; it also has the potential to increase the rate of metabolism for CYP2E1 substrates such as paracetamol and theophylline. Drugs that inhibit CYP3A4 may increase plasma concentrations of piperaquine and exacerbate the effect of QTc prolongation. Enzyme inducers may decrease plasma concentrations of piperaquine. Piperaquine should be avoided in patients taking potentially arrhythmogenic drugs including those that prolong the QT interval.

Pharmacokinetics

Piperaquine is slowly absorbed and peak plasma concentrations are generally reached 5 hours after an oral dose. It has a large volume of distribution and is more than 99% bound to plasma protein. *In vitro* studies show that piperaquine is mainly metabolised by the cytochrome P450 isoenzymes CYP3A4. It is eliminated slowly with an elimination half-life of about 22 days in adults and 20 days in children.

Ph. Eur. 8: (Primaquine Diphosphate). An orange crystalline powder. Soluble in water; practically insoluble in alcohol. Protect from light.

USP 36: (Primaquine Phosphate). An orange-red, odourless, crystalline powder. Soluble 1 in 15 of water; insoluble in chloroform and in ether. Its solutions are acid to litmus. Protect from light.

Uses and Administration

Primaquine is an 8-aminoquinoline antimalarial that is effective as a tissue schizontocide against intrahepatic forms of all types of *Plasmodium*. It is mainly used to produce radical cure of vivax and ovale malarias, but may also be given to reduce transmission of falciparum malaria. It also has some action against *Pneumocystis* and is used with clindamycin in the management of pneumocystis pneumonia. For further information, see below and p. 661.1.

Primaquine phosphate is given orally and doses may be expressed in terms of the base; primaquine phosphate 26.4 mg is equivalent to about 15 mg of primaquine base.

When used for *radical cure* of vivax or ovale malaria, a course of treatment with a blood schizontocide must be given first to kill any erythrocytic parasites. Primaquine phosphate is then given orally, usually in a dose equivalent to 15 mg (or 250 micrograms/kg) of the base daily for 14 days but higher doses or longer courses may be required to overcome resistance in some strains of *P. vivax* (see below); WHO has advised that for uncomplicated malaria acquired in South-East Asia (particularly Indonesia) and Oceania, the dose should be increased to 500 micrograms/kg daily. In the UK, the *BNF* suggests that while 15 mg (or 250 micrograms/kg) daily is appropriate for use in *P. ovale* malaria, 30 mg (or 500 micrograms/kg) daily is necessary or infections caused by *P. vivax*.

For patients with G6PD deficiency the use of up to 45 mg (or 750 micrograms/kg) once every 7 days for 8 weeks has been suggested to minimise haemolysis (but see under Adverse Effects, p. 661.2).

For details of doses in children, see below.

Administration in children. Primaquine may be used orally in children for **radical cure** of **malaria** caused by *P. ovale* or *P. vivax*. Doses are expressed in terms of primaquine base, and WHO[1,2] has suggested a dose of 250 micrograms/kg (to a maximum of 15 mg) once daily for 14 days; in South-East Asia and Oceania, the dose should be increased to 500 micrograms/kg (maximum 30 mg) daily. In the UK, the *BNFC* has recommended that, although the lower dose is appropriate for treatment of *P. ovale* malaria, the higher dose regimen should be used for all infections caused by *P. vivax*.

Although a lower age limit for the use of primaquine has not been formally established,[2] the *BNFC* suggests that it may be used in children over 6 months of age, but that specialist advice should be sought for younger children. Primaquine should be avoided in patients with severe G6PD deficiency, however in milder deficiency, a dose of 500 to 750 micrograms/kg once every 7 days for 8 weeks has been found to be without harmful effects.[3] (The *BNFC* also comments that this regimen is safe but suggests that the total daily dose should not exceed 45 mg.)

For a discussion on the use of primaquine to reduce transmission of falciparum malaria, see below.

Malaria. The overall treatment and prophylaxis of malaria and the place of primaquine in current recommendations are described on p. 644.1.

Despite the generally successful use of oral primaquine for **radical cure** of benign (non-falciparum) malarias, resistance of vivax (but not ovale) malaria is a known problem in some areas of the world,[1,2] and failures have occurred. The suggestion has been made that higher doses of primaquine (15 mg twice daily for 14 days, to give a total dose of 6 mg/kg assuming a body-weight of 70 kg) should be considered wherever the vivax malaria was acquired,[1-4] and this is the standard recommendation in the UK (see above). A systematic review[5] concluded that when used with chloroquine, a 14-day course of primaquine 15 mg daily was more effective than a 5-day course in preventing relapses of vivax malaria. The 5-day course of primaquine plus chloroquine appeared to be no better than chloroquine alone.

Variable responses to primaquine in the Amazonian region were attributed to considerable variation in the content of primaquine both between and within batches of tablets; primaquine content ranged from 19 to 168% of the labelled content.[6]

In the USA, the CDC[7] have suggested presumptive antirelapse therapy (or terminal prophylaxis) with primaquine at the end of prophylaxis to prevent relapses due to *Plasmodium vivax* or *P. ovale* in persons returning from prolonged exposure in areas where relapsing malaria is endemic. In those who have taken chloroquine, doxycycline, or mefloquine as prophylaxis, primaquine is usually given during the last 2 weeks of prophylaxis, but, when necessary, may also be taken immediately after prophylaxis is completed. When atovaquone plus proguanil is taken as prophylaxis, primaquine is preferably given during the last 7 days and then for an additional 7 days, but may also be given for 14 days after atovaquone plus proguanil prophylaxis is completed. The recommended daily oral dose of primaquine for terminal prophylaxis is 30 mg for adults and 500 micrograms/kg for children.

Primaquine has also been tried for **prophylaxis** of falciparum and vivax malaria; use for a year produced effective cover and was well tolerated by Javanese men without G6PD deficiency.[8] It was also effective for prophylaxis in Colombian military personnel; it was noted that primaquine prophylaxis could be stopped 1 week after departing the endemic area.[9]

The use of primaquine as a gametocytocide has the potential to **reduce the transmission** of falciparum malaria in low transmission areas and to help contain the

spread of artemisinin-resistant falciparum malaria.[10,11] WHO therefore initially suggested that primaquine be given as a single dose of 750 micrograms/kg (to a maximum of 45 mg) with an artemisinin derivative-based combination regimen for the treatment of uncomplicated *P. falciparum* malaria, provided the risk for G6PD deficiency was considered low or testing for deficiency was available.[10] However, testing for G6PD is not widely available in malaria endemic areas and concerns over primaquine's potential for haemolysis have limited its use. Following a review of safety and efficacy data, WHO has subsequently suggested that a lower dose of 250 micrograms/kg would be safer and equally effective and should be given on the first day of treatment (except in pregnant women and infants less than 1 year of age) without the need for G6PD testing.[10,12]

Pneumocystis pneumonia. Primaquine with clindamycin is used in the treatment of pneumocystis pneumonia as an alternative to co-trimoxazole[1] (see p. 567.2). Treatment has usually lasted 3 weeks, and US experts suggest primaquine be given orally in daily doses equivalent to 15 to 30 mg of the base, and clindamycin be given in doses of 600 to 900 mg intravenously or 300 to 450 mg orally every 6 to 8 hours.[2,3] In the UK, the *BNF* suggests clindamycin 600 mg orally every 8 hours with oral primaquine 30 mg daily for mild to moderate disease, but notes that the combination may cause considerable toxicity.

A randomised multicentre study[4] compared this latter regimen (primaquine 30 mg daily and clindamycin 600 mg three times daily) with co-trimoxazole and with a combination of dapsone and trimethoprim in 181 AIDS patients who had confirmed mild to moderate pneumocystis pneumonia. Primaquine-clindamycin was as effective as the other two regimens, although the authors suggested that the combination might be best avoided in patients with severe myelosuppression.

Primaquine with clindamycin is not normally recommended for prophylaxis although there are reports of it being tried.[5] A retrospective examination[6] of the records of patients who had received prophylaxis found that clindamycin with primaquine was less effective than co-trimoxazole or dapsone, although this could have been due in part to underdosing.

Adverse Effects

Adverse effects with therapeutic doses of primaquine are usually minimal but abdominal pain and gastric distress are more common if taken on an empty stomach. Larger doses may cause nausea and vomiting. Methaemoglobinaemia may occur occasionally. Haemolytic anaemia can occur in persons with G6PD deficiency (see below). Other uncommon effects include mild anaemia and leucocytosis. Hypertension and cardiac arrhythmias have been reported on rare occasions. Primaquine may rarely produce leucopenia or agranulocytosis, usually after overdosage. Other effects associated with overdosage include gastrointestinal symptoms, haemolytic anaemia, and methaemoglobinaemia with cyanosis.

Many adverse effects have been reported after use of primaquine[1] but some, including pruritus and disturbances of visual accommodation, are considered to be inadequately documented or doubtfully attributed to the drug.

Acute intravascular haemolysis is the most serious toxic hazard of primaquine, especially in people with G6PD deficiency, other defects of the erythrocytic pentose phosphate pathway of glucose metabolism, or some types of haemoglobinopathy. In individuals with G6PD deficiency the severity of haemolysis is directly related to the degree of deficiency and to the quantity of primaquine given. In patients with the African variant the standard course of primaquine generally produces a moderate and self-limiting anaemia, while in those with the Mediterranean and related Asian variants, haemolysis can result in progressive haemoglobinaemia and haemoglobinuria which can be fatal. Whenever possible, therapy with primaquine should be delayed until the acute stage of malaria has been brought under control by a blood schizontocide because of the risk of inducing haemolysis and compromising the gastrointestinal tolerance of therapy.

1. Clyde DF. Clinical problems associated with the use of primaquine as a tissue schizontocidal and gametocytocidal drug. *Bull WHO* 1981; **59:** 391–5.

Precautions

Primaquine should be used cautiously in acutely ill patients with any serious systemic disease characterised by a tendency to granulocytopenia such as rheumatoid arthritis or lupus erythematosus. It should also be used with care in patients with G6PD deficiency. Primaquine should be withdrawn if signs of haemolysis or methaemoglobinaemia occur and the blood count should be monitored periodically.

Breast feeding. Primaquine should not be used in nursing women, unless the breast-fed infant has been determined not to be G6PD-deficient.

Pregnancy. Primaquine should not be given during pregnancy; radical cure of vivax or ovale malarias with primaquine should be delayed in pregnant women until after delivery.[1]

1. Panisko DM, Keystone JS. Treatment of malaria—1990. *Drugs* 1990; **39:** 160–89.

Interactions

Primaquine should not be used with drugs liable to induce haemolysis or bone marrow depression. Theoretically, mepacrine may increase the plasma concentrations of primaquine resulting in a higher risk of toxicity, and it has been recommended that these drugs should not be used together.

Antimalarials. The pharmacokinetics of primaquine were not altered by *mefloquine* in healthy subjects,[1] although the effect of primaquine on mefloquine pharmacokinetics is uncertain (see under Mefloquine, p. 659.2). In a study in patients with malaria, *quinine* reduced the plasma concentrations of primaquine, although the clinical importance of the interaction was unclear.[1]

1. Edwards G, *et al.* Interactions among primaquine, malaria infection and other antimalarials in Thai subjects. *Br J Clin Pharmacol* 1993; **35:** 193–8.

Pharmacokinetics

Primaquine is readily absorbed from the gastrointestinal tract. Peak plasma concentrations occur about 1 to 2 hours after a dose and then rapidly diminish with a reported elimination half-life of 3 to 6 hours. It is widely distributed into body tissues.

Primaquine is rapidly metabolised in the liver. Its major metabolite carboxyprimaquine accumulates in the plasma on repeated dosage. Little unchanged drug is excreted in the urine.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Austral.*: Primacin; *Braz.*: Primakinder†; *India*: Malirid; Malquine; PMQ-INGA; Primacip.

Pharmacopoeial Preparations

USP 36: Primaquine Phosphate Tablets.

Proguanil Hydrochloride

(BANM, rINNM)

Bigumalum; Chloriguane Hydrochloride; Chloroguanide Hydrochloride; Chlorowodorek Prokwanilu; Hidrocloruro de proguanil; Proguanide Hydrochloride; Proguanilihydrokloridi; Proguanil, chlorhydrate de; Proguanil, hidrocloruro de; Proguanil hydrochlorid; Proguanil-hidroklorid; Proguanilhydrochlorid; Proguanilhydroklorid; Proguanil hydrochloridum; Proguanilo hidrochloridas; RP-3359; SN-12,837; Прогуанила Гидрохлорид.

1-(4-Chlorophenyl)-5-isopropylbiguanide hydrochloride.

$C_{11}H_{16}ClN_5HCl=290.2$

CAS — 500-92-5 (proguanil); 637-32-1 (proguanil hydrochloride).

ATC — P01BB01.

UNII — R71Y86M0WT.

Pharmacopoeias. In *Eur.* (see p. vii), *Int.*, and *US*.

Ph. Eur. 8: (Proguanil Hydrochloride). A white or almost white, crystalline powder. Slightly soluble in water; sparingly soluble in dehydrated alcohol; practically insoluble in dichloromethane. Protect from light.

USP 36: (Proguanil Hydrochloride). A white, crystalline powder. Slightly soluble in water; sparingly soluble in alcohol; practically insoluble in dichloromethane. Protect from light.

Stability. Although the Ph. Eur. 8 directs that proguanil hydrochloride should be protected from light, stability studies[1,2] suggest that it is a very stable compound with only small amounts of its major decomposition product 4-chloroaniline being formed during thermal and photochemical stress.

2. Taylor RB, *et al.* A chemical stability study of proguanil hydrochloride. *Int J Pharmaceutics* 1990; **60:** 185–90.

Uses and Administration

Proguanil is a biguanide compound that has little antimalarial activity until metabolised in the body to the active antimalarial drug cycloguanil. Cycloguanil, like pyrimethamine, inhibits plasmodial dihydrofolate reductase and thus disrupts synthesis of nucleic acids in the parasite. Cycloguanil is active against pre-erythrocytic forms and is a slow-acting blood schizontocide. It also has some sporontocidal activity, rendering the gametocytes non-infective to the mosquito vector.

The value of proguanil is limited by the rapid development of resistance.

Proguanil is used orally as the hydrochloride for the chemoprophylaxis of malaria, with chloroquine or atovaquone. The schizontocidal activity of cycloguanil on erythrocytic forms is too slow for cycloguanil or proguanil to be used alone for the treatment of malaria, but proguanil hydrochloride is given with atovaquone for the treatment of uncomplicated falciparum malaria (p. 644.1).

For *prophylaxis* of malaria in combination with chloroquine, the usual adult daily dose of proguanil hydrochloride is 200 mg taken after food. For prophylaxis in combination with atovaquone 250 mg, the daily dose of proguanil hydrochloride is 100 mg. It is generally recommended that chemoprophylaxis for travellers should start 1 week before exposure to malaria, but if this is not possible it can be started 1 to 2 days before travel. Use should continue throughout exposure and for at least 4 weeks (1 week when proguanil is given with atovaquone) after leaving a malarious area.

In the *treatment* of uncomplicated falciparum malaria, adult doses are proguanil hydrochloride 400 mg with atovaquone 1 g, each orally as a single dose for 3 consecutive days.

For children's doses in the prophylaxis and treatment of malaria, see p. 662.1.

Cycloguanil was also formerly given by intramuscular injection as an oily suspension of the embonate.

Reviews.

2. Matta P, *et al.* Atovaquone-proguanil for prophylaxis and treatment of malaria. *Ann Pharmacother* 2003; **37:** 1266–75.

3. Nakato H, *et al.* A systematic review and meta-analysis of the effectiveness and safety of atovaquone proguanil (Malarone) for chemoprophylaxis against malaria. *J Antimicrob Chemother* 2007; 60: 929–36.

Administration in children. Dosage recommendations for proguanil with **chloroquine** for **malaria prophylaxis** in children have varied. UK malaria experts[1] have suggested the following prophylactic oral doses of proguanil hydrochloride for children based on fractions of the adult dose of 200 mg daily:

- under 6.0 kg (up to 12 weeks of age): one-eighth the adult dose
- 6 to 9.9 kg (3 to 11 months): one-quarter the adult dose
- 10 to 15.9 kg (1 year to 3 years 11 months): three-eighths the adult dose
- 16 to 24.9 kg (4 years to 7 years 11 months): half the adult dose
- 25 to 44.9 kg (8 years to 12 years 11 months): three-quarters the adult dose
- 45 kg and over (13 years or more): the adult dose

They noted that body-weight was a better guide to dosage than age for children over 6 months.

Children may be given proguanil with **atovaquone** for the **prophylaxis** of malaria.[1] A daily dose based on either a paediatric tablet containing 25 mg of proguanil hydrochloride plus 62.5 mg of atovaquone *or* an adult tablet containing 100 mg of proguanil hydrochloride plus 250 mg of atovaquone is as follows:

- children weighing 5 to 8 kg: half of a paediatric tablet
- > 8 to 10 kg: three-quarters of a paediatric tablet
- > 10 to 20 kg: one paediatric tablet or one-quarter of the adult tablet
- > 20 to 30 kg: two paediatric tablets or half of the adult tablet
- > 30 to 40 kg: three paediatric tablets or three-quarters of the adult tablet
- > 40 kg: four paediatric tablets or one adult tablet

Doses of proguanil with atovaquone for the **treatment** of malaria, based on the adult dose of 400 mg of proguanil hydrochloride daily, are:

- children weighing 5 to 8 kg: one-eighth the adult dose
- 9 to 10 kg: three-sixteenths the adult dose
- 11 to 20 kg: one-quarter the adult dose
- 21 to 30 kg: half the adult dose
- 31 to 40 kg: three-quarters the adult dose
- 40 kg and over: the adult dose

Administration in renal impairment. Proguanil is excreted by the kidneys and should be given in reduced dosage or avoided in patients with renal impairment. The following oral doses have been recommended based on creatinine clearance (CC):

- CC 20 to 59 mL/minute: 100 mg daily
- CC 10 to 19 mL/minute: 50 mg every other day
- CC less than 10 mL/minute: 50 mg once weekly

Adverse Effects and Precautions

Apart from mild gastric intolerance, diarrhoea, and some reports of aphthous ulceration there appear to be few adverse effects associated with usual doses of proguanil hydrochloride. There have been rare reports of hypersensitivity reactions including urticaria and angioedema. Rare cases of seizures and psychotic events have also been reported. Haematological changes have been reported in patients with severe renal impairment. Overdosage may produce epigastric discomfort, vomiting, and renal irritation leading to haematuria.

Proguanil should be used with caution in patients with renal impairment; dosage should be reduced accordingly (see under Uses and Administration, above).

Proguanil may be taken during pregnancy, but UK guidelines recommend that folate supplements (folic acid 5 mg daily) should also be given; however, the combination of proguanil with atovaquone should be avoided as data regarding the safety of atovaquone are lacking.

For information on the adverse effects and precautions associated with the use of proguanil with atovaquone, see under p. 929.1.

Until 1985 proguanil was generally taken in a dose of 100 mg daily for malaria prophylaxis with few adverse effects. Although there was no increase in serious adverse effects when the dose was increased to 200 mg daily, and it began to be used with chloroquine, there were an increasing number of reports of reversible aphthous ulceration.[1] Chloroquine may exacerbate this effect.[2] There has also been a report of reversible alopecia in women and scaling of the skin in both men and women using proguanil.[3] More severe skin reactions have been coupled with symptoms such as acute eosinophilic pneumonia as part of a hypersensitivity reaction.[4]

Megaloblastic anaemia and pancytopenia have been associated with proguanil accumulation in patients with renal impairment.[5,6]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies pyrimethamine as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

For a discussion of the use of other antimalarials in patients with porphyria, see under Precautions for Chloroquine, p. 653.1.

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 12/10/11)

Interactions

Antidepressants. *Fluvoxamine* can virtually abolish[1] the metabolism of proguanil to its active metabolite cycloguanil via an inhibitory effect on the cytochrome P450 isoenzyme CYP2C19.

1. Jeppesen U, *et al.* The CYP2C19 catalyzed bioactivation of proguanil is abolished during fluvoxamine intake. *Eur J Clin Pharmacol* 1997; 52 (suppl): A134.

Warfarin. For a report of haematuria and high prothrombin ratio in a patient stabilised on warfarin who took proguanil for malaria prophylaxis, see p. 1532.2.

Pharmacokinetics

Proguanil is readily absorbed from the gastrointestinal tract after oral doses and peak plasma concentrations occur within about 4 hours. It is about 75% bound to plasma proteins. Proguanil is metabolised in the liver to the active metabolite cycloguanil. Peak plasma concentrations of cycloguanil occur about 1 hour after those of the parent drug. The elimination half-lives of both proguanil and cycloguanil are about 20 hours. About 40 to 60% of proguanil is eliminated in the urine, of which 60% is unchanged and 30% cycloguanil. There is also some elimination via the faeces. Proguanil is distributed into breast milk in small amounts (which are not adequate to provide chemoprophylaxis for the infant).

Early studies found proguanil to be well absorbed from the gastrointestinal tract with peak plasma concentrations occurring after about 4 hours.[1] In more recent studies, peak plasma concentrations of proguanil have been achieved within 2 to 4 hours.[2-4] Plasma protein binding for proguanil is 75%.[5] Proguanil is metabolised in the liver[3] to the active metabolite cycloguanil and to *p*-chlorophenylbiguanide which is inactive. Peak plasma concentrations of cycloguanil occur about 5.3 hours after doses of proguanil.[4] Unlike proguanil and *p*-chlorophenylbiguanide, cycloguanil is not concentrated in erythrocytes and thus concentrations of cycloguanil in plasma and whole blood are similar.[4] The elimination half-lives for proguanil and cycloguanil are about 20 hours.[3,4] A review of early studies states that 40 to 60% of a dose of proguanil is excreted in the urine, 60% of this as the unchanged drug, 30% as cycloguanil, and 8% as *p*-chlorophenylbiguanide.[1] About 10% of a dose is excreted in the faeces.[1] However, these values can vary greatly and wide interindividual variations in the ability to metabolise proguanil to cycloguanil have been reported.[3,6,7] Malaria prophylaxis with proguanil might be less effective in poor metabolisers although this has not been proved conclusively[8] and, anyway, other factors such as lack of protection against mosquitoes and sensitivity of the malaria parasite might be more important.[9]

Plasma concentrations of cycloguanil may be reduced in the third trimester of pregnancy.[10]

Pharmacopoeial Preparations

BP 2014: Proguanil Tablets.

Pyrimethamine *(BAN, rINN)*

BW-50-63; Pirimetamin; Pirimetamina; Pirimetaminas; Pyrimetamina; Pyrimetamiini; Pyrimetamin; Pyrimethamine; Pyriméthamine; Pyrimethaminum; RP-4753; Пириметамин.

5-(4-Chlorophenyl)-6-ethylpyrimidine-2,4-diyldiamine.

$C_{12}H_{13}ClN_4$=248.7

CAS — 58-14-0.

ATC — P01BD01.

UNII — Z3614QOX8W.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 8: (Pyrimethamine). An almost white crystalline powder or colourless crystals. Practically insoluble in water; slightly soluble in alcohol. Protect from light.

USP 36: (Pyrimethamine). A white, odourless, crystalline powder. Practically insoluble in water; soluble 1 in 200 of alcohol and 1 in 125 of chloroform; slightly soluble in acetone. Store in airtight containers. Protect from light.

Uses and Administration

Pyrimethamine is a diaminopyrimidine antimalarial used with a sulfonamide in the treatment of malaria (see p. 644.1) and toxoplasmosis (see p. 663.1). Pyrimethamine with sulfadoxine has also been used in the treatment of actinomycetoma (p. 663.1), for prophylaxis of pneumocystis pneumonia (p. 663.1), and in the treatment of isosporiasis (p. 663.1).

Pyrimethamine exerts its antimalarial activity by inhibiting plasmodial dihydrofolate reductase, thus indirectly blocking the synthesis of nucleic acids in the malaria parasite. It is active against pre-erythrocytic forms and is also a slow-acting blood schizontocide. It also has some sporontocidal activity; it does not prevent the formation of gametocytes but renders them non-infective to the mosquito vector. It is mainly effective against *Plasmodium falciparum* but has some activity against *P. vivax*.

The development of plasmodial resistance has rendered obsolete the use of pyrimethamine on its own in malaria. Combinations of pyrimethamine with long-acting sulfonamides, such as sulfadoxine or sulfametopyrazine, are now used, although resistance has also developed to them.

For the *treatment* of uncomplicated falciparum **malaria**, pyrimethamine is given orally with sulfadoxine in a fixed dose ratio of 1 to 20 (*Fansidar*). WHO recommends that a single dose of pyrimethamine 1.25 mg/kg plus sulfadoxine 25 mg/kg be used with a 3-day course of artesunate.

For details of doses in children, see below.

A combination of pyrimethamine with sulfametopyrazine has also been used in the treatment of malaria.

Pyrimethamine and pyrimethamine combinations are no longer recommended for *prophylaxis* of malaria. Combined preparations of pyrimethamine with sulfadoxine (*Fansidar*, and with dapsone in a fixed ratio of 1 to 8 (*Maloprim*), have been used in areas of chloroquine or multidrug resistance, although other antimalarials are now preferred.

Pyrimethamine given with a sulfonamide such as sulfadiazine is used in the treatment of **toxoplasmosis**. Alternatively, pyrimethamine may be given with clindamycin in AIDS patients with toxoplasmosis unable to tolerate a sulfonamide. For details of dosage regimens used, see p. 663.1.

Administration in children. Pyrimethamine may be used orally with sulfadoxine (as the fixed-dose combination

product *Fansidar*) in infants and children 2 months of age and older for the treatment of **uncomplicated falciparum malaria.** WHO[1] recommends a single oral dose of pyrimethamine 1.25 mg/kg (with sulfadoxine 25 mg/kg) be given with a 3-day regimen of artesunate.

Alternatively, US licensed product information provides the following dosing recommendations based on body-weight for children 2 months of age and older:

- 5 to 10 kg: 12.5 mg with sulfadoxine 250 mg
- 11 to 20 kg: 25 mg with sulfadoxine 500 mg
- 21 to 30 kg: 37.5 mg with sulfadoxine 750 mg
- 31 to 45 kg: 50 mg with sulfadoxine 1 g
- over 45 kg: as for adults

In infants and children, pyrimethamine may also be used with sulfadiazine for the management of toxoplasmosis. For further details and doses, see under Uses and Administration of Sulfadiazine, p. 362.1.

1. WHO. *Guidelines for the treatment of malaria.* 2nd ed. Geneva: WHO, 2010. Available at: http://whqlibdoc.who.int/publications/2010/9789241547925_eng.pdf (accessed 09/07/10) Update (issued April 2011) available at: http://www.who.int/malaria/publications/atoz/mal_treatchild_revised.pdf (accessed 20/05/11)

Isosporiasis. Isosporiasis (p. 921.3) usually responds well to treatment with co-trimoxazole, but there is a high incidence of recurrence in immunocompromised patients, such as those with AIDS, and some form of maintenance therapy is generally required. Oral therapy with co-trimoxazole 960 mg given three times weekly or pyrimethamine 25 mg with sulfadoxine 500 mg given weekly were found to be equally effective maintenance regimens.[1] Pyrimethamine given alone in daily doses of 50 to 75 mg with folate therapy may be of use in the treatment of patients sensitive to sulfonamides.[2]

1. Pape JW, *et al.* Treatment and prophylaxis of Isospora belli infection in patients with the acquired immunodeficiency syndrome. *N Engl J Med* 1989; **320**: 1044–7.
2. Weiss LM, *et al.* Isospora belli infection: treatment with pyrimethamine. *Ann Intern Med* 1988; **109**: 474–5.

Malaria. The overall treatment and prophylaxis of malaria and the place of pyrimethamine-sulfadoxine (Fansidar) in current recommendations are discussed on p. 644.1.

Mycetoma. For reference to the use of pyrimethamine as part of the treatment of actinomycetoma, see under Mycetoma, p. 193.1.

Pneumocystis pneumonia. For a mention of pyrimethamine with either dapsone or sulfadoxine for the prophylaxis of pneumocystis pneumonia, and a discussion of conventional prophylaxis and treatment, see p. 567.2. For details of doses used, see under Uses and Administration of Dapsone, p. 282.1.

Toxoplasmosis. Pyrimethamine is given, usually with sulfadiazine or another appropriate sulphonamide, in the treatment of toxoplasmosis (p. 924.2), including the management of congenital toxoplasmosis in neonates (see Administration in Children, under Sulfadiazine, p. 362.1, for doses), although the management of maternal and fetal infection may vary considerably from country to country. Folinic acid is also given to counteract the megaloblastic anaemia associated with these regimens.

In the US, guidelines for the treatment of opportunistic infections in HIV-infected adults and adolescents[1] consider pyrimethamine plus sulfadiazine to be the initial therapy of choice for *Toxoplasma gondii* encephalitis and recommend the following doses, based on body-weight, be given for at least 6 weeks:

- less than 60 kg: pyrimethamine 200 mg orally, followed by 50 mg daily plus sulfadiazine 1 g orally every 6 hours
- 60 kg or more: pyrimethamine 200 mg orally, followed by 75 mg daily plus sulfadiazine 1.5 g orally every 6 hours

Pyrimethamine with clindamycin is an alternative in patients unable to tolerate a sulfonamide, for further information see under Clindamycin, p. 271.1.

Other drugs that have been tried with pyrimethamine include azithromycin,[2] clarithromycin,[3] and doxycycline.[4,5]

For *long-term maintenance* therapy, US guidelines[1] recommend that pyrimethamine 25 to 50 mg be given orally once daily with sulfadiazine 2 to 4 g daily divided in 2 or 4 oral doses; clindamycin may be used as an alternative to sulfadiazine if necessary. Alternatively, pyrimethamine 25 mg daily has been used with atovaquone 750 mg orally every 6 to 12 hours.

Although not typically considered first-line therapy, pyrimethamine may also be used for *primary prevention* of toxoplasmosis with either atovaquone or dapsone in the following regimens:[1]

- 25 mg daily with atovaquone 1.5 g daily
- 50 mg once weekly with dapsone 50 mg daily
- 75 mg once weekly with dapsone 200 mg once weekly (although this regimen may be poorly tolerated[6])

Pyrimethamine with sulfadoxine, also given once weekly, was of benefit in bone marrow transplant recipients.[7]

Adverse Effects and Treatment

Use of pyrimethamine for prolonged periods, as used to be the case when it was **given alone** for the prophylaxis of malaria, can cause depression of haematopoiesis due to interference with folic acid metabolism. Rashes and hypersensitivity reactions also occurred.

Larger doses, such as those used in the treatment of toxoplasmosis, may cause gastrointestinal symptoms such as atrophic glossitis, abdominal pain, and vomiting; haematological effects such as megaloblastic anaemia, leucopenia, thrombocytopenia, and pancytopenia are also more likely to occur. CNS effects including headache, dizziness, and insomnia have also been reported.

Pulmonary eosinophilia has been reported in patients taking pyrimethamine **with other antimalarials.** Severe and sometimes fatal reactions have occurred when pyrimethamine has been used with sulfadoxine (*Fansidar*), including erythema multiforme and the Stevens-Johnson syndrome, and toxic epidermal necrolysis; there have also been isolated reports of hepatotoxicity. Agranulocytosis occurs more frequently when pyrimethamine is used with dapsone (*Maloprim*) and fatalities have been reported.

Acute overdosage with pyrimethamine can cause gastrointestinal effects and CNS stimulation with vomiting, excitability, and convulsions. Tachycardia, respiratory depression, circulatory collapse, and death may follow. Treatment of overdosage is symptomatic.

Adverse effects with dapsone. Between 1972 and 1988, the UK CSM received 76 reports of reactions that were attributed to the use of pyrimethamine with dapsone (*Maloprim*), of which 40 (53%) were considered to be serious, including 6 deaths.[1] The incidence was estimated to be 1 in 9100 for serious reactions and 1 in 60 200 for fatalities. Serious blood disorders including agranulocytosis, granulocytopenia, or leucopenia occurred in 15 patients (estimated incidence of 1 in 20 000), five of whom died. The other death was in a patient with myocarditis. Three patients had cyanosis due to methaemoglobinaemia. Respiratory disorders such as pulmonary eosinophilia, flu-like syndrome, and dyspnoea occurred in 6 patients. In 4 patients skin disorders were the principal effect and included epidermal necrolysis, angioedema, and bullous eruptions. Hepatic disorders were also reported in 4 patients. Three women using pyrimethamine-dapsone during pregnancy delivered malformed babies, one of them being stillborn. Other effects in 4 patients included convulsions, exacerbated epilepsy, pancreatitis, or a generalised allergic reaction.

A review[2] of 21 cases of agranulocytosis associated with pyrimethamine-dapsone concluded that, although agranulocytosis can occur very rarely in patients taking pyrimethamine or dapsone alone, agranulocytosis due to the combination appears to be caused by an idiosyncratic reaction to dapsone exacerbated by pyrimethamine. Of the 18 individuals for whom dosage was certain, 12 had been taking one tablet of pyrimethamine-dapsone twice weekly, twice the recommended dose of one tablet once weekly. Of the 9 patients who died, 6 had been taking one tablet twice weekly and one patient had taken one tablet once weekly; the dosage was uncertain in the remaining patients. The time of onset of symptoms had been 7 to 9 weeks after starting therapy in 16 of 19 of the patients.

Some consider that pyrimethamine with dapsone may produce some degree of immunosuppression and render users more susceptible to common infections. A higher incidence of non-specific upper respiratory-tract infections occurred in military recruits taking the combination than in those not given antimalarial prophylaxis.[3]

Pulmonary eosinophilia has also occurred in patients taking pyrimethamine with dapsone but, as there have also been similar reports of pulmonary toxicity in patients taking pyrimethamine with sulfadoxine (see below) or pyrimethamine with chloroquine, it has been suggested that pyrimethamine is probably the causative agent.[4]

1. Phillips-Howard PA. West LJ. Serious adverse drug reactions to pyrimethamine–sulphadoxine, pyrimethamine–dapsone and to amodiaquine in Britain. *J R Soc Med* 1990; **83**: 82–5.

3. Lee PS, Lau EYL. Risk of acute non-specific upper respiratory tract infections in healthy men taking dapsone–pyrimethamine for prophylaxis against malaria. *BMJ* 1988; **296**: 893–5.
4. Davidson AC, *et al.* Pulmonary toxicity of malaria prophylaxis. *BMJ* 1988; **297**: 1240–1.

Adverse effects with sulfonamides. Severe and potentially fatal cutaneous reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis have been associated with the combined use of pyrimethamine with sulfadoxine (*Fansidar*) for malaria prophylaxis. The reported incidence of these reactions has varied with surveys in the UK,[1] USA,[2] and Sweden[3] yielding similar results and a survey from Switzerland[4] finding a much lower incidence. The overall rate of serious reactions to pyrimethamine-sulfadoxine in the UK has been estimated to be 1 in 2100. The estimates for severe cutaneous reactions were 1 in 4900 in the UK, 1 in 5000 to 1 in 8000 in the USA, 1 in 10 000 in Sweden, and 1 in 150 000 in Switzerland, and the death rates were 1 in 11 100 in the UK, 1 in 11 000 to 1 in 25 000 in the USA, and 1 in 35 000 in Sweden; no fatalities were reported in Switzerland. Workers on the Swiss survey had suggested that the high incidence of cutaneous reactions reported in the USA might have been due to concurrent therapy with chloroquine but this has been disputed.[5] The authors of the UK survey[1] suggested that the lower incidence reported in Switzerland may have been due to the different methods used to estimate the amount of drug usage. Whether this toxicity is due to the combined use of pyrimethamine and sulfadoxine is unclear as the estimated frequency of fatal reactions associated with the use of sulfadoxine alone in Mozambique[6] was 1 in 50 000.

There have been isolated reports of other severe or life-threatening reactions associated with the use of pyrimethamine-sulfadoxine when used alone or with chloroquine, including hepatotoxicity[7-9] (estimated incidence of 1 in 11 100 in the UK[1]), fatal multisystem toxicity,[10] drug fever and photodermatitis,[11] agranulocytosis,[11] and erythroderma resembling Sézary syndrome.[12] Severe pulmonary reactions have also occurred[3,13] but, as similar reactions have also been reported when pyrimethamine has been used with other antimalarials, including dapsone, it has been suggested that pyrimethamine is the causative agent (see Adverse Effects with Dapsone, above). Hyperammonaemia and carnitine deficiency with deterioration in mental status has been reported in a patient given pyrimethamine and sulfadiazine for the treatment of toxoplasmosis.[14]

Severe megaloblastic anaemia in a patient taking pyrimethamine and sulfadiazine for toxoplasmosis of the CNS[15] was treated by withdrawing pyrimethamine and giving folinic acid orally with a single platelet infusion.

For a comparison of the incidence of pruritus induced by various antimalarials including pyrimethamine with sulfadoxine, see Effects on the Skin under Chloroquine, p. 652.2.

Precautions

Pyrimethamine may aggravate subclinical folic acid deficiency and it should not be given to patients with conditions associated with folate deficiency such as megaloblastic anaemia. Blood counts are required with prolonged treatment, and when large doses of pyrimethamine are used, as in the treatment of toxoplasmosis, blood counts should be checked twice weekly. Folinic acid, which does not interfere with the action of pyrimethamine against malaria or toxoplasmosis, has been given to prevent haematological toxicity due to pyrimethamine and its use is especially recommended if pyrimethamine is given during pregnancy. (Folic acid may be used as an alternative to folinic acid in malaria, but it interferes with the action of pyrimethamine against toxoplasmosis). For further information concerning use during pregnancy, see below.

Pyrimethamine should be given with caution to patients with renal or hepatic impairment. When patients with convulsive disorders need to receive large doses, as in the treatment of toxoplasmosis, it is recommended that small starting doses should be used.

When pyrimethamine is used with sulfonamides or dapsone, the general precautions applicable to those drugs should also be taken (see under Sulfamethoxazole, p. 366.1 and under Dapsone, p. 283.2) and treatment should be stopped immediately if any skin reactions, sore throat, or shortness of breath occurs.

Breast feeding. Pyrimethamine is distributed into breast milk[1] but as no adverse effects have been reported in breast-fed infants, the most recent guidance from the American Academy of Pediatrics considered breast feeding to be compatible with the use of pyrimethamine for malaria prophylaxis.[2] However, exposure of the infant to other folate antagonists should be avoided. The large doses of pyrimethamine used for treating toxoplasmosis may distribute into breast milk in sufficient quantities to interfere with folic acid metabolism in nursing infants.

Porphyria. For a discussion of the use of antimalarials in patients with porphyria, see under Precautions for Chloroquine, p. 653.1.

Pregnancy. There have been concerns over the use of pyrimethamine during pregnancy as it has been shown to be teratogenic in *animal* studies.[1] In one report, severe congenital defects in a stillborn infant were attributed to the use of pyrimethamine in early pregnancy,[2] but the association was considered to be questionable.[3] Other instances of congenital malformations with pyrimethamine and dapsone are given under Adverse Effects with Dapsone, p. 663.2.

Others[4] suggest that intermittent preventive therapy for malaria with pyrimethamine-sulfadoxine has a favourable safety profile in pregnancy. WHO considers that pyrimethamine combinations may be used after the first trimester of pregnancy in the treatment of toxoplasmosis,[5] but that pyrimethamine-sulfadoxine although considered safe for malaria treatment in the second or third trimesters, is likely to be ineffective because of increasing resistance.[6]

Interactions

Use of pyrimethamine with other folate antagonists such as co-trimoxazole, trimethoprim, methotrexate, proguanil, phenytoin, or zidovudine may exacerbate bone marrow depression. The absorption of pyrimethamine may be reduced by use with antacid salts or kaolin.

Pyrimethamine may displace other drugs from protein-binding sites, causing elevated concentrations of unbound drug; this may be of particular clinical concern for drugs (such as quinine and warfarin) that are both highly protein bound and have a narrow therapeutic index.

Lorazepam. Signs of mild liver toxicity in 2 of 5 subjects who received lorazepam and pyrimethamine appeared to confirm earlier suspicions that giving these drugs together could cause hepatotoxicity. Both patients tolerated each drug when given separately.[1]

1. Briggs M, Briggs M. Pyrimethamine toxicity. *BMJ* 1974; 1: 40.

Zidovudine. Studies *in vitro* and in *animals* suggest that zidovudine could reduce the efficacy of pyrimethamine in the treatment of toxoplasmic encephalitis.[1] Furthermore, the dose of zidovudine may need to be altered if these drugs are used together as there has been a report that pyrimethamine with sulfadoxine (*Fansidar*) prolonged the serum half-life of zidovudine.[2]

1. Israelski DM, *et al.* Zidovudine antagonizes the action of pyrimethamine in experimental infection with Toxoplasma gondii. *Antimicrob Agents Chemother* 1989; 33: 30–4.
2. Klein RS. Prophylaxis of opportunistic infections in individuals infected with HIV. *AIDS* 1989; 3 (suppl 1): S161–S173.

Pharmacokinetics

Pyrimethamine is almost completely absorbed from the gastrointestinal tract. Peak-plasma concentrations generally occur 2 to 4 hours after a dose and can vary widely between individuals; concentrations ranging from 260 to 1411 nanograms/mL may occur after daily oral doses of 25 mg. It is mainly concentrated in the kidneys, lungs, liver, and spleen; in AIDS patients given daily dose of pyrimethamine, concentrations of about one-fifth of those in the serum occur in the CSF. About 80 to 90% is bound to plasma proteins.

It is metabolised in the liver and slowly excreted via the kidney, the average half-life in plasma being about 4 days. Several metabolites have been detected in the urine. Pyrimethamine crosses the placenta. It is distributed into breast milk (see under Breast Feeding in Precautions, above).

Pyronaridine Phosphate *(rINNM)*

Fosfato de pironaridina; Malaridine Phosphate; Pironaridina, fosfato de; Pyronaridine, Phosphate de; Pyronaridini Phosphas; Пиронаридина Фосфат.

4-[(7-Chloro-2-methoxybenzo[*b*]-1,5-naphthyridin-10-yl)amino]-2,6,-bis[(pyrrolidin-1-yl)methyl]phenol phosphate.

$C_{29}H_{32}ClN_5O_3.4H_3PO_4$=910.0

CAS — 74847-35-1 *(pyronaridine)*; 76748-86-2 *(pyronaridine phosphate).*

UNII — 2T289F9ACO.

Pharmacopoeias. In *Chin.*

Uses and Administration

Pyronaridine is a naphthyridine derivative that has traditionally been used in China in the treatment of malaria (p. 644.1). Its use has also been investigated in Africa and in Thailand. It is a blood schizontocide active against *Plasmodium vivax* and against both chloroquine-sensitive and chloroquine-resistant strains of *P. falciparum*. The drug produced in China has been given as the phosphate orally or by intramuscular or intravenous injection.

A fixed-dose combination product of pyronaridine phosphate and artesunate has been developed to improve patient adherence and avoid monotherapy, and thereby decrease the risk of acquired drug resistance. This combination product is used for the treatment of acute uncomplicated infections caused by *P. vivax* and *P. falciparum* in areas of low transmission with evidence of artemisinin resistance; it should not be used to treat severe malaria. The ratio of pyronaridine phosphate to artesunate of 3 to 1 has been selected to provide the current dose recommendations for each of the individual drugs when given as monotherapy. The combination is given orally, as a single, 3-day treatment course, to children and adults weighing 20 kg or more. Recommended doses are given once daily for 3 days according to body-weight as follows:

- 20 to less than 24 kg: 180 mg pyronaridine phosphate with 60 mg artesunate
- 24 to less than 45 kg: 360 mg pyronaridine phosphate with 120 mg artesunate
- 45 to less than 65 kg: 540 mg pyronaridine phosphate with 180 mg artesunate
- 65 kg or more: 720 mg pyronaridine phosphate with 240 mg artesunate

Administration in children. The fixed-dose combination product of pyronaridine phosphate and artesunate may be given to children weighing 20 kg or more for the treatment of acute uncomplicated infections caused by *Plasmodium vivax* and *P. falciparum* in areas of low transmission with evidence of artemisinin resistance. For dose recommendations in these children, see above.

Adverse Effects and Precautions

Adverse effects of pyronaridine are usually mild and resolve within 2 days of starting treatment. The most commonly reported adverse effects are dizziness, headache, pruritus, and gastrointestinal effects such as diarrhoea, nausea, vomiting, and abdominal pain. There have also been some reports of allergic skin reactions, palpitations, and transient ECG changes with the use of higher doses.

The most common adverse effects associated with the use of a fixed-dose combination product of pyronaridine

phosphate and artesunate are abdominal pain, bradycardia, headache, hypoglycaemia, vomiting, and haematological changes such as eosinophilia, neutropenia, anaemia, and an increased platelet count; abnormal laboratory test results include transient raises of serum transaminases (mostly ALT). Syncope, isolated prolongation of the QTc interval, and hypersensitivity reactions occur rarely.

Pyronaridine phosphate-artesunate should not be used for malaria prophylaxis. It is also contra-indicated in those with underlying hepatic injury or significant hepatic abnormalities; liver function tests should be carried out before and after a treatment course. The combination should be used with caution in those with cardiovascular disorders such as congenital prolongation of QTc interval, cardiac arrhythmia, and heart failure. Caution is also advised in patients with hypokalaemia, in those being treated with other drugs that block potassium channels, and in those who have recently taken medicines known to prolong the QTc interval.

Pregnancy. Data on the use of pyronaridine phosphate in pregnant women are not available, although *animal* studies have not reported any teratogenic effects. The safety of pyronaridine phosphate-artesunate in pregnancy has also not been established and the potential risk is unknown. For further information on the use of artesunate in pregnancy see under Artemisinin Derivatives, p. 649.2.

Interactions

In vitro studies have shown that pyronaridine phosphate is an inhibitor of the cytochrome P450 isoenzyme CYP2D6 and of P-glycoprotein. It should therefore be used with caution in patients taking drugs that are metabolised by the cytochrome P450 isoenzyme CYP2D6 and that are substrates for P-glycoprotein.

Pharmacokinetics

Peak plasma concentrations for pyronaridine are generally reached between 2 and 8 hours after an oral dose. Pyronaridine and its metabolites are extensively distributed into tissues. It is about 92 to 95% bound to plasma protein and may also bind to melanin in the eye. *In vitro* studies show that the cytochrome P450 isoenzymes CYP1A2, CYP2D6, and CYP3A4 could be involved in the metabolism of pyronaridine and that it inhibits the activity of CYP2D6. Pyronaridine is eliminated slowly with an elimination half-life of between 14 and 18 days.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Kor.*: Pyramax.

Quinine *(BAN)*

Chinin; Chinina; Chininum; Kiniini; Kinin; Kinine; Kuinina; Quinina; Хинин.

(8*S*,9*R*)-6′-Methoxycinchonan-9-ol; (α*R*)-α-(6-Methoxy-4-quinolyl)-α-[(2*S*,4*S*,5*R*)-(5-vinylquinuclidin-2-yl)]methanol.

$C_{20}H_{24}N_2O_2$=324.4

CAS — 130-95-0 (anhydrous quinine).

ATC — P01BC01.

UNII — A7V27PHC7A.

Description. Quinine is the chief alkaloid of various species of *Cinchona* (Rubiaceae). It is an optical isomer of quinidine.

Quinine Bisulfate *(BANM)*

Chininum Bisulfuricum; Neutral Quinine Sulphate; Quinina, bisulfato de; Quinine Acid Sulphate; Quinine Bisulphate; Quinini Bisulfas; Двусернокислый Хинин; Хинина бисульфат.

$C_{20}H_{24}N_2O_2H_2SO_4.7H_2O$=548.6

CAS — 549-56-4 (anhydrous quinine bisulfate).

ATC — P01BC01.

UNII — M201HC068W (anhydrous quinine bisulfate); GNS01V2R3N (quinine bisulfate heptahydrate).

Pharmacopoeias. In *Br., Int.*, and *Viet.*

BP 2014: (Quinine Bisulphate). Colourless crystals or a white crystalline powder. It effloresces in dry air. Freely soluble in water; sparingly soluble in alcohol. A 1% solution in water has a pH of 2.8 to 3.4. Protect from light.

Quinine Dihydrochloride *(BANM)*

Chinini Dihydrochloridum; Neutral Quinine Hydrochloride; Quinina, dihidrocloruro de; Quinine Acid Hydrochloride; Quinini Dihydrochloridum; Двухлористоводородный Хинин; Хинина Дигидрохлорид.

$C_{20}H_{24}N_2O_2.2HCl$=397.3

CAS — 60-93-5.

ATC — P01BC01.

UNII — 8C3EMH7D9X.

Pharmacopoeias. In *Br., Chin.*, and *Int.*

Viet. includes the injection.

BP 2014: (Quinine Dihydrochloride). A white or almost white powder. Very soluble in water; soluble in alcohol. A 3% solution in water has a pH of 2.0 to 3.0. Protect from light.

Quinine Etabonate

Euquinina; Euquinine; Quinina, etilcarbonato de; Quinine Ethyl Carbonate; Хинина Этабонат.

$C_{23}H_{28}N_2O_4$=396.5

CAS — 83-75-0.

ATC — P01BC01.

Pharmacopoeias. In *Fr.*

Quinine Hydrochloride *(BANM)*

Basic Quinine Hydrochloride; Chinin hydrochlorid dihydrát; Chininhydrochlorid; Chinini Hydrochloridum; Chininii Chloridum; Chininium Chloratum; Chinino hidrochloridas; Chininum Hydrochloricum; Chininy chlorowodorek; Kiniini-hydrokloridi; Kinin-hidroklorid; Kininhydroklorid; Quinina, hidrocloruro de; Quinine, chlorhydrate de; Quinine Monohydrochloride; Quinini Hydrochloridum; Quinini Hydrochloridum Dihydricum; Хинина Гидрохлорид.

$C_{20}H_{24}N_2O_2HCl.2H_2O$=396.9

CAS — 130-89-2 (anhydrous quinine hydrochloride); 6119-47-7 (quinine hydrochloride dihydrate).

ATC — P01BC01.

UNII — 71158Y0T33 (quinine hydrochloride dihydrate); 7CS0WNO31M (anhydrous quinine hydrochloride).

Pharmacopoeias. In *Eur.* (see p. vii), *Int., Jpn*, and *Viet.*

Ph. Eur. 8: (Quinine Hydrochloride). White or almost white, or colourless, fine, silky needles, often grouped in clusters. Soluble in water; freely soluble in alcohol. A 1% solution in water has a pH of 6.0 to 6.8. Protect from light.

Quinine Sulfate *(BANM)*

Basic Quinine Sulphate; Chinin sulfát dihydrát; Chinini sulfas; Chinino sulfatas; Chininsulfat; Chininum Sulfuricum; Chininy siarczan; Kiniinisulfaatti; Kininsulfat; Kinin-szulfát; Quinina, sulfato de; Quinine, sulfate de; Quinine Sulphate; Quinini Sulfas; Quinini Sulfas Dihydricus; Хинина Сульфат.

$(C_{20}H_{24}N_2O_2)_2.H_2SO_4.2H_2O$=783.0

CAS — 804-63-7 (anhydrous quinine sulfate); 6119-70-6 (quinine sulfate dihydrate).

ATC — P01BC01.

UNII — KF7Z0E0Q2B.

Pharmacopoeias. In *Chin., Eur.* (see p. vii), *Int., Jpn, US*, and *Viet.*

Ph. Eur. 8: (Quinine Sulfate). A white or almost white, crystalline powder or fine, colourless needles. Slightly soluble in water; sparingly soluble in boiling water and in alcohol. A 1% suspension in water has a pH of 5.7 to 6.6. Protect from light.

USP 36: (Quinine Sulfate). It is the sulfate of an alkaloid obtained from the bark of species of *Cinchona*. White, odourless, fine needle-like crystals, usually lusterless, making a light and readily compressible mass. It darkens on exposure to light. Soluble 1 in 500 of water and 1 in 120 of alcohol; sparingly soluble in water at 100 degrees; slightly soluble in chloroform; freely soluble in alcohol at 80 degrees and in a mixture of 2 parts of chloroform and one part of dehydrated alcohol; very slightly soluble in ether. Its saturated solution in water is neutral or alkaline to litmus. Protect from light.

Sorption. For reference to loss of quinine sulfate from solutions during membrane filtration, see Chloroquine, p. 650.2.

Uses and Administration

Quinine is a cinchona alkaloid and a 4-methanolquinoline antimalarial that is a rapid-acting blood schizontocide with activity against *Plasmodium falciparum, P. vivax, P. ovale*, and *P. malariae*. It is active against the gametocytes of *P. malariae* and *P. vivax*, but not against mature gametocytes of *P. falciparum*. The precise mechanism of action of quinine is unclear but it may interfere with lysosome function or nucleic acid synthesis in the malaria parasite. Since it has no activity against exoerythrocytic forms, quinine does not produce a radical cure in vivax or ovale malarias. The increasing spread of resistance to chloroquine has been responsible for the re-emergence of quinine as an important drug in the treatment of falciparum malaria (p. 666.1). Quinine is not generally used for malaria prophylaxis.

Quinine is also used to treat the protozoal infection babesiosis (p. 666.1) and for the relief of nocturnal leg cramps (p. 666.2).

Quinine has mild analgesic and antipyretic properties and is sometimes included in preparations used for the symptomatic relief of the common cold and influenza; additional salts that have been used for this purpose include the camsilate and the gluconate.

Quinine is also used as a bitter and a flavour (p. 666.1).

Quinine is used as several salts and 100 mg of anhydrous quinine is equivalent to about:

- 169 mg of quinine bisulfate
- 122 mg of quinine dihydrochloride
- 122 mg of quinine etabonate
- 130 mg of quinine hydrobromide
- 122 mg of quinine hydrochloride
- 121 mg of quinine sulfate

For the treatment of **malaria** quinine is given orally, usually as the sulfate, hydrochloride, or dihydrochloride, or parenterally as the dihydrochloride; quinine etabonate is sometimes used orally because unlike other quinine salts, which are intensely bitter, it is tasteless. They all contain about the same amount of quinine and any of them can be used when the dose is cited in terms of "quinine salt"; this is not the case for the bisulfate, which contains a correspondingly smaller amount of quinine. Quinine formate is sometimes given parenterally.

A course of treatment with quinine for falciparum malaria usually lasts 7 days and is accompanied by follow-on treatment with clindamycin, tetracycline, or doxycycline; in uncomplicated infections treatment should preferably be given by the oral route. The usual *oral* dose is 600 mg of quinine salt given every 8 hours for 7 days.

In severe or complicated falciparum malaria, or when the patient is unable to take oral medication, quinine should be given parenterally by slow intravenous infusion, but this can be hazardous and patients generally need monitoring, particularly for signs of cardiotoxicity. Therapy should be changed to the oral route as soon as possible to complete the course. To obtain therapeutic concentrations rapidly with parenteral therapy, quinine is often given in an initial loading dose followed by maintenance doses. A recommended *intravenous* dosage regimen suggested by WHO is an initial loading dose of 20 mg/kg of quinine dihydrochloride (up to a maximum of 1.4 g) given over 4 hours with maintenance infusions being started 8 hours later, calculated from the start of the previous infusion. Alternatively, in intensive care units, an initial loading dose of 7 mg/kg may be given over 30 minutes followed immediately by the first of the maintenance infusions. Maintenance infusions consist of 10 mg/kg (up to a maximum of 700 mg) given over 4 hours every 8 hours. A loading dose should not be given if the patient has received quinine, quinidine, mefloquine, or halofantrine, during the previous 12 hours. If parenteral therapy is required for more than 48 hours the maintenance dose of quinine dihydrochloride should be reduced to 5 to 7 mg/kg.

If intravenous infusion is not possible, quinine dihydrochloride has been given *intramuscularly*. Doses, including the loading dose, are the same as those used intravenously; the drug should be diluted in sodium chloride 0.9% to a concentration of 60 to 100 mg of the dihydrochloride per mL and the loading dose should be divided between two injection sites, preferably each anterior thigh (not the buttock). However, intramuscular injection can be irritant and there have been concerns regarding its safety and efficacy (see under Malaria, p. 666.1).

For details of doses in children and advice on dosing in renal or hepatic failure, see below and p. 666.1, respectively.

When used for the relief of nocturnal **leg cramps**, quinine is given at night in an oral dose of 200 to 300 mg of the sulfate or bisulfate. Quinine benzoate has also been used.

Administration in children. Quinine may be used orally in children for the treatment of **uncomplicated falciparum malaria**, or parenterally when malaria is severe or oral

therapy is not possible. Doses are expressed in terms of quinine salt.

For treatment of uncomplicated malaria a dose of 10 mg/kg orally every 8 hours[1] for 7 days may be used, along with clindamycin for follow-on treatment.[2] When parenteral therapy is required, quinine may be given by slow intravenous infusion at a rate not exceeding 5 mg/kg per hour, but if this is not possible the intramuscular route may be considered.[2] Parenteral doses and administration are as for adults (see p. 665.3).

2. WHO. *Guidelines for the treatment of malaria*. 2nd ed. Geneva: WHO, 2010. Available at: http://whqlibdoc.who.int/publications/2010/9789241547925_eng.pdf (accessed 19/07/10) Update (issued April 2011) available at: http://www.who.int/malaria/publications/atoz/mal_treatchild_revised.pdf (accessed 20/05/11)

Administration in hepatic impairment. Quinine may accumulate in patients with hepatic impairment, and WHO[1] has therefore suggested that quinine doses for severe malaria be reduced by one-third after the first 48 hours of treatment in patients with severe hepatic impairment. Similarly, in the UK the *BNF* suggests that when *intravenous* quinine is used in patients with severe hepatic impairment, the maintenance dose should be reduced to 5 to 7 mg/kg of quinine salt every 8 hours.

1. WHO. *Guidelines for the treatment of malaria*. 2nd ed. Geneva: WHO, 2010. Available at: http://whqlibdoc.who.int/publications/2010/9789241547925_eng.pdf (accessed 07/07/11) Update (issued April 2011) available at: http://www.who.int/malaria/publications/atoz/mal_treatchild_revised.pdf (accessed 07/07/11)

Administration in renal impairment. Quinine may accumulate in severe renal impairment, and WHO[1] has suggested that quinine doses for severe malaria should be reduced by one-third in such patients if severe renal failure persists after 48 hours of treatment. Some licensed product information also gives recommendations: when *oral* quinine is required for malaria treatment in patients with chronic, severe renal impairment, the usual dose may be given as an initial loading dose, followed at 12-hour intervals by half the usual dose. In the UK, the *BNF* suggests that when *intravenous* quinine is used in severe renal failure, the maintenance dose should be reduced to 5 to 7 mg/kg of quinine salt every 8 hours.

No dose adjustment is required for patients undergoing haemodialysis or haemofiltration.

Babesiosis. Although there is no established specific treatment for babesiosis (p. 920.2), a combination of quinine and clindamycin has been used.[1,2] For suggested doses see under Clindamycin, p. 270.3. Quinine with azithromycin was reported to be effective in a patient who had not responded to quinine with clindamycin.[3]

Flavouring. The Joint FAO/WHO Expert Committee on Food Additives concluded that quinine levels in soft drinks of up to 100 mg/litre (as quinine base) were not of toxicological concern.[1] However, because of the possibility of hypersensitivity reactions in some individuals, the committee recommended that consumers be informed of the presence of quinine in food or beverages.

Malaria. Quinine has had an important role in the treatment of falciparum malaria (see p. 644.1). Quinine salts are normally given orally (any quinine lost through vomiting within one hour of an oral dose should be replaced by additional doses)[1] or in severe infection by slow intravenous infusion of the dihydrochloride.[2] If intravenous formulations of quinine are unavailable quinidine may be used as an alternative; for further details, see under the Uses and Administration of Quinidine, p. 1481.3.

If facilities for intravenous infusion, including monitoring, are not available quinine may be given by deep intramuscular injection.[2] The use of the intramuscular route has been controversial because of concerns over safety and efficacy but there is some evidence of benefit.[3–6] Intramuscular injections of quinine can be irritant and have caused pain, focal necrosis, and abscess formation; fatal tetanus has developed in some patients.[7] It has been suggested that some such reactions may be related to the use of preparations formulated in urethane or other irritant substances. Diluted solutions of quinine dihydrochloride 60 mg/mL adjusted to neutral pH appear to be less painful than the usual undiluted preparation of 300 mg/mL.

If facilities do not exist to give quinine parenterally then patients with severe malaria should receive quinine by mouth or nasogastric tube.

Quinine as formerly standardised used to contain a higher concentration of cinchona alkaloids and there might be synergy between mixtures of these alkaloids.[8] In practice no advantage has been shown by such mixtures over quinine alone in the treatment of chloroquine-resistant falciparum malaria.[9]

Muscle spasm. Quinine (usually as quinine sulfate or bisulfate) has traditionally been used for nocturnal cramps (p. 2014.1) but there has been concern over its efficacy and potential for adverse effects, especially in the elderly. In the USA, for example, the FDA ruled that quinine products should no longer be used for the management of nocturnal cramps.[1,2] A similar ban has been imposed in Australia.[3] Meta-analyses[4,5] concluded that although quinine was effective in the treatment of nocturnal cramps in ambulatory patients the risk of serious adverse effects should be borne in mind. It was recommended that patients should be closely monitored while the efficacy of quinine is assessed over a period of at least 4 weeks. In contrast, a later Cochrane review[6] found moderate quality evidence to suggest that when quinine was used to treat muscle cramps for up to 60 days, the incidence of serious adverse effects was not significantly different than with placebo. Some[7] have recommended that treatment be stopped every 3 months to see whether it is still needed.

Haemodialysis-induced cramp (p. 1781.3) has been reported to respond to treatment with quinine[8,9] but similar concerns apply.

Adverse Effects

Quinine or its salts given in usual therapeutic doses may give rise to a train of symptoms known as cinchonism, characterised in its mild form by tinnitus, impaired hearing, headache, nausea, and disturbed vision, with, in its more severe manifestations, vomiting, abdominal pain, diarrhoea, and vertigo.

Cinchonism may also occur after small doses in patients hypersensitive to quinine, but urticaria and flushing of the skin with intense pruritus are the most frequent reactions seen in these patients. Other effects include fever, rashes, and dyspnoea. Angioedema may also occur and asthma can be precipitated. Thrombocytopenia and other blood disorders have been reported. Thrombocytopenic purpura has been associated with quinine hypersensitivity. Haemoglobinuria occurs rarely.

Other adverse effects of quinine include hypoglycaemia, hypoprothrombinaemia, and renal failure.

The main symptoms of overdosage, which can be fatal, include gastrointestinal effects, oculotoxicity, CNS disturbances, and cardiotoxicity. Visual disturbances including sudden blindness are usually slowly reversible but there may be residual damage. Overdosage is discussed in detail p. 667.2. Quinine can produce cardiovascular toxicity similar to that seen with quinidine, including conduction disturbances, arrhythmias, anginal symptoms, and hypotension leading to cardiac arrest and circulatory failure. Severe or even fatal cardiovascular toxicity can result from rapid intravenous dosage of quinine.

Large amounts of quinine can induce abortion; congenital malformations, particularly of the optic and auditory nerves, have been reported after failure to induce abortion with quinine. However, quinine should not be withheld from pregnant women with life-threatening malaria (see also under Pregnancy in Precautions, p. 668.1).

Intramuscular injections of quinine can be irritant and have caused pain, focal necrosis, and abscess formation; tetanus has developed in some patients (see under Malaria in Uses and Administration, above).

Effects on the blood. Between 1966 and 1975 the Swedish Adverse Drug Reaction Committee received 43 reports of *thrombocytopenia* attributable to quinine or quinidine[1] and the Boston Collaborative Drug Surveillance Program had 11 similar reports in patients studied between 1972 and 1981.[2] Up to October 2004, there had also been 228 cases of thrombocytopenia reported to the Australian Adverse Drug Reactions Advisory Committee, including 6 fatalities.[3] In the USA, the FDA has continued to receive reports of serious adverse events, including fatalities, despite efforts to restrict the use of quinine in response to existing toxicity concerns. Between April 2005 and October 2008, 24 domestic reports of serious haematological adverse events were received, of which 87.5% were thrombocytopenia requiring hospitalisation. The median time to onset of toxicity, and median reported quinine dose were 13.5 days and 325 mg daily respectively.[4] A similar analysis by Health Canada[5] of 71 reports of serious adverse effects suspected of being associated with quinine sulfate up to September 2010 included 43 cases where the indication had been leg cramps, for which the drug was not licensed; in 20 of these the adverse effect had been thrombocytopenia, often severe, while other adverse effects had included Stevens-Johnson syndrome, vasculitis, and arrhythmias. Quinine-induced thrombocytopenia appears to be a hypersensitivity reaction and beverages containing quinine as a bitter in concentrations as low as 20 micrograms/mL have precipitated thrombocytopenic purpura in previously sensitised individuals.[6]

Although quinine can cause *haemolysis*, there is some doubt over the traditional view that irregular dosage with quinine predisposes patients with malaria to *blackwater fever*, a syndrome of severe haemolytic anaemia, haemoglobinuria, oliguria, and renal failure.[7] Some of the patients affected may have had G6PD deficiency.[7] Haemolytic-uraemic syndrome[8–10] and pancytopenia with coagulopathy and renal impairment[11,12] have also been associated with the use of quinine.

There have also been reports of *disseminated intravascular coagulation*, including one fatality, after use of quinine by patients with quinine hypersensitivity.[13–15] In one case[15] the hypersensitivity reaction closely mimicked septic shock.

There have been isolated reports of *agranulocytosis* due to quinine.[16]

Effects on the ears. Although ototoxicity such as tinnitus or deafness is known to be a possible adverse effect of quinine, reversible hearing loss may also occur. While one group of workers[1] found the reduction in auditory acuity to be greatest at higher frequencies, another group[2] have found that hearing loss was generally equal across the range of frequencies tested and appeared to be related to the plasma concentration of quinine.

2. Karlsson KK, *et al.* Audiometry as a possible indicator of quinine plasma concentration during treatment of malaria. *Trans R Soc Trop Med Hyg* 1990; 84: 765–7.

Effects on the eyes. Oculotoxicity after overdosage with quinine is well recognised (see below), but there has also been a report of blindness in two patients occurring during supposedly routine therapy.[1]

1. Waddell K. Blindness from quinine as an antimalarial. *Trans R Soc Trop Med Hyg* 1996; 90: 331–2.

Effects on glucose metabolism. Hypoglycaemia is now recognised to be a frequent complication of falciparum malaria and it is often associated with a poor prognosis. Children, pregnant women, and patients with severe disease appear to be particularly at risk. It is important to recognise that hypoglycaemia rather than cerebral malaria may be the cause of coma. Hypoglycaemia may also be induced by antimalarial therapy; first episodes of hypoglycaemia have been detected after patients received quinine[1-3] or quinidine[4] intravenously, although others have not found that quinine led to the development of hypoglycaemia.[5,6]

Quinine has also been reported to induce hypoglycaemia during treatment for leg cramps.[7]

7. Limburg PJ, *et al.* Quinine-induced hypoglycemia. *Ann Intern Med* 1993; 119: 218–19.

Effects on the heart. Cardiotoxicity after overdosage with quinine is well recognised, and prolongation of the QT interval has been noted with therapeutic doses. There has also been a report[1] of fatal ventricular fibrillation with QT prolongation in an elderly patient who received standard doses of quinine by slow intravenous infusion for falciparum malaria. It was noted that the patient had some prolongation of the QT interval before starting quinine and also that her free quinine concentrations were unusually high despite total quinine concentrations considered to be within the therapeutic range.

1. Bonington A, *et al.* Fatal quinine cardiotoxicity in the treatment of falciparum malaria. *Trans R Soc Trop Med Hyg* 1996; 90: 305–7.

Effects on the kidneys. See Effects on the Blood, p. 666.3.

Effects on the liver. Although hepatitis has been associated with quinidine therapy (see p. 1482.2), there appear to be few reports of hepatotoxicity due to quinine usage. Granulomatous hepatitis has been reported in 2 patients taking quinine,[1,2] but the diagnosis in the first of these cases was challenged as the histological findings were considered to be more indicative of non-specific reactive hepatitis.[3] Hepatotoxicity due to quinine hypersensitivity has been reported in another patient.[4] Symptoms of hepatotoxicity occurred within 24 hours in a further patient taking quinine for nocturnal leg cramps.[5]

Effects on the skin. Urticaria, cutaneous flushing, various rashes, and pruritus are the commonest symptoms of hypersensitivity reactions to quinine.

Topical contact with quinine may cause contact as well as photocontact allergy, but quinine can also induce photosensitivity reactions after systemic dosage.[1-3] Photosensitivity associated with quinine intake from excessive consumption of tonic water has been reported;[4] fixed drug eruptions due to quinine in tonic water have also occurred.[5] There have also been reports of eczematous dermatitis,[1] oedema and erythema,[6] hyperpigmentation,[7] and lichen planus.[6] Both phototoxic[6] and photoallergic[1] mechanisms have been suggested. Fatal cutaneous vasculitis related to quinine treatment for nocturnal cramps has been reported.[8]

For a comparison of the incidence of pruritus induced by various antimalarials, see under Chloroquine, p. 652.2.

Hypersensitivity. For reference to hypersensitivity reactions associated with quinine, see Effects on the Blood (p. 666.3), Effects on the Liver (above), and Effects on the Skin (above).

Overdosage. Cinchonism may occur with therapeutic doses of quinine and symptoms include nausea, vomiting, tinnitus, deafness, headache, vasodilatation, and slightly disturbed vision. These symptoms may also occur in acute overdosage, but the visual disorders may be severe and there may be CNS disturbances and cardiotoxicity. A lethal dose or lethal plasma-quinine concentration has not been established but fatalities have been reported[1] in adults after doses of 2 to 8 g and in children after 1 g.

An analysis[2] of 165 cases of acute quinine poisoning revealed that: 21% had no symptoms, nausea with or without vomiting occurred in 47%, visual disturbances in 42%, tinnitus in 38%, other auditory disturbances in 23%, sinus tachycardia in 23%, and other ECG abnormalities in 8%. Mild impairment of consciousness was reported in 14% of the patients while 7 (4%) patients had deeper grades of coma. Of the 5 patients who died, 4 developed intractable ventricular arrhythmias and the fifth had a Jacksonian seizure followed by cardiac arrest. Another analysis,[3] of 96 cases of quinine intoxication reported in Scotland between 1997 and 2002, noted that there had been no changes in the pattern of poisoning from that in older studies; 6 cases involved moderate to serious toxicity after ingestion of 10 g or more. Intentional overdose was most common in patients aged between 11 and 30; children aged 10 or less were at greatest risk of accidental ingestion but toxicity was often not severe because the quantities were smaller. Both auditory and ocular toxicity appeared to be dose-related.

The effects of oculotoxicity may include blurred vision, defective colour perception, visual field constriction, and total blindness.[2,4] The onset of symptoms may vary from a few hours to a day or more after ingestion.[2,4] Suggested mechanisms for the oculotoxicity of quinine include an action on the retinal vasculature to produce ischaemia or a direct toxic effect on the retina.[1] Visual loss in one group of patients[4] was associated with plasma-quinine concentrations in excess of 10 micrograms/mL. However, in another group plasma-quinine concentrations were considered to be an imprecise guide to predicting visual disturbances.[2] The speed and degree of visual recovery varies. Of 70 patients with visual disturbances after quinine poisoning, 39 subsequently had a period of total blindness.[2] Permanent visual deficits remained in 19 of these but no patient had permanent bilateral blindness. All of the 31 patients who had blurred vision recovered full visual acuity.

It is considered that the actions of quinine on the myocardium are similar to those of quinidine but that it is less potent.[1] Sinus tachycardia and minor ECG changes are the most common cardiovascular effects. Conduction abnormalities and ventricular dysrhythmias may occur with severe poisoning. Ventricular tachycardia is mostly associated with cardiogenic shock or circulatory collapse. Hypokalaemia may also occur.[1]

Treatment of Adverse Effects

In acute overdosage with quinine or its salts multiple doses of activated charcoal (p. 1537.3) may be given to adults or children who present within one hour of ingesting more than the equivalent of 30 mg/kg of quinine base or any amount in a child under 5 years of age; gastric lavage may also be considered for use in adults. Other measures aimed at enhancing the elimination of quinine are largely ineffective. Treatment is mostly symptomatic with attention being given to maintaining blood pressure, respiration, and renal function, and to treating arrhythmias (for further information, see Acute Poisoning, p. 1537.1).

Vasodilators and stellate ganglion block have been used to prevent or reverse visual impairment but there is little evidence to support their use.

It has been suggested that, as quinine has antimuscarinic effects, gastric emptying may be delayed and considerable amounts of drug might be removed from the stomach beyond the usual 4 hours.[1] Others consider that gastric lavage is of doubtful value as quinine is rapidly absorbed and vomiting has often occurred before admission.[2] However, studies in healthy subjects and poisoned patients suggest that oral activated charcoal may increase the elimination of quinine.[3,4] Other methods of increasing elimination are probably ineffective. In a study involving 16 patients with quinine poisoning forced acid diuresis, haemodialysis, haemoperfusion, or plasma exchange were all found to be ineffective in increasing quinine elimination.[5]

Stellate ganglion block has been recommended to prevent or reverse retinal damage, the rationale being that quinine-induced oculotoxicity might arise from retinal arteriolar constriction. However, clinical studies have failed to find sufficient improvement to justify its use.[6,7] Intravenous nitrates produced beneficial responses in 2 patients.[8]

Precautions

Quinine and its salts are contra-indicated in patients with a history of hypersensitivity to quinine or quinidine and in patients with tinnitus or optic neuritis. They should not be used in the presence of haemolysis. They should be used with caution in patients with atrial fibrillation, cardiac conduction defects, or heart block. Quinine should be avoided in patients with myasthenia gravis as it may aggravate their condition.

Pregnancy in a patient with malaria is not generally regarded as a contra-indication to the use of quinine.

As quinine has been implicated in precipitating blackwater fever it is generally contra-indicated in patients who have already suffered an attack. Quinine may also cause haemolysis in some types of G6PD deficiency and should be used with care (but see also below).

It is important that when quinine is given intravenously it should be given by slow infusion and the patient observed closely for signs of cardiotoxicity. Blood-glucose concentrations should also be monitored. Problems that have been associated with intramuscular use are discussed under Malaria in Uses and Administration, p. 666.1.

Breast feeding. Although quinine is distributed into breast milk in small amounts,[1] the most recent guidance from the American Academy of Pediatrics considered that the use of quinine was probably compatible with breast feeding.[2]

1. Phillips RE, *et al.* Quinine pharmacokinetics and toxicity in pregnant and lactating women with falciparum malaria. *Br J Clin Pharmacol* 1986; 21: 677–83.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 19/04/04)

Glucose-6-phosphate deficiency. Although licensed product information has noted that quinine may cause hae-

molysis in G6PD deficient patients (and in some countries, contra-indicates its use by such patients), a review[1] noted that haemolysis has not been seen in published studies, and re-affirmed an earlier conclusion[2] that full therapeutic doses may be safely administered to G6PD-deficient patients.

2. Beutler E. Glucose-6-phosphate dehydrogenase deficiency. *N Engl J Med* 1991; 324: 169–74.

Liver disease. See under Pharmacokinetics, below.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies quinine as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

For a discussion of the use of other antimalarials in patients with porphyria, see under Precautions for Chloroquine, p. 653.1.

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 12/10/11)

Pregnancy. The use of quinine in large doses as an abortifacient in the past has led to concern over its use during pregnancy, but no evidence of an oxytocic effect was found when it was used to treat severe falciparum malaria in women in the third trimester of pregnancy.[1]

Congenital abnormalities including damage to the auditory and optic nerves have been seen, usually after attempted abortions, but WHO[2] considers quinine to be safe when used in normal therapeutic doses during pregnancy (although the problem of hypoglycaemia in the second and third trimesters may mean that artemisinin derivatives are preferred). Jitteriness attributed to quinine withdrawal has been reported in an infant whose mother had drunk large quantities of tonic water containing quinine during the last 17 weeks of pregnancy.[3]

As malaria is potentially serious during pregnancy and poses a threat to the mother and fetus, there appears to be little justification for withholding treatment in the absence of a suitable alternative. However, pregnant patients treated for malaria are at special risk from hypoglycaemia exacerbated or caused by quinine-induced hyperinsulinaemia (see under Effects on Glucose Metabolism in Adverse Effects, p. 667.1) and should be managed appropriately.

Renal impairment. See under Pharmacokinetics, below.

Interactions

As quinine shares many of the actions of quinidine, interactions seen between quinidine and other drugs (see p. 1483.1) might also occur with quinine. Both have actions on skeletal muscle and may potentiate the effects of drugs with neuromuscular-blocking activity (see under Antiarrhythmics on p. 2031.3). There is an increased risk of inducing ventricular arrhythmias if quinine is given with halofantrine (see p. 655.1) or other drugs that prolong the QT-interval such as amiodarone, the antihistamines astemizole and terfenadine, cisapride, moxifloxacin, and the antipsychotics pimozide and thioridazine. There may be an increased risk of convulsions when quinine is given with mefloquine. Quinine may also potentiate the effects of hypoglycaemic drugs.

Antibacterials. Elimination of quinine has been reported to increase in patients also receiving *rifampicin*.[1]

1. Wanwimolruk S, *et al.* Marked enhancement by rifampicin and lack of effect of isoniazid on the elimination of quinine in man. *Br J Clin Pharmacol* 1995; 40: 87–91.

Amantadine. For a report of quinine reducing renal clearance of amantadine, see Antiarrhythmics, p. 892.2.

Anticoagulants. Quinine can cause hypoprothrombinaemia and thereby enhance the effect of anticoagulants. In one report, reductions in *warfarin* dosage were necessary after ingestion of large amounts of tonic water containing quinine (see p. 1532.2).

Antimalarials. Quinine and *chloroquine* may be antagonistic when used for falciparum malaria (see p. 653.2). For a report of quinine reducing plasma concentrations of *primaquine*, see p. 661.2.

Antivirals. In a pharmacokinetic study,[1] co-administration with *ritonavir* (in an oral dose of 200 mg twice daily) led to increases of about fourfold in the AUC and peak-plasma concentration of quinine; a modest, but significant increase in plasma concentrations of ritonavir was also noted. The authors of the study suggest that a downward dose adjustment of quinine may be necessary, given the magnitude of the plasma-concentration increase possible for the drug, and the seriousness of its adverse effects.

Although there appears to be no evidence regarding potential interaction with other HIV-protease inhibitors, they all have the potential to affect cytochrome P450 isoenzyme CYP3A4 (although to a lesser extent than ritonavir) and therefore might be expected to raise serum-concentrations of quinine (a substrate of CYP3A4); therefore, such combinations should be used with caution. UK licensed product information for *saquinavir* suggests its use (ritonavir-boosted) with quinine is contra-indicated, due to a potential risk for cardiac arrhythmia.

1. Soyinka JO, *et al.* Pharmacokinetic interactions between ritonavir and quinine in healthy volunteers following concurrent administration. *Br J Clin Pharmacol* 2010; 69: 262–70.

Cardiovascular drugs. Quinidine has been reported to increase serum-digoxin concentrations (see Quinidine under Antiarrhythmics, p. 1356.2) and quinine has reduced total body clearance of digoxin (see Antimalarials, p. 1357.1).

For a report of quinine inhibiting the metabolism of *flecainide*, see p. 1384.3.

Histamine H_2-antagonists. *Cimetidine* has been reported to reduce the clearance of quinine and prolong its elimination half-life in a study in healthy subjects; no significant effect was seen with *ranitidine*.[1]

1. Wanwimolruk S, *et al.* Effects of cimetidine and ranitidine on the pharmacokinetics of quinine. *Br J Clin Pharmacol* 1986; 22: 346–50.

Immunosuppressants. For a report of quinine decreasing plasma concentrations of *ciclosporin*, see p. 1957.1.

Tobacco smoking. A single-dose study in healthy subjects has suggested that blood concentrations of quinine are lower in heavy smokers than in non-smokers, potentially impairing efficacy.[1]

1. Wanwimolruk S, *et al.* Cigarette smoking enhances the elimination of quinine. *Br J Clin Pharmacol* 1993; 36: 610–14.

Pharmacokinetics

The pharmacokinetics of quinine are altered significantly by malaria infection, the major effects being reductions in both its apparent volume of distribution and its clearance.

Quinine is rapidly and almost completely absorbed from the gastrointestinal tract and peak concentrations in the circulation occur about 1 to 3 hours after oral doses of the sulfate or bisulfate. Plasma protein binding is about 70% in healthy subjects and rises to 90% or more in patients with malaria. Quinine is widely distributed throughout the body. Concentrations attained in the CSF of patients with cerebral malaria have been reported to be about 2 to 7% of those in the plasma.

Quinine is extensively metabolised in the liver and rapidly excreted mainly in the urine. Estimates of the proportion of unchanged quinine excreted in the urine vary from less than 5 to 20%. Excretion is increased in acid urine. The elimination half-life is about 11 hours in healthy subjects but may be prolonged in patients with malaria. Small amounts of quinine also appear in the bile and saliva.

Quinine crosses the placenta and is distributed into breast milk (see Breast Feeding, p. 667.3).

Administration in liver disease. Reduced clearance of quinine and prolonged elimination half-life have been reported in patients with acute hepatitis B given a single intravenous dose.[1] The results suggested that quinine accumulation after multiple doses could be greater in patients with hepatitis, even once hepatic function had returned to normal. In another study[2] patients with moderate chronic liver disease were given quinine orally the half-life was prolonged but total clearance was not affected.

2. Auprayoon P, *et al.* Pharmacokinetics of quinine in chronic liver disease. *Br J Clin Pharmacol* 1995; 40: 494–7.

Administration in renal impairment. As urinary clearance comprises only 20% of total clearance of quinine, it appears that high plasma concentrations reported in patients with severe falciparum malaria and acute renal failure may be related more to the severity of the malaria, and associated pharmacokinetic changes, rather than to any reduction in the glomerular filtration rate.[1]

Continuous veno-venous high-volume haemofiltration appeared to have little effect on the pharmacokinetics of quinine,[2] suggesting that no dose supplementation would be needed in anuric patients undergoing this procedure. There were significant changes in the pharmacokinetics of quinine in 6 patients with chronic renal failure after a single oral dose.[3] The changes included a prolonged half-life, but there was no clear relationship between severity of renal failure and the degree of impairment of quinine clearance.

Profile

Tafenoquine is an 8-aminoquinoline antimalarial and more lipophilic derivative of primaquine. It acts as a tissue schizontocide and is under investigation as the succinate for the radical cure and prevention of relapse in vivax malaria. It may also have a role in the prophylaxis of falciparum malaria. Although it has been suggested to be better tolerated than primaquine, tafenoquine still carries a risk of haemolysis in G6PD-deficient patients.

Antimigraine Drugs

Cluster headache, p. 670
Medication-overuse headache, p. 670
Migraine, p. 670
Post-dural puncture headache, p. 671
Tension-type headache, p. 671

This chapter reviews the management of headache, in particular migraine and cluster headache, and the drugs used mainly for their treatment. The mechanisms of head pain or headache are not fully understood but may involve neurovascular changes (as in migraine and cluster headache), muscle contraction (tension headache), nerve lesions (neuralgias), direct head injury, infection (meningitis), or referred pain (sinusitis, toothache, eye disorders). Headache is also an adverse effect of many drugs including, paradoxically, those used to treat it. The International Headache Society has published guidelines to aid the diagnosis of the various headache types. Patients may have more than one headache disorder simultaneously and require separate treatment for each.

Cluster headache

Cluster headache (migrainous neuralgia, histaminic cephalalgia, Horton's syndrome) is of unknown aetiology but may be neurovascular in origin.[1-5] Patients have one or more short-lived attacks of intense unilateral head pain, usually at the same time of day (often at night). These are associated with autonomic symptoms such as conjunctival injection or lachrymation, miosis or ptosis, nasal congestion or rhinorrhoea, forehead or facial sweating, and eyelid oedema. Restlessness during the attacks is characteristic. The period during which attacks occur is called a cluster period; it may last several weeks or months. In the typical episodic form of cluster headache, cluster periods are followed by periods of remission lasting for months or years but in the more rare chronic form, patients may have cluster periods lasting for more than a year, or with short periods of remission in between. Substances such as alcohol, histamine, or glyceryl trinitrate can precipitate headache attacks during cluster periods, but not during periods of remission. There is speculation that sleep-disordered breathing[6] and increased body heat[7] may also trigger cluster headaches.

The **treatment** of individual acute attacks during a cluster period is difficult because the headache is short-lived and oral analgesics are unlikely to be absorbed fast enough to produce much benefit.[1,3,4] Inhalation of 100% oxygen should be considered in all patients.[8-11] It is rapid and effective in aborting attacks, but has practical difficulties. Some consider subcutaneous sumatriptan to be the acute therapy of choice in cluster attacks;[4,5,8-13] intranasal sumatriptan or zolmitriptan are possible alternatives, although less effective.[1,4,8,12] Oral zolmitriptan may be considered for patients who cannot tolerate subcutaneous or intranasal triptans and oxygen, or who prefer oral medication.[4] Intranasal instillation of lidocaine may be considered in patients who have still not responded.[8-11] It has been reported to be of some benefit but most patients do not obtain complete pain relief.[1,3,4,9] Intranasal dihydroergotamine[1,4] and inhaled ergotamine have also been used to treat acute attacks; injectable dihydroergotamine has usually been reserved for emergency settings.[4]

Since individual attacks are difficult to treat it is probably more effective to manage cluster headache by **prophylaxis** once a cluster period has started. The changing or combining of prophylactic treatment has also been advised by some.[12] If patients do not respond to the maximum possible dose of a drug within a week, Verapamil is usually considered the preventive therapy of choice,[1,4,8-13] particularly in patients with chronic long-lasting cluster periods.[5] Lithium may also be useful for the episodic or chronic form of the disorder.[9-13] Despite a lack of studies, oral corticosteroids are considered by some to be effective in the prophylaxis of cluster headache,[8,10,12] including those with short-lasting cluster periods (less than 2 months).[5] Methysergide, pizotifen, and valproate have also been tried.[1,3,5,9-11] Ergotamine may be used rectally in the short-term management of episodic cluster headache, if attacks are predictable;[10,12] it should not be used for prolonged periods. Other drugs under investigation include gabapentin, melatonin, and topiramate.[4,9-11,13]

Paroxysmal hemicrania is a rare variant of cluster headache and differs mainly in the high frequency and shorter duration of individual attacks. One of its features, which may be diagnostic, is its invariable response to indometacin.[10]

Medication-overuse headache

Overuse of drugs such as ergotamine, triptans, and analgesics (including opioids and combination preparations containing caffeine or butalbital) to treat headache or migraine can lead to dependence and paradoxical chronic daily headache in headache-prone patients.[1-5] Such headaches do not appear to occur with regular use of analgesics to treat other disorders except occasionally in patients with a history of migraine.[1] Medication-overuse headaches, also referred to as rebound, analgesic abuse, or analgesic-induced headaches, can be difficult to treat and are relieved by withdrawal of the offending drug, but the primary headache may still persist and revert to its previous pattern of occurrence. Furthermore, stopping abruptly can exacerbate headache and produce other symptoms of withdrawal. This may then lead the patient to resume treatment to relieve the headache thereby setting up a vicious circle.

Options for outpatient **treatment** include either abrupt or gradual withdrawal of the overused drug. Abrupt withdrawal has been suggested if the headache has been caused by the use of simple analgesics, ergot derivatives, or triptans, and gradual withdrawal if it is due to opioids.[6,7] Aggravation of symptoms may be managed by the use of naproxen, prednisolone, or amitriptyline.[6,7] Substitution with long-acting NSAID or intramuscular dihydroergotamine has been tried in withdrawal from ergotamine or analgesics;[8,9] However, withdrawal symptoms may persist for up to 2 weeks and detoxification from ergotamine or analgesics may require hospitalisation; intravenous metoclopramide and repetitive intravenous dihydroergotamine may be required to control nausea and vomiting and intractable headache, respectively.[8] Withdrawal from triptans has been reported to be of shorter duration with no intensive withdrawal symptoms; however, triptan overuse produces headaches at a faster rate and at lower dosages compared with ergotamine and analgesics, and is associated with an increase in migraine attack frequency.[1]

General advice on the **prevention** of medication-overuse headache has included limiting the frequency of use of such drugs,[1,3,4,8] and starting prophylactic therapy in migraine patients having more than 2 headache days a week.[3]

Migraine

Migraine is characterised by recurrent attacks of headache that typically last 4 to 72 hours. Attacks persisting for longer than 72 hours are referred to as status migrainosus. The headache is usually a unilateral pulsating pain that is aggravated by movement and is usually of sufficient severity to disturb or prevent daily activities. It is frequently accompanied by nausea, vomiting, or other gastrointestinal disturbances and there may be photophobia and phonophobia. Migraine with aura (classic migraine) is characterised by an aura consisting of visual or sensory symptoms that lasts less than an hour. The headache usually follows the aura directly, or within 1 hour, but may begin simultaneously with the aura. In addition, aura can occur without headache. Migraine without aura (common migraine) is the more common form occurring in about 75% of patients with migraine. Premonitory symptoms may occur before a migraine attack (with or without aura). Familial hemiplegic migraine is a rare syndrome in which migraine with aura may be preceded or accompanied by dysphasia, confusion, and hemiparesis. Basilar-type migraine is another rare form of migraine with aura in which there may be disturbances of the brain stem or occipital lobes accompanied by symptoms such as decreased level of consciousness, vertigo, ataxia, dysarthria, and diplopia.

Migraine is described as a neurovascular headache. Traditionally, intracranial vasoconstriction was considered responsible for the aura and extracranial vasodilatation for the headache. However, it appears that vascular events may be secondary to neuropathic changes and the liberation of vasoactive substances including serotonin (5-HT), catecholamines, histamine, kinins, neuropeptides such as calcitonin gene-related peptide (CGRP), and prostaglandins.

There are several factors that may precipitate migraine attacks. These include anxiety, physical and emotional stress, a change in sleep pattern, bright lights, fasting, some foods, and menstruation. Menstrual migraine is characterised by attacks without aura which are most likely to occur within 2 days of the start of menstruation. Migraine may also be precipitated by drugs including combined oral contraceptives and oestrogens, and glyceryl trinitrate. The frequency of migraine attacks can be reduced if such precipitating factors can be identified and avoided. Quiet, darkness, and sleep can ease an attack, with sleep heralding recovery.

The drug **treatment** of migraine may be tailored to the severity of individual disease from the outset (stratified care) or may begin with simple analgesics and be subsequently adjusted according to response (step strategy); in the UK stepped care seems to be increasingly preferred. Acute treatment of menstrual migraine is the same as for migraine however, as menstrual migraine may be of longer duration treatment may need to be repeated over several consecutive days.

Simple **analgesics** (paracetamol or NSAIDs including aspirin) are effective if taken at the earliest signs of an attack; weak opioid analgesics such as codeine are sometimes included in oral compound analgesic preparations. However, the frequent use of analgesics is best avoided to decrease the risk of medication-overuse headaches. Other drugs used with analgesics in antimigraine preparations have included caffeine and the sympathomimetic vasoconstrictor isometheptene. Dispersible and effervescent analgesic preparations are preferable because of their more rapid absorption.

If the initial treatment of migraine is delayed, absorption of oral drugs may be compromised by development of gastric stasis and nausea and vomiting. The addition of **antiemetics** such as buclizine and cyclizine, and the **prokinetic** drugs metoclopramide and domperidone is recommended if needed; they are often included in compound antimigraine preparations. Prokinetic drugs also

have the advantage of promoting gastric emptying and normal peristalsis. If nausea and vomiting are prominent rectal administration may be necessary.

Attacks not responding to simple analgesics such as NSAIDs may be treated with specific antimigraine drugs such as the selective serotonin (5-HT_1) agonists (e.g. sumatriptan) or the ergot derivatives ergotamine and dihydroergotamine; poor absorption and adverse effects limit the use of ergot derivatives and selective serotonin (5-HT_1) agonists are preferred.

Serotonin (5-HT_1) agonists are highly effective in relieving the pain and nausea of a migraine attack. There are a number of **triptans** available; patient characteristics and preferences vary in response to use and can sometimes be unpredictable. Some patients experience recurrence of the headache within 24 to 48 hours and often respond to a second dose. Finding the best triptan to suit the individual patient may involve trial and error; a change in formulation should also be considered. Triptans should not be used in patients with major risk factors for, or suffering from, cardiovascular disease. The main concern with all triptans is their potential for coronary vasoconstriction and no triptan appears to be safer than the others. Medication-overuse headaches have also been noted with triptan use.

Ergot derivatives are rarely needed now in the treatment of migraine. If **ergotamine** is used it should be given at the first warning of an attack; the earlier it is given, the more effective the treatment. Since its oral bioavailability is poor and may be reduced further during a migraine attack, ergotamine has sometimes been given in sublingual or rectal preparations. Ergotamine can also exacerbate nausea and vomiting; metoclopramide or domperidone, or in severe cases the phenothiazines chlorpromazine or prochlorperazine, may be given. Dihydroergotamine may be of use if parenteral treatment is required; it can also be given intranasally but there is less experience with this route. Patients who fail to respond to monotherapy may find combination treatment, such as a simple analgesic with a triptan, helpful particularly in prolonged attacks.

Patients who rapidly develop severe migraine may be given **parenteral** dihydroergotamine or sumatriptan. Some consider parenteral metoclopramide to be suitable first-line treatment. Intramuscular diclofenac has also been recommended. If there is no response to these drugs, dopamine antagonists, such as chlorpromazine or prochlorperazine, given parenterally may be effective in relieving the pain of acute migraine attacks. Prolonged attacks (status migrainosus) may require intravenous administration of dihydroergotamine with metoclopramide. The NSAIDs naproxen or diclofenac are better than specific antimigraine drugs for long duration attacks that are really migraine with a superseding tension-type headache.

Other drugs that may be given alone or in combination include corticosteroids or pethidine. Lidocaine has been given intravenously for the emergency treatment of migraine; intranasal lidocaine has also been tried. The opioid agonist-antagonist butorphanol, given by nasal spray, has been advocated, but its place in therapy, if any, remains to be established. Other drugs that have been investigated include CGRP antagonists; intravenous valproic acid has also shown promise in aborting acute attacks.

Guidelines have been issued for the treatment of migraine in **children and adolescents**. For acute treatment, ibuprofen and paracetamol were found to be effective in children aged 6 years and over; sumatriptan nasal spray should be considered in those aged 12 years and over.

Prophylactic treatment should be considered for patients in whom abortive measures are ineffective or migraine attacks occur frequently, or for those with less frequent but severe or prolonged attacks. Some recommend prophylaxis if attacks occur more often than once or twice a month. Prophylaxis can reduce the severity and/or frequency of attacks but does not eliminate them completely and patients still need additional abortive or symptomatic treatment. Drugs suggested for prophylaxis have a range of actions which reflects uncertainty over the pathogenesis of migraine. It is important to give prophylactic drugs for an adequate period before assessing their efficacy; a general guide of 6 to 8 weeks is advisable. Once an optimum effect has been achieved the need for continuing prophylaxis should be reviewed at intervals of about 3 to 6 months. Treatment is best withdrawn gradually, over 2 to 3 weeks.

The main prophylactic drugs are **beta blockers**, tricyclic **antidepressants**, and the **antiepileptics**, topiramate and valproate. Propranolol is considered by many to be the prophylactic drug of choice. Lethargy appears to be the most common adverse effect. Other beta blockers reported to be effective are those that, like propranolol, possess no intrinsic sympathomimetic activity; these include atenolol, metoprolol, nadolol, and timolol. The potential for beta blockers to interact with some serotonin (5-HT_1) agonists and ergotamine should be borne in mind. Tricyclic antidepressants, particularly amitriptyline, given in gradually increasing doses at night are useful for preventing migraine, especially in patients who also have depression or tension-type headache, although antimuscarinic adverse effects may occur. Valproate is also used for preventing migraine. Nausea appears to be the most common adverse effect. Topiramate is the main alternative to valproate. Weight loss and paraesthesia are commonly reported adverse effects. Topiramate or valproate are particularly useful in patients who also have epilepsy or bipolar disorder. Gabapentin may also be used for the prophylaxis of migraine.

Other drugs have been used for the prophylaxis of migraine. Of the drugs with calcium-channel blocking activity, flunarizine appears to be effective, and has been suggested for use in children, and verapamil may be useful, but evidence for the efficacy of other calcium-channel blockers such as diltiazem, nifedipine, or nimodipine is less convincing; NSAIDs may be worth trying. Pizotifen, an antihistamine and serotonin antagonist, has been widely used but evidence for its efficacy is limited; it may be tried in children. The use of methysergide, a potent serotonin antagonist, has declined because of serious adverse effects, in particular retroperitoneal fibrosis. MAOIs such as phenelzine have been used occasionally but are best reserved for severe cases refractory to other forms of prophylactic treatment. Cyproheptadine, an antihistamine and serotonin antagonist, has been used for migraine prophylaxis, particularly in children. Botulinum A toxin is used for the prophylaxis of headaches in adults with chronic migraine. Other drugs used for the prophylaxis of migraine have included butterbur, clonidine, cyclandelate, indoramin, feverfew, and the ergot derivative metergoline. Positive results have been seen with magnesium and riboflavin. Investigated drugs which have shown potential for prevention of migraine attacks include: baclofen, candesartan, lisinopril, montelukast, and venlafaxine. Despite promising initial results, there is limited evidence to support the use of SSRIs.

Post-dural puncture headache

For the management of headache associated with lumbar puncture or spinal anaesthesia, see Post-dural Puncture Headache under Local Anaesthetics, p. 1983.1.

Tension-type headache

Tension-type headaches, also referred to as muscle-contraction headaches, are probably the commonest form of headache. They are characterised by bilateral pain, which unlike migraine is continuous and non-pulsatile. The pain is often described by the patient as feeling like a tight band pressed around the head. Headaches of this type may be precipitated by many factors including psychosocial stress or muscular stress. Many patients also have associated symptoms of anxiety or depression. Tension-type headaches and migraine often co-exist and may then be referred to as combination or mixed headaches. Some patients only experience isolated acute attacks of tension-type headache (episodic tension-type headache), but others may develop chronic tension-type headache which is difficult to treat.

Treatment is aimed at removing the underlying causes where these can be identified. Simple massage may help if muscle contraction is a prominent component of the pain. Non-opioid analgesics, such as aspirin or other NSAIDs and paracetamol, may be tried for individual acute attacks of headache, but analgesic overuse must be avoided as this can lead to chronic headache resistant to other measures (see Medication-overuse Headache, p. 670.2). Opioids alone or in combination preparations with other analgesics should also be avoided. Hypnotics or sedatives have sometimes been used in combination preparations with analgesics in the management of tension-type headache that disrupts sleep but, because of the potential for abuse, they should be avoided in chronic headaches. Muscle relaxants appear to have little place in the management of tension-type headache; although some patients may respond, results are generally disappointing. Other drugs that have been tried include valproate and botulinum A toxin. **Prophylaxis** is preferable to regular short-term use of analgesics in controlling chronic tension-type headache. Tricyclic antidepressants, particularly amitriptyline, are generally considered as first choice, although benefit is rarely complete. The mode of action is unclear and appears to be independent of any antidepressant action. In most cases, improvement is seen with low doses, but full antidepressant doses are necessary in the presence of underlying depression. Addition of a beta blocker such as propranolol may sometimes be of benefit for patients with some migraine features. The antiepileptic topiramate has also been tried with some success.

Almotriptan Malate *(BANM, USAN, rINNM)*

Almotriptán, Malate d'; Almotriptán, malato de; Almotriptani Malas; LAS-31416 (almotriptan); Malato de almotriptán; PNU-180638E; Альмотриптана Малат.

1-[(3-[2-(Dimethylamino)ethyl]indol-5-yl]methyl)sulfonyl] pyrrolidine malate (1:1).

$C_{17}H_{25}N_3O_2S,C_4H_6O_5$=469.6

CAS — 154323-57-6 (almotriptan); 181183-52-8 (almotriptan malate).

ATC — N02CC05.

ATC Vet — QN02CC05.

UNII — PJP312605E.

Uses and Administration

Almotriptan malate is a selective serotonin (5-HT_1) agonist with actions and uses similar to those of sumatriptan (p. 679.3). It is used for the acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. Almotriptan is given orally as the malate, and doses are expressed in terms of the base; almotriptan malate 8.75 mg is equivalent to about 6.25 mg of almotriptan.

The recommended dose of almotriptan is 12.5 mg in the UK and 6.25 or 12.5 mg in the USA. If this is ineffective, a second dose should not be taken for the same attack. If symptoms recur within 24 hours after an initial response, a second dose may be taken after an interval of at least 2 hours. No more than 2 doses should be taken in a 24-hour period. For doses in hepatic and renal impairment see below.

Administration in hepatic or renal impairment. In patients with hepatic or severe renal impairment, no more than 12.5 mg of oral almotriptan should be taken in 24 hours; a starting dose of 6.25 mg may be used. No dose adjustment is needed in patients with mild to moderate renal impairment.

Migraine. For comparison of the relative benefits of different triptans in migraine, see under Sumatriptan, p. 680.1.

Adverse Effects and Precautions

As for Sumatriptan, p. 680.2 and p. 681.2.

Almotriptan should be given with caution to patients with hepatic impairment or severe renal impairment.

Patients with hypersensitivity to sulfonamides may theoretically show a similar reaction to almotriptan. (For discussion of cross-reactivity in sulfonamides and sulfa drugs see Hypersensitivity under Sulfamethoxazole, p. 365.3.)

Incidence of adverse effects. Results from studies involving more than 2500 patients with migraine suggested that adverse effects of almotriptan were infrequent.[1] The commonest adverse effects reported were dizziness, nausea and vomiting, headache, paraesthesia, fatigue, and drowsiness, all of which occurred in less than 3% of patients. The incidence of chest symptoms was 0.2% in 2 large phase III studies.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies almotriptan as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Interactions

As for Sumatriptan, p. 681.3.

Pharmacokinetics

After oral doses, peak plasma-almotriptan concentrations occur in about 1 to 3 hours, with a bioavailability of about 70%. Protein binding is about 35%. Almotriptan is metabolised mainly by monoamine oxidase type A to the inactive indole acetic acid derivative, and to a lesser extent by cytochrome P450 isoenzymes CYP3A4 and CYP2D6 to the inactive gamma-aminobutyric acid derivative. More than 75% of an oral dose is excreted in the urine and the remainder in faeces. About 40% of the dose in the urine is excreted as unchanged drug. The plasma elimination half-life is about 3.5 hours in healthy subjects, increasing to about 7 hours in patients with severe renal impairment.

Distribution into milk has been found in studies in *rats.*

UNII — 81AXN7R2QT.

Pharmacopoeias. In *Eur.* (see p. vii), *Jpn*, and *US.*

Ph. Eur. 8: (Dihydroergotamine Mesilate). Colourless crystals or a white or almost white crystalline powder. Slightly soluble in water and in alcohol; sparingly soluble in methyl alcohol. A 0.1% solution in water has a pH of 4.4 to 5.4. Protect from light.

USP 36: (Dihydroergotamine Mesylate). A white to slightly yellowish powder, or off-white to faintly red powder, having a faint odour. Soluble 1 in 125 of water, 1 in 90 of alcohol, 1 in 175 of chloroform, and 1 in 2600 of ether. pH of a 0.1% solution in water is between 4.4 and 5.4. Protect from light.

Dihydroergotamine Tartrate *(BANM, rINNM)*

Dihidroergotamina, tartrato de; Dihidroergotamino tartratas; Dihidroergotamin-tartarát; Dihydroergotamiinitartraatti; Dihydroergotamine, Tartrate de; Dihydroergotamini Tartras; Dihydroergotamin-tartarát; Dihydroergotamintartrat; Tartrato de dihidroergotamina; Дигидроэрготамина Тартрат.

$(C_{33}H_{37}N_5O_5)_2,C_4H_6O_6$=1317.5

CAS — 5989-77-5.

ATC — N02CA01.

ATC Vet — QN02CA01.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Dihydroergotamine Tartrate). Colourless crystals or a white or almost white crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol. A 0.1% suspension in water has a pH of 4.0 to 5.5. Protect from light.

Uses and Administration

Dihydroergotamine is a semisynthetic ergot alkaloid that has weaker oxytocic and vasoconstrictor effects than ergotamine (p. 674.1). Its activity as a 5-HT_1 agonist is believed to contribute to its antimigraine action. It is used in the treatment of migraine and cluster headache, and in the treatment of orthostatic hypotension. It has also been used for the prophylaxis of venous thromboembolism (see p. 673.1).

Dihydroergotamine is commonly used as the mesilate by subcutaneous, intramuscular, or intravenous injection, although it may also be given as a nasal spray or orally.

For the treatment of **migraine** and to terminate an acute attack of **cluster headache**, dihydroergotamine mesilate is usually given by subcutaneous or intramuscular injection in doses of 1 mg repeated, if necessary, after 30 to 60 minutes up to a maximum daily dose of 3 mg. If a more rapid effect is desired it may be given intravenously in doses of 0.5 or 1 mg up to a maximum daily dose of 2 mg. The total weekly dose given by any route of injection should not exceed 6 mg. The usual nasal dose of dihydroergotamine mesilate for an acute attack of migraine is 500 micrograms sprayed into each nostril as a 0.4% solution followed after 15 minutes by an additional 500 micrograms in each nostril. A total intranasal dose of 2 mg per attack should not be exceeded. In the USA, the maximum licensed intranasal dose in 24 hours is 3 mg and in a 7-day period is 4 mg, while maximum daily doses of up to 4 mg with a maximum dose of 12 mg in a 7-day period have been given in other countries. Dihydroergotamine may also be given orally; up to 10 mg daily has been given for the treatment of acute attacks of migraine while lower oral doses are recommended for migraine prophylaxis.

Dihydroergotamine mesilate has also been used alone or with etilefrine hydrochloride (p. 1379.1) in the treatment of **orthostatic hypotension**, in usual oral doses of up to 10 mg daily in divided doses. Doses of up to 40 to 60 mg have been used in some patients.

Dihydroergotamine tartrate has been used for indications similar to those of the mesilate.

Medication-overuse headache. Dihydroergotamine may be used in the treatment of medication-overuse headache (p. 670.2), including symptoms of ergotamine withdrawal.

Migraine and cluster headache. Although sumatriptan is often the treatment of choice to abort acute attacks of migraine that do not respond to simple analgesic preparations, parenteral dihydroergotamine, especially with an antiemetic, is an alternative for patients who develop severe or refractory migraine (p. 670.3).[1-3] Preparations for intranasal[4] and oral use are also available and one for inhalation[5] is under development. In a comparative study, relief of migraine was slower after subcutaneous dihydroergotamine than after subcutaneous sumatriptan, but headache recurred less often.[6] In other studies, intranasal dihydroergotamine was not as effective as subcutaneous[7] or intranasal[8] sumatriptan.

Dihydroergotamine is also used in the treatment of cluster headache (p. 670.1), usually in emergency settings, where it is given to abort individual headache attacks.

Orthostatic hypotension. Dihydroergotamine may be of use in patients with refractory orthostatic hypotension (p. 1634.3). It is sometimes used in preparations with sympathomimetics such as etilefrine. After parenteral dihydroergotamine, standing blood pressure is increased, but total peripheral resistance and supine blood pressure are also increased.[1] It does not prevent postprandial hypotension, presumably because it does not constrict the splanchnic veins, although use with caffeine may overcome this problem. The main disadvantage of dihydroergotamine, however, is that it is ineffective, or at best weakly effective, when given orally, although there has been some evidence that oral ergotamine tartrate may be of value.

Dihydroergotamine has been suggested for use in the prevention of hypotension associated with epidural[2] or spinal anaesthesia,[3] the usual management of which is discussed in Treatment of Adverse Effects of Local Anaesthetics, p. 1983.1. It has also been tried in the management of hypotension associated with haemodialysis.[4]

Venous thromboembolism. Standard prophylaxis for surgical patients at high risk of venous thromboembolism (p. 1274.1) is usually with anticoagulants, with unfractioned or low-molecular-weight heparin being the most widely used. Dihydroergotamine can reduce venous stasis by vasoconstriction of capacitance vessels and has enhanced postoperative prophylaxis when used with heparin.[1] The use of dihydroergotamine with low-molecular-weight heparin has been shown to be of similar efficacy to dihydroergotamine with heparin.[2,3] However, although dihydroergotamine might enhance the effect of heparin, a US National Institutes of Health consensus conference warned of the potential risk associated with its vasoconstrictive effects, and the contra-indications to its use[4] (see also Effects on the Cardiovascular System, under Adverse Effects, below).

Adverse Effects and Treatment

As for Ergotamine Tartrate, p. 674.2, although vasoconstriction may be less pronounced and the frequency of nausea and vomiting lower with dihydroergotamine mesilate than with ergotamine tartrate. Dihydroergotamine does not appear to produce physical dependence.

Effects on the cardiovascular system. There have been conflicting reports on the risk of vasospasm in patients given dihydroergotamine with heparin for thromboembolism prophylaxis. Vasospastic or necrotic reactions have been reported on several occasions during such therapy.[1-4] In an Austrian study of 147 290 patients given drug prophylaxis for thromboembolism, complications attributable to ergotism were seen in 142 of 61 092 (0.23%) who received dihydroergotamine and heparin.[5] Others,[6] however, saw only 1 case of vasospasm in 5100 trauma patients (0.02%) given the combination. In 1989 the Swedish Adverse Drug Reactions Advisory Committee reported[7] that up to the end of September 1987 the manufacturer had received 201 reports of vasospastic reactions associated with the use of *Orstanorm* (dihydroergotamine + lidocaine) with heparin. Permanent damage occurred in 59% of these patients. Vasospastic reactions had occurred more frequently in patients who had undergone surgery for trauma and the prognosis for such patients was generally poorer than for others. Since the risk of permanent damage appeared to be related to treatment length the Committee recommended that this preparation should not be given for more than 7 days.

Fibrosis. For reference to fibrosis associated with the administration of dihydroergotamine, see Methysergide Maleate, p. 677.2.

Precautions

As for Ergotamine Tartrate, p. 675.1.

Cardiovascular disorders. For specific contra-indications and precautions in cardiovascular disorders, see under Ergotamine, p. 675.1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies dihydroergotamine as porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be taken in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Interactions

As for Ergotamine (p. 675.2).

Use with other vasoconstrictive drugs, including supplementary antimigraine treatment with ergotamine or sumatriptan, should be avoided.

Pharmacokinetics

Peak plasma-dihydroergotamine concentrations occur within about 1 to 2 hours after oral doses, about 30 minutes after intramuscular injection, about 15 to 45 minutes after subcutaneous injection, and about 45 to 55 minutes after intranasal doses. However, the bioavailability of dihydroergotamine after oral doses is very low; values ranging from less than 0.1 to 1.5% have been reported. Although dihydroergotamine is incompletely absorbed from the gastrointestinal tract, the low bioavailability is considered to be determined primarily by extensive first-pass hepatic metabolism. Bioavailability after intranasal doses is 43%. Dihydroergotamine is 90 to 95% bound to plasma proteins.

Dihydroergotamine undergoes extensive metabolism, the major metabolite, 8′-β-hydroxydihydroergotamine, being active. Plasma concentrations of this metabolite are greater than those of dihydroergotamine. A further oxidation step produces 8′,10′-dihydroxydihydroergotamine, which is also active. Other metabolites are also formed. Most of a dose is excreted as metabolites, mainly in the bile; 5 to 10% is excreted in the urine of which only trace amounts are of unchanged drug. The elimination of dihydroergotamine is biphasic; half-lives of about 1 to 2 hours and 22 to 32 hours have been reported for the 2 phases, respectively.

Eletriptan Hydrobromide

(BANM, USAN, rINNM)

Eletriptaanihydrobromidi; Élétriptan; Bromhydrate d'; Eletriptán, hidrobromuro de; Eletriptanhydrobromid; Eletriptani Hydrobromidum; Hidrobromuro de eletriptán; UK-116044-04; Элетриптана Гидробромид.

3-[[(*R*)-1-Methyl-2-pyrrolidinyl]methyl]-5-[2-(phenylsulfonyl)ethyl]indole hydrobromide.

$C_{22}H_{26}N_2O_2S,HBr$=463.4

CAS — 143322-58-1 (eletriptan); 177834-92-3 (eletriptan hydrobromide).

ATC — N02CC06.

ATC Vet — QN02CC06.

UNII — M4TW832TA3.

Uses and Administration

Eletriptan hydrobromide is a selective serotonin (5-HT_1) agonist with actions and uses similar to those of sumatriptan (p. 679.3). It is used for acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. Eletriptan is given orally as the hydrobromide, but doses are expressed in terms of the base; eletriptan hydrobromide 24.2 mg is equivalent to about 20 mg of eletriptan.

UK licensed product information recommends a usual dose of 40 mg; if this is ineffective, a second dose should not be taken for the same attack. If symptoms recur within 24 hours after an initial response, a second dose may be taken after an interval of at least 2 hours. Doses of 80 mg may be used in subsequent attacks, but should not be repeated within a 24-hour period. US licensed product information allows a lower dose of 20 mg with a maximum single dose of 40 mg and a maximum daily dose of 80 mg. For doses in renal impairment, see below.

Administration in renal impairment. UK licensed product information for eletriptan recommends an oral dose of 20 mg in patients with mild to moderate renal impairment; the maximum daily dose should not exceed 40 mg. Eletriptan should not be used in severe impairment.

Migraine. For comparison of the relative benefits of different triptans in migraine, see under Sumatriptan, p. 680.1.

Adverse Effects and Precautions

As for Sumatriptan, p. 680.2 and p. 681.2.

Eletriptan should not be used in patients with severe hepatic impairment; however, this is due to a lack of data. No dosage adjustment is needed in mild or moderate hepatic impairment. Blood pressure effects of eletriptan are increased in renal impairment and therefore UK licensed product information recommends that it should be used with caution in patients with mild to moderate renal impairment; its use in those with severe renal impairment is contra-indicated.

Breast feeding. Eletriptan is distributed into breast milk. The licensed product information states that in a study of 8 women given a single, 80-mg dose of eletriptan, the mean total amount excreted into breast milk over 24 hours was 0.02% of the dose. Nonetheless, caution is advised when eletriptan is used in breast-feeding women; infant exposure can be minimised by avoiding breast feeding for 24 hours after treatment.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies eletriptan as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Interactions

As for Sumatriptan, p. 681.3.

Eletriptan should not be given with potent inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as erythromycin and ketoconazole; increased plasma levels of eletriptan have been noted after such combinations. It is recommended that eletriptan should not be taken within at least 72 hours of treatment with such drugs.

Pharmacokinetics

After oral doses eletriptan is rapidly and well absorbed (at least 81%) and has a bioavailability of about 50%. Peak plasma concentrations occur within 1.5 hours. Eletriptan is about 85% protein bound. It is mainly metabolised by the hepatic cytochrome P450 isoenzyme CYP3A4. Non-renal clearance accounts for about 90% of the elimination of eletriptan and the plasma elimination half-life is about 4 hours. A small amount is distributed into breast milk.

Ergotamiinitartraatti; Ergotamin Tartarat; Ergotamin Tartrat; Ergotamina, tartrato de; Ergotamine, tartrate d'; Ergotamini Tartras; Ergotamino tartratas; Ergotamin-tartarát; Ergotamin-tartrat; Ergotaminy winian; Tartrato de ergotamina; Эрготамина Тартрат.

(5'*S*)-12'-Hydroxy-2'-methyl-5'-benzylergotaman-3',6',18-trione tartrate; (5'*S*)-12'-Hydroxy-2'-methyl-3',6',18-trioxo-5-benzylergotaman (+)-tartrate.

$(C_{33}H_{35}N_5O_5)_2C_4H_6O_6$=1313.4

CAS — 113-15-5 (ergotamine); 379-79-3 (ergotamine tartrate).

ATC — N02CA02.

ATC Vet — QN02CA02.

UNII — MRU5XH3B48.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Ergotamine Tartrate). Slightly hygroscopic, colourless crystals or a white or almost white crystalline powder. It may contain 2 molecules of methanol of crystallisation. Slightly soluble in alcohol. Aqueous solutions slowly become cloudy owing to hydrolysis; this may be prevented by the addition of tartaric acid. A 0.25% suspension in water has a pH of 4.0 to 5.5. Store in airtight glass containers at a temperature of 2 degrees to 8 degrees. Protect from light.

USP 36: (Ergotamine Tartrate). Colourless odourless crystals or a white or yellowish-white crystalline powder. Soluble 1 in about 3200 of water, but soluble 1 in about 500 of water in the presence of a slight excess of tartaric acid; soluble 1 in 500 of alcohol. Store at a temperature not exceeding 8 degrees. Protect from light.

Stability in solution. References.

Uses and Administration

Ergotamine is an alkaloid derived from ergot (p. 2137.1). It has marked vasoconstrictor effects, and a partial agonist action at serotonin (5-HT) receptors; it also has a powerful oxytocic action on the uterus, although less so than ergometrine (p. 2136.2). It is used in migraine and cluster headache, and has been tried in orthostatic hypotension.

Ergotamine is commonly used as the tartrate. It is usually given orally, but has also been given sublingually, rectally, and by oral inhalation. It was formerly given by subcutaneous or intramuscular injection. Caffeine is sometimes given with ergotamine tartrate with the intention of improving the latter's absorption, although whether it does so is not clear. Antiemetics such as cyclizine hydrochloride are sometimes included in combination preparations with ergotamine tartrate.

Ergotamine is used in **migraine** unresponsive to non-opioid analgesics. However, its adverse effects limit its use and prevent use for prophylaxis. It is most effective when given as early as possible in a migraine attack, preferably during the prodromal phase.

The usual oral dose is 2 mg of ergotamine tartrate; if necessary, doses of 1 to 2 mg may be given at half-hourly intervals thereafter. Usually not more than 6 mg should be given in 24 hours; some licensed product information recommends not more than 8 mg for each attack. The recommended minimum interval between successive 24-hour courses is 4 days, and the total weekly dose is limited to a maximum of 12 mg, although some recommend a lower weekly limit of 10 mg. It is also recommended that patients should receive no more than 2 courses in each month. Similar doses may be given sublingually.

Ergotamine tartrate may also be given rectally as suppositories, especially if the oral route is not effective or not practicable. The rectal dose of ergotamine tartrate is 2 mg repeated, if necessary, one hour later. Usually, not more than 4 mg should be given for each attack and not more than 10 mg in one week with an interval of at least 4 days between successive 24-hour courses.

Ergotamine is used in patients with **cluster headache** to treat individual attacks of headache. Doses used are similar to those given to treat migraine. It has also been used to prevent headache attacks during cluster periods, when it is usually given daily in low doses for up to 2 weeks, either orally or rectally (see below).

Migraine and cluster headache. Ergotamine was formerly one of the main drugs used to treat acute attacks of migraine (p. 670.3) unresponsive to non-opioid analgesics, but triptan serotonin (5-HT_1) agonists such as sumatriptan are now preferred. Since ergotamine may exacerbate the nausea and vomiting that commonly develops as a migraine attack progresses it is often necessary to give an antiemetic as well. Poor oral bioavailability may be reduced further during a migraine attack and ergotamine has sometimes been given sublingually, rectally, or by oral inhalation. Adverse effects limit the dose that can be used for an individual attack and prevent the long-term use that would be required for migraine prophylaxis.

Ergotamine may be used similarly in cluster headache (p. 670.1) to treat individual headaches during a cluster period. Ergotamine is also used in low doses given orally or rectally for limited periods of up to 2 weeks in the prophylaxis of headache attacks during a cluster period. Regimens that have been tried for such prophylaxis include 1 to 2 mg of ergotamine tartrate given 1 to 2 hours before an expected attack or 1 to 2 hours before bedtime for nocturnal attacks. The total maximum dose of ergotamine tartrate that may be given weekly for the prevention of cluster headache is less well established than for the treatment of migraine. Ergotamine is often given for only 5 to 6 days in each week, which allows the patient to assess whether the cluster period has ended.

Orthostatic hypotension. Ergotamine and dihydroergotamine may be of use in patients with refractory orthostatic hypotension (p. 1634.3). Ergotamine is believed[1] to be less selective than dihydroergotamine (p. 672.3) in its actions and affects both venous capacitance and peripheral resistance.[2,3] However, the oral bioavailability of ergotamine is greater[2] than that of dihydroergotamine and there have also been some reports of successful treatment with inhaled[3,4] or rectal[3] ergotamine.

Adverse Effects

The adverse effects of ergotamine may be attributed either to its effects on the CNS, or to vasoconstriction of blood vessels and possible thrombus formation.

After therapeutic doses nausea and vomiting commonly occur as a result of the direct emetogenic effect of ergotamine; some patients may also have abdominal pain. Weakness and muscle pains in the extremities and numbness and tingling of the fingers and toes may occur. There may occasionally be localised oedema and itching in hypersensitive patients. Treatment should be stopped if symptoms of vasoconstriction develop. Susceptible patients, especially those with sepsis, liver disease, kidney disease, or occlusive peripheral vascular disease, may show signs of acute or chronic poisoning with normal doses of ergotamine.

Symptoms of acute overdosage include nausea, vomiting, diarrhoea, extreme thirst, coldness, tingling, and itching of the skin, a rapid and weak pulse, hypertension or hypotension, shock, confusion, convulsions, and unconsciousness; fatalities have been reported. Further symptoms of peripheral vasoconstriction or of cardiovascular disturbances, as seen in chronic ergotamine poisoning, may also occur but may be delayed.

In chronic poisoning or ergotism, resulting from therapeutic overdosage or the use of ergotamine in susceptible patients, severe circulatory disturbances may develop. The extremities, especially the feet and legs, become numb, cold, tingling, and pale or cyanotic, with muscle pain; there may be no pulse in the affected limb. Eventually gangrene develops in the toes and sometimes the fingers. Anginal pain, tachycardia or bradycardia, and hypertension or hypotension have been reported. Myocardial infarction has occurred rarely. Pleural and pericardial fibrosis may occur with excessive use and there have been rare cases of fibrosis of the cardiac valves. Chronic, intractable headache (rebound headache) may occur and is also a major withdrawal symptom following the development of ergotamine dependence (see under Precautions, p. 675.1). Other adverse effects include confusion and convulsions. On rare occasions symptoms of vasoconstriction of blood vessels in the brain, eye, intestines, and kidneys occur. Anorectal ulceration, sometimes leading to rectal necrosis and stenosis or rectovaginal fistula, has been reported after excessive use of suppositories containing ergotamine.

Effects on the cardiovascular system. Reports[1-5] of adverse cardiovascular effects associated with ergotamine, including mention of fatalities.

Fibrosis. For reference to fibrosis associated with the use of ergotamine tartrate, see Methysergide Maleate, p. 677.2.

Treatment of Adverse Effects

Treatment of acute poisoning with ergotamine is symptomatic (see also p. 1537.1). Although the benefit of gastric decontamination is uncertain, activated charcoal may be given to patients who present within 1 hour of ingesting a toxic dose (more than 125 micrograms/kg in adults) or any amount in a child or in adults with peripheral vascular disease, ischaemic heart disease, severe infection, or hepatic or renal impairment. Alternatively, gastric lavage may be considered in adults within 1 hour of ingesting a potentially life-threatening overdose. In chronic poisoning, withdrawal of ergotamine may be all that is required in some patients.

In both acute and chronic poisoning, attempts must be made to maintain an adequate circulation to the affected parts of the body in order to prevent the onset of gangrene. In severe arterial vasospasm vasodilators such as sodium nitroprusside by intravenous infusion have been given; heparin and dextran 40 have also been advocated to minimise the risk of thrombosis. Analgesics may be required for severe ischaemic pain.

Cardiovascular effects. Sodium nitroprusside has been used in severe ergotamine poisoning for its vasodilating and hypotensive actions; it should, however, be used with care if hypotension is a symptom of poisoning. It is usually given by intravenous infusion[1-4] although there have also been reports of intra-arterial infusion for ergotamine-induced ischaemia;[5,6] for details of precautions, see p. 1498.1.

Many other drugs have been used in the treatment of circulatory disturbances induced by ergotamine. These include oral captopril,[7] alprostadil by intra-arterial infusion,[8,9] and glyceryl trinitrate by intravenous infusion.[10,11]

Precautions

Ergotamine tartrate is contra-indicated in patients with severe or uncontrolled hypertension, shock, severe or persistent sepsis, peripheral vascular disease, ischaemic heart disease, temporal arteritis, hyperthyroidism, or hepatic or renal impairment. It is also contra-indicated in those with basilar or hemiplegic migraine. Ergotamine tartrate should be used with care in patients with anaemia. It is contra-indicated in pregnancy because of its oxytocic effect (see also below).

Patients should be warned to keep within the recommended dosage. Some symptoms of overdosage may mimic those of migraine. Numbness or tingling of the extremities generally indicates that ergotamine should be stopped. Although ergotamine is used for limited periods in the prevention of episodic cluster headache, it should not be given prophylactically in other circumstances, as prolonged use may give rise to gangrene. Dependence has occurred with regular use of ergotamine tartrate even if dosage recommendations are adhered to (see below).

Dizziness and feelings of anxiety have been reported; if affected, patients should avoid driving or operating machinery.

Breast feeding. Although the last available guidance from the American Academy of Pediatrics included ergotamine among those drugs that may be given with caution to breast-feeding mothers,[1] it notes that maternal use in doses equivalent to those given for the treatment of migraine has been associated with vomiting, diarrhoea, and convulsions in nursing infants. UK licensed product information recommends that ergotamine tartrate should be avoided during breast feeding; the distribution of unchanged drug and metabolites into breast milk presents a risk of ergotism in the infant and repeated doses of ergotamine may impair lactation.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/01/09)

Cardiovascular disorders. US licensed product information contra-indicates the use of dihydroergotamine in patients with ischaemic heart disease and other cardiovascular disorders such as uncontrolled hypertension, peripheral arterial disease, or coronary artery vasospasm; it is also recommended that dihydroergotamine should not be given to those with a family history of ischaemic heart disease, to postmenopausal women, men aged over 40, or to those with other ischaemic risk factors such as hypertension, hypercholesterolaemia, smoking, diabetes, or obesity, unless cardiovascular evaluation to exclude such disease has been carried out. Similar precautions and contra-indications, which resemble those that apply to serotonin (5-HT_1) agonists such as sumatriptan (p. 681.2), may be applicable to other ergot derivatives used in migraine such as ergotamine.

In other countries, warnings concerning the use of ergot derivatives in patients with risk factors for myocardial ischaemia appear to be less stringent, although caution is clearly advisable.

Dependence. Dependence can develop insidiously when ergotamine tartrate is used for more than 2 days each week, even if total daily or weekly dosage recommendations are observed.[1] Individual reports indicate a state of addiction characterised by a predictable and irresistible pattern of drug usage, the development of tolerance to adverse effects, and a syndrome of withdrawal on stopping the drug. Ergotamine-dependent patients suffer from daily, or almost daily, migraine headaches, often referred to as medication-overuse headaches or 'rebound headaches', which are only alleviated by ergotamine. Intensifying headache with autonomic disturbances occurs within 24 to 48 hours of withdrawal of ergotamine and may continue for 72 hours or longer. As with other medication-overuse headaches (p. 670.2), supportive and symptomatic measures should be taken to treat the withdrawal syndrome.

1. Saper JR. Ergotamine dependency—a review. *Headache* 1987; **27:** 435–8.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, does not classify the porphyrinogenic risk for single-ingredient preparations containing ergotamine although combinations containing the drug are classified as porphyrinogenic; such products should be prescribed only for compelling reasons and precautions should be taken in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Pregnancy. Ergotamine is contra-indicated in pregnancy because of its oxytocic effect. Accidental dosage of ergotamine in the form of a *Cafergot* suppository (ergotamine tartrate 2 mg and caffeine 100 mg) to a patient at 39 weeks of pregnancy caused uterine contractions and fetal tachycardia.[1] An emergency caesarean section was undertaken because of suspected placental abruption but no clear signs of retroplacental haemorrhage were found. The neonate recovered quickly after delivery and had developed normally during the next 10 years.

Jejunal atresia has been reported[2] in an infant born prematurely to a woman who had taken ergotamine tartrate 6 to 8 mg daily, as *Cafergot* tablets, throughout her pregnancy. Two cases of Möbius syndrome (a condition characterised by facial paralysis as a result of hypoplasia of cranial nerve nuclei) have been associated with exposure to ergotamine during the first trimester of pregnancy.[3,4] In the first report[3] the mother had inadvertently been given three *Cafergot* suppositories within a period of 1 to 2 hours and at the time had uterine cramping and a bloody vaginal discharge. The second mother[4] had used 2-mg ergotamine suppositories on a regular basis during the first 8 weeks of pregnancy.

Interactions

The vasoconstrictor effects of ergotamine are enhanced by sympathomimetics such as adrenaline. There is also an increased risk of peripheral vasoconstriction during use of ergotamine with beta blockers.

Ergotamine is metabolised by the cytochrome P450 isoenzyme CYP3A4 and consequently it should not be given with potent inhibitors of this isoenzyme; elevated ergotamine concentrations sufficient to cause ergotism may occur with azole antifungals, macrolide antibacterials such as erythromycin and clarithromycin, and HIV-protease inhibitors including indinavir and ritonavir. Use of tetracycline with ergotamine may also increase the risk of ergotism and should be avoided.

Ergotamine should not be used with or given until several hours *after stopping* a serotonin (5-HT_1) agonist, since there is an additional risk of prolonged vasospastic reactions; at least 6 hours is advised for almotriptan, rizatriptan, sumatriptan, and zolmitriptan, and at least 24 hours for eletriptan, frovatriptan, and naratriptan. Conversely, a delay is advised *before starting* a serotonin agonist in patients who have been receiving ergotamine: almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, or zolmitriptan should not be given until at least 24 hours after stopping the use of preparations containing ergotamine.

Antibacterials. Acute reactions ranging from minor ergotism[1] to severe vasospasm[2] have been reported in patients given *erythromycin* in addition to ergotamine. There are also reports of acute ergotism in patients given ergotamine tartrate with *clarithromycin*[3,4] or *troleandomycin*.[5] The theoretical possibility exists that there may be a similar interaction with *azithromycin*. Ergotism has also been reported in patients given erythromycin[6] or troleandomycin[7] with dihydroergotamine.

1. Lagier G, *et al.* Un cas d'ergotisme mineur semblant en rapport avec une potentialisation de l'ergotamine par l'éthylsuccinate d'érythromycine. *Therapie* 1979; **34:** 515–21.
2. Ghali R, *et al.* Erythromycin-associated ergotamine intoxication: arteriographic and electrophysiologic analysis of a rare cause of severe ischemia of the lower extremities and associated ischemic neuropathy. *Ann Vasc Surg* 1993; **7:** 291–6.

4. Ausband SC, Goodman PE. An unusual case of clarithromycin associated ergotism. *J Emerg Med* 2001; **21:** 411–13.
5. Matthews NT, Havill JH. Ergotism with therapeutic doses of ergotamine tartrate. *N Z Med J* 1979; **89:** 476–7.
6. Leroy F, *et al.* Dihydroergotamine-erythromycin-induced ergotism. *Ann Intern Med* 1988; **109:** 249.
7. Franco A, *et al.* Ergotisme aigu par association dihydroergotamine-triacétyloléandomycine. *Nouv Presse Med* 1978; **7:** 205.

Antidepressants. There have been isolated case reports[1] of the serotonin syndrome (p. 443.2) in patients given dihydroergotamine with *amitriptyline, imipramine, paroxetine,* or *sertraline.*

1. Mathew NT, *et al.* Serotonin syndrome complicating migraine pharmacotherapy. *Cephalalgia* 1996; **16:** 323–7.

Antimigraine drugs. Arterial occlusion has been reported[1] in 2 patients given *methysergide* with a high parenteral dosage of ergotamine for cluster headache; the combination should be avoided. Use of ergotamine as supplementary antimigraine medication in patients receiving *dihydroergotamine* is not recommended.

For reports of arterial vasoconstriction in patients taking *beta blockers* and antimigraine drugs, see below. See also Interactions, above for a comment on the risk of vasospastic reactions with serotonin (5-HT_1) agonists such as *sumatriptan.*

1. Joyce DA, Gubbay SS. Arterial complications of migraine treatment with methysergide and parenteral ergotamine. *BMJ* 1982; **285:** 260–1.

Antivirals. There have been reports of ergotism in patients given ergotamine with combination antiviral treatment for HIV infection. It was suggested that the ergotism might have been caused by inhibition of ergotamine metabolism by *ritonavir* in 4 cases,[1-4] *indinavir* in one,[5] and *nelfinavir*[6] in another. One of the patients given ritonavir,[4] who had taken three 1-mg tablets of ergotamine tartrate over the 4 days before presentation, also developed signs of cerebrovascular involvement and eventually went into an irreversible coma.

The metabolism of ergot alkaloids may be inhibited by *delavirdine* or *efavirenz.*

Beta blockers. Peripheral vasoconstriction was reported in a patient with migraine after addition of *propranolol* to regular use of *Cafergot* (ergotamine and caffeine) suppositories twice daily.[1] This combination has been used without complication by others, who suggested that excessive dosage of ergotamine tartrate, rather than an interaction between ergotamine and propranolol, was responsible.[2] However, arterial vasoconstriction has been reported after use of methysergide with propranolol and *oxprenolol* with ergotamine.[3] Such combinations should therefore be used with caution.

Glyceryl trinitrate. Glyceryl trinitrate has been reported to increase the oral bioavailability and plasma concentrations of dihydroergotamine in patients with orthostatic hypotension.[1]

1. Bobik A, *et al.* Low oral bioavailability of dihydroergotamine and first-pass extraction in patients with orthostatic hypotension. *Clin Pharmacol Ther* 1981; **30:** 673–9.

Tacrolimus. Ergotamine may inhibit the metabolism of tacrolimus by cytochrome P450 isoenzymes (see p. 1977.3).

Pharmacokinetics

Absorption of ergotamine from the gastrointestinal tract is poor and may be further decreased by the occurrence of gastric stasis during migraine attacks. Bioavailability is also reduced by a high first-pass hepatic metabolism. Ergotamine has been given rectally or by inhalation in an attempt to overcome these effects, with some improvement in absorption, but bioavailability is still about 5% or less. Absorption of sublingual ergotamine is very poor. There is considerable interindividual variation in the bioavailability of ergotamine, regardless of the route. Caffeine is sometimes included in oral and rectal preparations of ergotamine to improve the latter's absorption, although whether it does so is not clear. Drugs such as metoclopramide are sometimes given with the aim of alleviating gastric stasis and thus improve the absorption of ergotamine.

Plasma protein binding is about 93 to 98%. Ergotamine is metabolised extensively in the liver via the cytochrome P450 isoenzyme CYP3A4; the majority of metabolites are excreted in the bile. About 4% of a dose is excreted in the urine. Some of the metabolites are pharmacologically active. The elimination of ergotamine is biphasic; half-lives of about 2 and 21 hours have been reported for the 2 phases, respectively. Ergotamine or its metabolites have been detected in breast milk.

Feverfew

Camomille, grande; Matrem; Matricaria; Mattram; Mutterkraut; Nat' kopretiny řimbaby; Partenio; Reunuspäivänkakkara; Rimbaba Obyčajná; Spilcuță; Tanaceti Parthenii Herba; Tanaceto; Vaistinių skaistenių žolė; Wermod Wen; Пиретрум Девичий; Őszi margitvirág; Девичья Трава.

ATC Herb — HN02CW5005 (Tanacetum parthenium: leaf).
UNII — 6GE7Z0761K (Tanacetum parthenium); Z64FK7P217 (Tanacetum parthenium leaf).

Pharmacopoeias. In *Eur.* (see p. vii) and in *US*. *US* also describes Powdered Feverfew.

Ph. Eur. 8: (Feverfew). The dried, whole or fragmented aerial parts of *Tanacetum parthenium*. It contains not less than 0.2% of parthenolide ($C_{15}H_{20}O_3$ = 248.3), calculated with reference to the dried drug. It has a camphoraceous odour. Protect from light.

USP 36: (Feverfew). It consists of the dried leaves of *Tanacetum parthenium* (Asteraceae), collected when the plant is in flower. Store in a dry place. Protect from light.

Uses and Administration

Feverfew consists of the dried leaves of the plant *Tanacetum parthenium* (Asteraceae). It is a traditional herbal remedy used in the prophylaxis of migraine. Its effects have been attributed to the plant's content of sesquiterpene lactones, notably parthenolide. A preparation of the dried leaf powder, which has been standardised to provide a minimum of 0.2% parthenolide, is available in some countries. A suggested oral dose is 250 mg daily; a lower dose of 100 mg daily has also been given.

Extracts of feverfew, particularly parthenolide-free extracts which have been promoted as less sensitising, have been used for their supposed anti-inflammatory benefits in cosmetics and topical products.

Parthenolide has also been investigated for its antineoplastic potential.

Migraine. Feverfew is a traditional herbal remedy used in the prophylaxis of migraine (p. 670.3). Studies of standardised preparations of the freeze-dried powdered leaf have produced variable results in preventing or ameliorating migraine attacks, and a systematic review[1] has concluded that its efficacy in preventing migraine is unproven.

1. Pittler MH, Ernst E. Feverfew for preventing migraine. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2004 (accessed 27/04/05).

Rheumatoid arthritis. Feverfew has anti-inflammatory activity *in vitro* and has been tried in the treatment of rheumatic diseases. However, an evidence-based report by the Arthritis Research Campaign[1] in the UK considered that it was ineffective in rheumatoid arthritis (p. 13.2), although adverse effects were minor with short-term use.

1. Arthritis Research Campaign. Complementary and alternative medicines for the treatment of rheumatoid arthritis, osteoarthritis and fibromyalgia (issued February 2009). Available at: http://www.arthritisresearchuk.org/pdf/Complementary%20and%20alternative%20medicines_110120101543331.pdf (accessed 25/11/10)

Adverse Effects and Precautions

Most adverse effects noted with feverfew are mild and reversible. Mouth ulceration and soreness have been reported, and may be due to sensitisation; if they occur feverfew should be withdrawn. Contact dermatitis has also been reported. Gastrointestinal effects such as nausea, constipation or diarrhoea, and heartburn occur rarely and there have been spontaneous reports of eosinophilia, abnormal liver function tests, renal failure, Raynaud's phenomenon, and hypertension. Withdrawal symptoms such as rebound headache, anxiety, and insomnia have been seen in long-term users of feverfew who stop treatment suddenly.

Feverfew is reputed to have abortifacient properties and it is recommended that preparations should not be used in pregnancy.

Effects on the blood. There have been suggestions that feverfew may increase the risk of bleeding during surgery or in patients taking anticoagulants. However, although inhibition of platelet aggregation has been reported *in vitro* or in *animals* a review[1] of clinical studies noted that feverfew did not appear to affect haematological safety parameters.

1. Pittler MH, Ernst E. Feverfew for preventing migraine. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2004 (accessed 27/04/05).

Interactions

It has been suggested that feverfew may enhance the effects of anticoagulants (but see Effects on the Blood, above).

$C_{14}H_{17}N_3O.C_4H_6O_4.H_2O$=379.4
CAS — 158930-17-7.
ATC — N02CC07.
ATC Vet — QN02CC07.
UNII — D28J6W18HY.

Uses and Administration

Frovatriptan is a selective serotonin (5-HT_1) agonist with actions and uses similar to those of sumatriptan (p. 679.3). It is used for the acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. Frovatriptan is given orally as the succinate although doses are expressed in terms of the base; frovatriptan succinate 3.9 mg is equivalent to about 2.5 mg of frovatriptan.

The recommended dose is 2.5 mg; if this is ineffective, a second dose should not be taken for the same attack. If symptoms recur after an initial response, the dose may be repeated after an interval of at least 2 hours. The maximum dose of frovatriptan in 24 hours is 5 mg in the UK although, in the USA, a maximum daily dose of 7.5 mg is allowed.

Adverse Effects and Precautions

As for Sumatriptan, p. 680.2 and p. 681.2.

UK licensed product information recommends that frovatriptan should not be used in patients with severe hepatic impairment (Child-Pugh class C); however, this is due to a lack of data and no dosage adjustment is needed in mild or moderate hepatic impairment.

Interactions

As for Sumatriptan, p. 681.3.

Frovatriptan is metabolised by the cytochrome P450 isoenzyme CYP1A2; fluvoxamine, a potent inhibitor of this isoenzyme, has been shown to increase the blood concentrations of frovatriptan by 27 to 49%.

Pharmacokinetics

After oral doses, peak plasma-frovatriptan concentrations occur in 2 to 4 hours, and bioavailability is about 20% in men and 30% in women. Food may delay the time to peak plasma concentrations by about 1 hour. Frovatriptan is 15% protein bound. It is mainly metabolised by the hepatic cytochrome P450 isoenzyme CYP1A2. About 32% of an oral dose is excreted in the urine and 62% in faeces. The plasma elimination half-life of frovatriptan is about 26 hours.

Distribution into milk has been found in studies in *rats*.

Pharmacopoeias. In *Br.* and *US.*

BP 2014: (Methysergide Maleate). A white or almost white crystalline powder which may have a yellow or pink tinge; odourless or almost odourless. Slightly soluble in water and in methyl alcohol; practically insoluble in chloroform and in ether. A 0.2% solution in water has a pH of 3.7 to 4.7. Store at a temperature of 2 degrees to 8 degrees. Protect from light.

USP 36: (Methysergide Maleate). A white to yellowish-white or reddish-white, crystalline powder. Is odourless or has not more than a slight odour. Soluble 1 in 200 of water and 1 in 165 of alcohol; soluble 1 in 3400 of chloroform; practically insoluble in ether. pH of a 1 in 500 solution is between 3.7 and 4.7. Store in airtight containers at a temperature of 2 degrees to 8 degrees. Protect from light.

Uses and Administration

Methysergide maleate is a semisynthetic ergot alkaloid. It is a potent serotonin antagonist and, compared with ergotamine, has only weak vasoconstrictor and oxytocic effects. It may be used to prevent severe recurrent migraine (p. 670.3) and headache attacks during cluster periods (p. 670.1), although its use has declined because of adverse effects. It is ineffective in the treatment of acute attacks.

Methysergide is given orally as the maleate but doses are often expressed in terms of the base; 1.33 mg of methysergide maleate is equivalent to about 1 mg of methysergide. A usual dosage is 2 to 6 mg daily given in divided doses with meals. It is suggested that treatment should be started with 1 mg at bedtime and doses increased gradually over about 2 weeks; the minimum effective dose should be used. Careful and regular observation of the patient is essential because of the high incidence of adverse effects and it is recommended that treatment should only be carried out under hospital supervision. If treatment still proves to be ineffective after 3 weeks, further use is unlikely to be of benefit. Treatment should not be continued for more than 6 months, after which it should be gradually withdrawn over 2 or 3 weeks and then stopped for at least a month for reassessment. Some have considered that treatment courses should not exceed 3 months without a break.

Methysergide maleate has also been used to control diarrhoea associated with carcinoid syndrome (see under Neuroendocrine Tumours, p. 716.3) in high doses equivalent to 12 to 20 mg of methysergide daily.

As a serotonin antagonist, methysergide might be expected to help reverse the serotonin syndrome (p. 443.2).

Reviews.

1. Koehler PJ, Tfelt-Hansen PC. History of methysergide in migraine. *Cephalalgia* 2008; **28**: 1126–35.

Adverse Effects

Gastrointestinal effects such as nausea, vomiting, heartburn, and abdominal pain are common on initial treatment with methysergide maleate, as are dizziness and drowsiness. Other CNS effects reported include ataxia, insomnia, weakness, restlessness, lightheadedness, euphoria, and hallucinations. Peripheral or localised oedema, leg cramps, and weight gain have occurred and there have been occasional reports of rashes, loss of hair, joint and muscle pain, neutropenia, and eosinophilia. Orthostatic hypotension and tachycardia have been noted. There have been isolated reports of myocardial infarction particularly in patients with ischaemic heart disease or when given with other vasoconstrictive drugs, both of which are contra-indications for methysergide therapy.

Arterial spasm has occurred in some patients, and may present as paraesthesia of the extremities or anginal pain, as with ergotamine (p. 674.2); if such symptoms occur methysergide should be withdrawn, although rebound headaches may occur if it is withdrawn suddenly. Vascular insufficiency of the lower limbs may represent arterial spasm or fibrotic changes. Treatment should be stopped at the first signs of impaired peripheral circulation. Retroperitoneal fibrosis, with obstruction of abdominal blood vessels and ureters, pleuropulmonary fibrosis, and fibrotic changes in heart valves have occurred in patients on long-term treatment. Methysergide must be withdrawn immediately if fibrosis occurs. Retroperitoneal fibrosis is usually reversible, but other fibrotic changes are less readily reversed.

Effects on the skin. Scleroderma-like changes to the legs, in addition to aortic fibrosis in the absence of retroperitoneal fibrosis, was associated with long-term methysergide therapy in a 63-year old woman.[1] The patient presented with a 2-month history of inflammatory oedema of the legs and feet.

1. Kluger N, *et al.* Methysergide-induced scleroderma-like changes of the legs. *Br J Dermatol* 2005; **153**: 224–5.

Fibrosis. Fibrosis has been associated with the long-term use of methysergide maleate. In one early report[1] in 27 patients retroperitoneal fibrosis was attributed to use of methysergide for periods of 9 to 54 months in doses ranging from 2 to 28 mg daily. There was partial or complete regression of fibrosis in 13 of the patients whose treatment was withdrawn. Improvement usually began within a few days, in some cases with the aid of prednisone. The other 14 patients were treated by surgery; those few who continued taking methysergide had difficult postoperative courses. Cardiac murmurs occurred in 7 patients, and regressed wholly or partially in 3 after therapy was stopped. Fibrotic changes affecting the aorta, heart valves, and pulmonary tissues occurred in a few of the patients. Others have reported the development of endocardial fibrosis indicated by cardiac murmurs in 48 patients receiving methysergide.[2] The murmurs gradually regressed in 27 when methysergide was stopped. Retroperitoneal fibrosis was present in 9 patients and pleuropulmonary fibrosis in 2. A patient with fibrosis of the iliac vein has been described.[3]

A few cases of retroperitoneal fibrosis associated with ergotamine tartrate or dihydroergotamine have also been noted.[1] These 2 drugs have also been implicated in a few other cases of retroperitoneal fibrosis or other fibrotic disorders in patients taking high doses for long periods.[4-7]

7. Malaquin F, *et al.* Pleural and retroperitoneal fibrosis from dihydroergotamine. *N Engl J Med* 1989; **321**: 1760.

Treatment of Adverse Effects

As for Ergotamine Tartrate, p. 674.3.

Methysergide maleate should be withdrawn immediately if fibrosis develops. Corticosteroids have been used to treat fibrosis, although surgery may be required.

Precautions

As for Ergotamine Tartrate, p. 675.1.

In addition, methysergide maleate is contra-indicated in valvular heart disease, pulmonary and collagen diseases, diseases of the urinary tract, phlebitis and cellulitis of the lower extremities, and debilitated states. It should be used with caution in patients with peptic ulcer disease because it may increase gastric acidity. Patients should be closely supervised. Methysergide should not be given continuously for more than 6 months and should normally be withdrawn gradually (see Uses and Administration, above). However, it should be withdrawn immediately if symptoms of fibrosis or arterial spasm develop.

Interactions

Interactions involving those ergot alkaloids used mainly in the management of migraine are discussed under ergotamine (p. 675.2). References specific to methysergide may be found there under the headings Antimigraine Drugs (p. 675.2) and Beta Blockers (p. 675.3).

Pharmacokinetics

Methysergide maleate is rapidly absorbed from the gastrointestinal tract with peak plasma concentrations occurring within about one hour of ingestion. It is 66% bound to plasma proteins. Methysergide undergoes extensive first-pass hepatic metabolism to methylergometrine (p. 2137.3). About 50% of an oral dose is excreted in the urine as unchanged drug and metabolites. The elimination of methysergide is biphasic; half-lives of about 2.7 hours and 10 hours have been reported for the 2 phases respectively.

Pharmacopoeias. In *US.*

USP 36: (Naratriptan Hydrochloride). A white to pale yellow solid. Soluble in water. Store in airtight containers at a temperature not exceeding 30 degrees.

Uses and Administration

Naratriptan is a selective serotonin ($5\text{-}HT_1$) agonist with actions and uses similar to those of sumatriptan (p. 679.3). It is used for the acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. It is given orally as the hydrochloride, and doses are expressed in terms of the base; naratriptan hydrochloride 1.11 mg is equivalent to about 1 mg of naratriptan.

The recommended dose of naratriptan in the UK is 2.5 mg; in the USA a dose of 1 or 2.5 mg is allowed. If no response is obtained with the initial dose, a second dose should not be taken for the same attack. If symptoms recur after an initial response, the dose may be repeated after an interval of 4 hours, to a maximum of 5 mg in any 24-hour period. For doses in hepatic or renal impairment see below.

Administration in hepatic or renal impairment. Naratriptan is contra-indicated in patients with severe hepatic (Child-Pugh class C) or severe renal impairment (creatinine clearance less than 15 mL/minute). In patients with mild to moderate hepatic or renal impairment, the recommended maximum oral dose in 24 hours is 2.5 mg and a lower starting dose should be considered.

Migraine. For comparison of the relative benefits of different triptans in migraine, see under Sumatriptan, p. 680.1.

2. Tfelt-Hansen PC. Published and not fully published double-blind, randomised, controlled trials with oral naratriptan in the treatment of migraine: a review based on the GSK Trial Register. *J Headache Pain* 2011; 12: 399–403.

Adverse Effects and Precautions

As for Sumatriptan, p. 680.2 and p. 681.2.

Naratriptan should not be used in patients with severe hepatic (Child-Pugh class C) or renal (creatinine clearance less than 15 mL/minute) impairment. Naratriptan should be used with caution in mild or moderate renal or hepatic impairment. Patients with hypersensitivity to sulfonamides may theoretically show a similar reaction to naratriptan. (For discussion of cross-reactivity in sulfonamides and sulfa drugs see Hypersensitivity under Sulfamethoxazole, p. 365.3.)

Medication-overuse headache. For a report of an association between naratriptan and medication-overuse headache, see under Adverse Effects of Sumatriptan, p. 681.2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies naratriptan as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Interactions

As for Sumatriptan, p. 681.3.

Pharmacokinetics

After oral doses, peak plasma-naratriptan concentrations occur at 2 to 3 hours, and bioavailability is reported to be 63% in men and 74% in women. Plasma protein binding is about 29%. Naratriptan undergoes some hepatic metabolism via a wide range of cytochrome P450 isoenzymes. It is mainly excreted in the urine with 50% of a dose being recovered as unchanged drug and 30% as inactive metabolites. The elimination half-life is 6 hours, and is significantly prolonged in patients with renal or hepatic impairment.

Distribution into milk has been found in studies in *rats*.

Pharmacopoeias. In *Br.*

BP 2014: (Pizotifen Malate). A white or slightly yellowish-white, odourless or almost odourless, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol and in chloroform; sparingly soluble in methyl alcohol. Protect from light.

Uses and Administration

Pizotifen is a sedating antihistamine (p. 610.1) that has strong serotonin antagonist and weak antimuscarinic properties. It also antagonises the action of tryptamine. Pizotifen is used, usually as the malate, for the prophylaxis of migraine and for the prevention of headache attacks during cluster periods. It is not effective in treating an acute attack. Doses of pizotifen malate are expressed in terms of the base; pizotifen malate 1.45 mg is equivalent to about 1 mg of pizotifen. Pizotifen hydrochloride has also been used in the management of migraine.

The usual oral dose is the equivalent of 1.5 mg of pizotifen daily either in three divided doses or as a single dose at night. Gradual increase from an initial dose of 500 micrograms may help to avoid undue drowsiness. Doses may vary from 500 micrograms up to a maximum of 4.5 mg daily; not more than 3 mg should be given as a single dose.

For details of doses in children, see below.

Administration in children. For the prophylaxis of migraine and for the prevention of headache attacks during cluster periods, children aged over 2 years may be given up to 1.5 mg daily of pizotifen orally, although the maximum single dose (at night) should not exceed 1 mg. Gradual increase from an initial dose of 500 micrograms may help to avoid undue drowsiness.

Abdominal migraine. Abdominal migraine is a recurrent disorder seen mainly in children and characterised by episodic midline abdominal pain lasting for up to 72 hours. The pain is severe enough to disrupt normal activities and may be associated with pallor, anorexia, nausea, and vomiting.[1,2] Sleep, and sometimes vomiting, terminate the attack.

In one small study pizotifen was found to be effective for the prophylaxis of abdominal pain in children with abdominal migraine;[3] however, a systematic review concluded that there was only weak evidence in favour of such use in recurrent abdominal pain and suggested that pizotifen should only be used in the context of clinical trials or in children with severe problems refractory to conventional management.[4] Prophylactic treatment with propranolol or cyproheptadine may also be of benefit.[5]

5. Worawattanakul M, *et al.* Abdominal migraine: prophylactic treatment and follow-up. *J Pediatr Gastroenterol Nutr* 1999; 28: 37–40.

Migraine and cluster headache. Pizotifen has been widely used for the prophylaxis of migraine (p. 670.3) but evidence for its efficacy is limited. It has also been tried in the management of cluster headache (p. 670.1) to prevent headache attacks during a cluster period.

References.

Adverse Effects and Precautions

As for the sedating antihistamines in general, see p. 613. and p. 613.3.

Increased appetite and weight gain may occur with pizotifen. Drowsiness may be troublesome.

Incidence of adverse effects. Adverse effects were noted in 22 of 47 patients with severe migraine given pizotifen to 2 mg daily.[1] These reactions included weight increase (15 patients), muscle pain or cramps (3 patients), heavy or restless legs (3 patients), fluid retention (3 patients), drowsiness (2 patients), more frequent milder headaches (patients), facial flushing (1 patient), reduced libido (patient), exacerbation of epilepsy (1 patient), and dreaming (2 patients). Adverse effects necessitating withdrawa occurred in 11 patients.

1. Peet KMS. Use of pizotifen in severe migraine: a long-term study. *Curr Med Res Opin* 1977; 5: 192–9.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies pizotifen as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Interactions

As for the sedating antihistamines in general, see p. 614.3.

Antihypertensives. After a report[1] of loss of blood pressure control when treatment with pizotifen was started in a patient receiving *debrisoquine* the manufacturer suggested that since pizotifen had a similar chemical structure to the tricyclic antidepressants it might antagonise the actions of adrenergic neurone blockers in a similar manner.

1. Bailey RR. Antagonism of debrisoquine sulphate by pizotifen (Sandomigran). *N Z Med J* 1976; 1: 449.

Pharmacokinetics

Pizotifen is well absorbed from the gastrointestinal tract and peak plasma concentrations occur about 5 hours after a single oral dose. Over 90% is bound to plasma proteins. Pizotifen undergoes extensive metabolism. Over half of a dose is excreted in the urine, mainly as metabolites; a significant proportion is excreted in the faeces. The primary metabolite of pizotifen (*N*-glucuronide conjugate) has a long elimination half-life of about 23 hours.

Distribution into milk has been found in *animal* studies.

CAS — 144034-80-0 (rizatriptan); 145202-66-0 (rizatriptan benzoate).
ATC — N02CC04.
ATC Vet — QN02CC04.
UNII — WR978S7QHH.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Rizatriptan Benzoate). A white or almost white powder or crystals. Soluble in water; sparingly soluble in alcohol; slightly soluble in dichloromethane. It shows polymorphism.

USP 36: (Rizatriptan Benzoate). A white to almost white crystalline powder. Soluble in water; sparingly soluble in alcohol; slightly soluble in dichloromethane.

Uses and Administration

Rizatriptan is a selective serotonin ($5\text{-}HT_1$) agonist with actions and uses similar to those of sumatriptan (below). It is used for the acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. Rizatriptan is given as the benzoate, and doses are expressed in terms of the base; rizatriptan benzoate 14.5 mg is equivalent to about 10 mg of rizatriptan.

The licensed dose in the UK of rizatriptan is the equivalent of 10 mg orally. If this is ineffective, a second dose should not be taken for the same attack. If symptoms recur after an initial response, a further dose of 10 mg may be taken after an interval of at least 2 hours. In the USA licensed doses of 5 or 10 mg are used. The recommended maximum dose in 24 hours is 20 mg in the UK and 30 mg in the USA. A reduced dose of 5 mg is recommended in patients also receiving propranolol (see Interactions, below), with the maximum dose in 24 hours reduced to 10 mg in the UK and 15 mg in the USA. It is also recommended that doses of the 2 drugs should be separated by at least 2 hours.

For doses in children and in hepatic or renal impairment, see below.

Administration in children. In the USA, rizatriptan is licensed for the treatment of acute migraine in children and adolescents aged 6 to 17 years. A single oral dose of 5 mg may be given to children weighing less than 40 kg and 10 mg to those weighing 40 kg or more. In children also receiving propranolol (see Interactions, below), a single dose of rizatriptan 5 mg is recommended in those who weigh 40 kg or more; however, it should not be given to those who weigh less than 40 kg. The safety and efficacy of a second dose have not been established.

Administration in hepatic or renal impairment. UK licensed product information recommends that in patients with mild to moderate hepatic or renal impairment, the oral dose of rizatriptan should be reduced to 5 mg. If the headache recurs after an initial response, a further dose of 5 mg may be taken after an interval of at least 2 hours. The recommended maximum dose in 24 hours in these patients is 10 mg. It is also recommended that rizatriptan should not be used in patients with severe hepatic or renal impairment.

Migraine. For comparison of the relative benefits of different triptans in migraine, see under Sumatriptan, p. 680.1.

6. Göbel H. Efficacy and tolerability of rizatriptan 10 mg compared with sumatriptan 100 mg: an evidence-based analysis. *Expert Rev Neurother* 2010; **10**: 499–506.

Adverse Effects and Precautions

As for Sumatriptan, p. 680.2 and p. 681.2. Toxic epidermal necrolysis has also been reported with rizatriptan.

Rizatriptan should be given with caution to patients with mild or moderate hepatic or renal impairment; UK licensed product information contra-indicates its use in more severe impairment.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies rizatriptan as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Interactions

As for Sumatriptan, p. 681.3.

Propranolol increases plasma-rizatriptan concentrations and it is recommended that lower doses of rizatriptan should be used in patients receiving both drugs (see Uses and Administration, above).

Pharmacokinetics

After oral doses, peak plasma-rizatriptan concentrations occur in about 1 to 2.5 hours depending on the formulation. Bioavailability is about 40 to 45%. Food may delay the time to peak plasma concentrations of the tablet formulation by about 1 hour. Plasma protein binding is low (14%).

Rizatriptan is metabolised mainly by monoamine oxidase type A to the inactive indole acetic acid derivative. The active metabolite *N*-monodesmethyl-rizatriptan is formed to a minor degree; other minor metabolites are also produced. About 14% of an oral dose is excreted in the urine as unchanged rizatriptan, 51% as the indole acetic acid metabolite, and no more than 1% as *N*-monodesmethyl-rizatriptan. The plasma half-life is about 2 to 3 hours.

Distribution into milk has been found in studies in *rats.*

1. Fish DN, *et al.* Stability of sumatriptan succinate in extemporaneously prepared oral liquids. *Am J Health-Syst Pharm* 1997; **54**: 1619–22.

Uses and Administration

Sumatriptan is a selective serotonin agonist that acts at $5\text{-}HT_1$ receptors and produces vasoconstriction of cranial arteries. Drugs such as sumatriptan, which are commonly known as triptans, are believed to act mainly at $5\text{-}HT_{1B}$ and $5\text{-}HT_{1D}$ subtype receptors and are therefore sometimes referred to as $5HT_{1B/1D}$-receptor agonists.

Sumatriptan is used for the acute treatment of migraine attacks and of cluster headache. It should not be used for prophylaxis. It may be given orally, subcutaneously, or transdermally as the succinate and intranasally as the base. Doses are expressed in terms of the base; sumatriptan succinate 70 mg is equivalent to about 50 mg of sumatriptan.

For the acute treatment of **migraine** sumatriptan should be used as soon as possible after the onset of the headache phase, but efficacy is independent of the duration of the attack before starting treatment. If no response is obtained with the initial dose by any route, a second dose should not be given for the same attack.

- It is given *orally* to adults aged 18 years and over; the recommended dose in the UK is 50 mg, although some patients may require 100 mg. A clinical response can be expected after about 30 minutes. If symptoms recur after an initial response, further doses may be given provided that there is a minimum interval of 2 hours between doses and that not more than 300 mg is taken in any 24-hour period. US licensed product information recommends that a lower dose of 25 mg may be used, although some patients require 50 or 100 mg. This may be followed by a second dose of up to 100 mg if the headache returns or the patient has a partial response provided that the total daily dose does not exceed the recommended maximum of 200 mg. A minimum interval of 2 hours is recommended between doses. A tablet supplying a dose equivalent to 85 mg of sumatriptan, as a fixed-dose combination with 500 mg of naproxen sodium, is also available in the USA; a single dose may be taken, repeated once within 24 hours if necessary, with a minimum interval of 2 hours.
- When used *intranasally* a clinical response can be expected in 15 minutes. UK licensed product information recommends that patients aged 18 years and over may be given a single dose of 20 mg into one nostril, although 10 mg may be effective in some patients. US licensed product information recommends that a dose of 5, 10, or 20 mg may be used. If symptoms recur, a second dose may be given at least 2 hours after the first dose. Not more than 40 mg should be used in a 24-hour period.
- In patients aged 18 years and over sumatriptan may be self-administered by *subcutaneous injection* in a single dose of 6 mg; a clinical response may be expected after 10 to 15 minutes. If symptoms recur, a second dose of 6 mg may be injected at least one hour after the first dose; not more than 12 mg should be given in a 24-hour period. US licensed product information recommends that it may also be used in single doses of 1 to 5 mg if adverse effects are dose-limiting. A *needle-free subcutaneous delivery system* is also available for the delivery of 6-mg doses.
- An *iontophoretic transdermal* delivery system, supplying 6.5 mg of sumatriptan over 4 hours, may also be used by patients aged 18 years and over. It should be applied to dry, intact, and non-irritated skin on the upper arm or thigh; it should not be applied to a previous application site until the skin remains erythema free for at least 3 days. If symptoms recur, a second system may be applied to a different site at least 2 hours after activation of the first system; not more than 2 systems should be used in a 24-hour period.

For the acute treatment of **cluster headache,** sumatriptan succinate is given by subcutaneous injection in similar doses to those used for migraine.

For doses in children and in hepatic impairment, see below and p. 680.1, respectively.

Administration in children. Sumatriptan may be given for the treatment of acute **migraine** in children and adolescents. Although not licensed for oral paediatric use in the UK, the *BNFC* suggests that a single *oral* dose of 25 mg may be given to children aged 6 to 10 years, 50 mg to those aged 10 to 12 years, and 50 to 100 mg to those aged

12 to 18 years. The dose may be repeated once after at least 2 hours if symptoms recur after an initial response. Children aged 10 to 18 years may also be given the usual adult *subcutaneous* dose (see p. 679.3).

In the UK, *intranasal* sumatriptan is licensed for use in adolescents aged 12 to 17 years in a dose of 10 mg into one nostril; the dose may be repeated after at least 2 hours if symptoms recur within 24 hours although not more than 20 mg should be used within a 24-hour period. Alternatively, the *BNFC* suggests that the usual adult dose of 10 to 20 mg (see p. 679.3) may be used in those aged 12 years and over.

If no response is obtained with the initial dose by any route, a second dose should not be given for the same attack.

Sumatriptan has also been tried in the treatment of acute **cluster headache.** The *BNFC* suggests that children aged 10 to 18 years may be given *subcutaneous* doses similar to those suggested in adults (see p. 679.3); alternatively, sumatriptan may be given *intranasally* to children aged 12 to 18 years in doses similar to those suggested for use in adolescents with migraine.

Administration in hepatic impairment. Sumatriptan should be used with caution in patients with hepatic impairment. An oral dose of up to 50 mg is considered suitable. It should not be given to patients with severe impairment.

High-altitude disorders. Sumatriptan has been tried with some success in a small study[1] for the prevention of symptoms of acute mountain sickness (p. 1276.2).

1. Jafarian S, *et al.* Sumatriptan for prevention of acute mountain sickness: randomized clinical trial. *Ann Neurol* 2007; 62: 273–7.

Migraine and cluster headache. The use of sumatriptan and other triptans in the treatment of cluster headache (p. 670.1) and migraine (p. 670.3) has been reviewed.[1-7]

In **migraine** serotonin (5-HT_1) agonists are preferred to ergotamine for the treatment of acute attacks unresponsive to simple analgesics.

There are several *different triptans* clinically available. In a meta-analysis of 53 studies (involving 24 089 patients) and a separate analysis of all direct comparative studies of 5 other triptans with sumatriptan, all were found to be more effective than placebo.[2] At the marketed doses, all oral triptans (almotriptan, eletriptan, naratriptan, rizatriptan, sumatriptan, and zolmitriptan) were effective and well tolerated. Almotriptan, eletriptan, or rizatriptan were considered to provide the highest likelihood of consistent success. A review of the efficacy of the 5 triptans available in the USA also showed pain relief at 2 hours was comparable for all.[3] Almotriptan 12.5 mg offered high tolerability and good efficacy; eletriptan 80 mg provided high efficacy and low recurrence; and rizatriptan 10 mg was associated with consistent and rapid freedom from pain.[2] Frovatriptan was not included in the analyses, but publicly available data suggested lower efficacy. Only sumatriptan, though, has parenteral and transdermal formulations;[8] the 6-mg subcutaneous formulation is considered to be the fastest and most effective acute treatment[2] but there is a lack of comparative data with the newer iontophoretic transdermal delivery preparation.[8]

About 21 to 57% of patients who initially respond to sumatriptan have a *recurrence* of their headache within 24 to 48 hours; this may be related in part to its short half-life. Such recurrences usually respond to a second dose[9,10] but if a first dose is ineffective subsequent doses for the same attack are of no benefit and should not be given. Sumatriptan is considered[11] to be effective when given at any time once the headache phase of migraine has started but giving it during migraine aura appears to be of little benefit since it does not affect the aura or prevent or delay the development of headache.[12] Repeated or long-term use does not appear to be associated with reduced efficacy.[13,14] For reports of an association between sumatriptan and medication-overuse headache, see under Adverse Effects, p. 681.2. Oral sumatriptan may also be combined with naproxen sodium;[15-17] the combination is reported to be slightly more effective than either drug alone.[18]

Sumatriptan's efficacy appears to be maintained in *menstrual migraine*, a condition which is considered to be less responsive to treatment than nonmenstrual migraine;[19] it has also been given in a fixed-dose oral combination with naproxen sodium.[20,21] Frovatriptan,[22] rizatriptan,[23] and zolmitriptan[24] have also been found to be effective in menstrual migraine.

Experience of subcutaneous use in *children* has been reported.[25] Results of a randomised, placebo-controlled study[26] of intranasal sumatriptan in adolescents aged 12 to 17 years showed evidence of efficacy, tolerability, and safety in this age group; it was felt that the nasal spray might be particularly well suited for adolescent use. Intranasal sumatriptan has also been tried in younger children (aged 8 years and over) with some success.[27] For doses in children, see p. 679.3. The use of other triptans in children with migraine has also been reviewed.[28]

Subcutaneous sumatriptan has also been shown to be effective in relieving acute attacks of headache in patients with **cluster headache.** In studies about 75% of patients have obtained relief within 15 minutes of a 6-mg subcutaneous injection;[29,30] the use of higher doses was found to be of no advantage. Long term efficacy appears to be maintained[31] but the significance of the transient increase in the frequency of attacks seen in some patients remains to be determined.[32] It does not appear to be effective for the prevention of headache during cluster periods.[33] Another triptan found to be effective in the treatment of episodic cluster headache is zolmitriptan.[34]

Adverse Effects

The most commonly reported adverse effects of serotonin (5-HT_1) agonists such as sumatriptan include dizziness, flushing, weakness, drowsiness, and fatigue. Nausea and vomiting may occur. Dyspnoea and sensory disturbance including paraesthesia and hypoaesthesia have been reported. Pain or sensations of heaviness, heat or cold, pressure, or tightness have also been commonly reported, can affect any part of the body including the throat and chest, and may be intense. These symptoms may be due to vasospasm, which on rare occasions has resulted in severe cardiovascular events including cardiac arrhythmias, myocardial ischaemia, or myocardial infarction. There have been isolated reports of associated cerebrovascular events in patients receiving sumatriptan. Transient increases in blood pressure may occur soon after treatment. Rarely, significant increases in blood pressure, including hypertensive crisis with acute impairment of organ systems, have occurred even in patients without a history of hypertension. Hypotension, bradycardia or tachycardia, palpitations, peripheral vascular disorders such as Raynaud's syndrome, and ischaemic colitis have been reported. Visual disturbances have also occurred.

Medication-overuse headache has been reported with sumatriptan and may necessitate withdrawal of the drug. Sumatriptan has occasionally been associated with minor disturbances in hepatic function. There have also been rare reports of seizures with sumatriptan. Hypersensitivity reactions ranging from rashes to, more rarely, anaphylaxis have occurred.

Transient pain at the injection site is common after subcutaneous sumatriptan injections; stinging, burning, erythema, bruising, and bleeding have also been reported. Irritation of the nasal mucosa and throat and epistaxis have been reported after intranasal use. Application site reactions such as pain, paraesthesia, pruritus, warmth, and discomfort have been commonly reported after use of the iontophoretic transdermal delivery preparation.

Incidence of adverse effects. In a Dutch postmarketing survey[1] completed by 1187 patients the most common adverse reactions attributed to sumatriptan were paraesthesia (reported by 11.7% of patients), dizziness (8.1%), feeling of heaviness (8.0%), chest pain (7.9%), nausea and/or vomiting (7.3%), drowsiness/sedation (7.0%), flushing (5.1%), fatigue (4.6%), pressure in throat (3.3%), headache (3.1%), injection site reaction (3.0%), palpitations (2.8%), abdominal pain (2.6%), muscle pain (2.4%), and dyspnoea (2.2%).

The safety and tolerability of the triptans have been reviewed.[2,3]

Effects on the cardiovascular system. About 10 months after sumatriptan injection had been made available commercially, the UK CSM noted that it had received 34 reports of pain or tightness in the chest and 2 reports of myocardial ischaemia.[1] The Netherlands Centre for Monitoring of Adverse Reactions to Drugs declared about the same time that it had received 12 reports of chest or anginal pain mostly associated with oral sumatriptan.[2] A later postmarketing survey based on data from Dutch general practitioners identified chest pain in 1.3% of 1727 patients,[3] a figure considered to be lower than that seen in earlier studies, but in a subsequent questionnaire completed by 1187 of these patients 7.9% reported chest pain.[4] The Australian Adverse Drug Reactions Advisory Committee (ADRAC)[5] stated in December 1994 that it had received 114 reports of chest pain since sumatriptan had been marketed in mid 1992. Most patients had recovered quickly but 2 had died. The first developed a fatal myocardial infarction after coronary artery dissection but the causal relation with sumatriptan was unclear. The second patient, who had hypertrophic obstructive cardiomyopathy, developed ventricular fibrillation a few hours after the onset of chest pain and this led to fatal cardiac arrest

One group of workers[6] who studied the effect of sumatriptan 16 mg given subcutaneously suggested that the symptoms of chest pain might be due to an effect of sumatriptan on oesophageal function, but others have argued against this suggestion.[7] ADRAC[5] considered that the reaction in the 28 reports of throat tightness they had received by December 1994 was a different reaction to that of chest pain, and probably resulted from changes in oesophageal motility.

Several reports have provided details of individual cases of the adverse cardiovascular effects of sumatriptan including arrhythmias (ventricular tachycardia,[8] ventricular fibrillation,[8,9] or atrial fibrillation[10,11]), acute myocardial infarction,[12-19] and unstable angina.[20] Most of these reports concerned subcutaneous sumatriptan, but myocardial infarction[14,17-19] and cardiac arrhythmias[9,11] (sometimes fatal) may occur after oral use. These adverse effects have also been reported in patients with no predisposing factors.[9,12,17-19]

A review[21] of published reports on chest pain as well as relevant data held by the UK manufacturer considered that the risk of myocardial ischaemia after vasoconstriction induced by sumatriptan was small. However, the contra-indications and cautions given under Precautions,

p. 681.2, should be observed. A study[22] published in 2004 of over 63 500 migraine patients in the UK General Practice Research Database failed to find an increased risk of cardiovascular death in those patients treated with serotonin agonists.

Effects on the cerebrovascular system. Adverse cerebrovascular effects have been reported after the use of subcutaneous sumatriptan including hemiparesis,[1] stroke,[2,3] and intracerebral haemorrhage.[4] Cerebral vasospasm has also been reported[5] with the use of oral sumatriptan. However, a study[6] of over 63 500 migraine patients in the UK General Practice Research Database failed to find an increased risk of stroke in those patients treated with serotonin agonists.

6. Hall GC, *et al.* Triptans in migraine: the risks of stroke, cardiovascular disease, and death in practice. *Neurology* 2004; 62: 563–8.

Effects on the gastrointestinal tract. Ischaemic colitis and mesenteric ischaemia have been reported in a few patients receiving sumatriptan,[1-3] including repeated episodes in 2 patients,[2] each within hours of a dose; some of these episodes were associated with doses above the recommended daily maximum.[2]

Oesophageal constriction or throat tightness has been reported in some patients using sumatriptan and may be due to a direct effect on the oesophagus (see Effects on the Cardiovascular System, p. 680.3).

3. Naik M, *et al.* Sumatriptan-associated ischemic colitis. *Dig Dis Sci* 2002; 47: 2015–16.

Effects on the respiratory system. See Asthma under Precautions, below.

Hypersensitivity. Reactions to sumatriptan such as rashes and, more rarely, anaphylaxis have been noted by the manufacturer. Published reports include angioedema occurring in a patient 5 minutes after subcutaneous sumatriptan,[1] and urticaria occurring 20 to 24 hours after oral or subcutaneous sumatriptan in another patient.[2]

2. Pradalier A, *et al.* Delayed urticaria with sumatriptan. *Cephalalgia* 1996; 16: 280–1.

Medication-overuse headache. Sumatriptan and other triptans may have a similar risk of misuse to that associated with analgesics and ergotamine compounds in patients with medication-overuse headache (p. 670.2). There have been reports[1-3] of patients using one or more daily doses of sumatriptan to control migraine.. Many of the patients had a history of abuse of other antimigraine drugs and were using sumatriptan to prevent recurrence of headache. Whether misuse of sumatriptan was due to addiction or rebound headache, as seen with ergotamine, is unknown. A postmarketing study in 952 patients receiving sumatriptan found that 36 of the patients (4%) used sumatriptan daily or more than 10 times each week. This overuse was related to poor efficacy and not to rebound headache.[4] One study[5] and an anecdotal report[6] suggest that, rather than producing euphoria or other effects associated with drugs of abuse such as morphine, sumatriptan is more likely to be associated with dysphoria and apathetic sedation.

The development of medication-overuse headache has also been reported with other serotonin (5-HT_1) agonists including naratriptan and zolmitriptan.[7] Indeed, US licensed product information for the triptans states that the safety of treating an average of more than 3 or 4 migraine attacks in a 30-day period has not been established.

Precautions

Sumatriptan and other serotonin (5-HT_1) agonists should only be used where there is a clear diagnosis of migraine or cluster headache and care should be taken to exclude other potentially serious neurological conditions. They should not be used for prophylaxis and should not be given to patients with basilar, hemiplegic, or ophthalmoplegic migraine.

Serotonin (5-HT_1) agonists are contra-indicated in patients with uncontrolled hypertension, ischaemic heart disease (coronary artery disease), a history of myocardial infarction, coronary vasospasm (Prinzmetal's angina), peripheral vascular disease, or a previous cerebrovascular accident or transient ischaemic attack. Unrecognised cardiovascular disease should be excluded before the use of serotonin (5-HT_1) agonists in postmenopausal women, men over 40 years of age, and those with risk factors for ischaemic heart disease. If chest pain and tightness occur during use, appropriate investigations should be performed. Sumatriptan should not be used intravenously because of the increased risk of producing coronary vasospasm.

Drowsiness may occur after treatment with serotonin (5-HT_1) agonists and patients thus affected should not drive or operate machinery.

Sumatriptan should be used with caution in patients with hepatic or renal impairment, and should generally be avoided if hepatic impairment is severe.

There have been rare reports of seizures after use of sumatriptan and it should therefore be used with caution in patients with a history of epilepsy or other conditions predisposing to seizures. Patients with hypersensitivity to sulfonamides may have a similar reaction to sumatriptan. (For discussion of cross-reactivity in sulfonamides and sulfa drugs see Hypersensitivity under Sulfamethoxazole, p. 365.3.)

Asthma. The manufacturers reviewed data from more than 75 clinical studies of sumatriptan involving 12 701 patients and reported[1] that the incidence of adverse events related to asthma did not differ between patients with or without the condition. Earlier there had been concern over the safety of sumatriptan in patients with asthma after 2 reports of bronchospasm and a report of a patient with asthma who died during a study of sumatriptan although the patient had not received sumatriptan in the month before her death.

1. Lloyd DK, Pilgrim AJ. The safety of sumatriptan in asthmatic migraineurs. *Cephalalgia* 1993; 13: 201–4.

Breast feeding. No adverse effects have been seen in breast-fed infants of mothers given sumatriptan, and the last available guidance from the American Academy of Pediatrics considered that it is therefore usually compatible with breast feeding.[1] However, licensed product information suggests that infant exposure can be minimised by avoiding breast feeding for 12 hours after treatment. Product information for other triptans suggests avoiding breast feeding for 24 hours.

The distribution of sumatriptan into breast milk after a 6-mg subcutaneous dose has been studied in 5 mothers.[2] The mean total recovery of sumatriptan in breast milk was estimated to be 14.4 micrograms or 0.24% of the dose. It was calculated that on a weight-adjusted basis an infant could receive a maximum of 3.5% of the maternal dose.

2. Wojnar-Horton RE, *et al.* Distribution and excretion of sumatriptan in human milk. *Br J Clin Pharmacol* 1996; 41: 217–21.

Cerebrovascular disorders. A patient with a superior sagittal sinus thrombosis who presented with headache and was misdiagnosed as having migraine variant developed a cortical stroke within minutes of a second 6-mg subcutaneous injection of sumatriptan.[1] The importance of establishing a diagnosis of typical migraine or cluster headache before using sumatriptan was emphasised and caution given against its use in any patient who may have unstable cerebrovascular disease or raised intracranial pressure. Additionally, there was no clinical evidence that a second injection would relieve a headache when the initial injection had been ineffective.

1. Cavazos J, *et al.* Sumatriptan-induced stroke in sagittal sinus thrombosis. *Lancet* 1994; 343: 1105–6.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sumatriptan as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Pregnancy. Sumatriptan crosses the placenta; however, only a very small quantity reaches the fetus. A literature review concluded that exposure to sumatriptan in pregnancy posed no additional risk of birth defects compared with that in the general population,[1] but as for other drugs sumatriptan should only be used in pregnancy when the benefit justifies the potential risk to the fetus.

1. Hilaire ML, *et al.* Treatment of migraine headaches with sumatriptan in pregnancy. *Ann Pharmacother* 2004; 38: 1726–30.

Interactions

Sumatriptan and other serotonin (5-HT_1) agonists should not be given with ergotamine or related compounds (including methysergide) since there is an increased risk of vasospastic reactions. In addition, a delay is advised *before starting* a serotonin (5-HT_1) agonist in patients who have been receiving ergotamine or related compounds: sumatriptan, almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, or zolmitriptan should not be given until at least 24 hours after stopping the use of ergotamine preparations. Conversely, ergotamine should not be given until 6 hours *after stopping* these drugs or at least 24 hours in the case of eletriptan, frovatriptan, and naratriptan. Serotonin (5-HT_1) agonists should not be given together.

Sumatriptan or rizatriptan should not be used with, and for 2 weeks after stopping, an MAOI. Use with the selective monoamine oxidase type B inhibitor selegiline is thought unlikely to provoke an interaction, but see p. 916.1. Opinion varies on the use of zolmitriptan with inhibitors of monoamine oxidase type A such as moclobemide. In the UK licensed product information recommends that the maximum dose of zolmitriptan should be reduced when used with inhibitors of monoamine oxidase type A whereas in the USA it contra-indicates such combinations. There have been rare reports of serotonin syndrome associated with the use of triptan serotonin (5-HT_1) agonists with SSRIs or serotonin and noradrenaline reuptake inhibitors (SNRIs), but see also under Antidepressants, below.

Oral sumatriptan appeared to delay gastric emptying and might affect the absorption of other drugs, as judged by its delaying effect on paracetamol absorption in migraine patients.[1]

1. Rani PU, *et al.* Sumatriptan delays paracetamol absorption in migraine patients. *Clin Drug Invest* 1996; 11: 300–304.

Antidepressants. Sumatriptan and rizatriptan are metabolised mainly by monoamine oxidase type A and licensed product information advises that patients taking *MAOIs*, including reversible selective type A inhibitors such as moclobemide, should not be given these triptan serotonin (5-HT_1) agonists. Clearance of zolmitriptan was decreased after moclobemide and UK licensed product information recommends a reduced dose of zolmitriptan if the drug is used with an inhibitor of monoamine oxidase type A; in the USA, the use of these drugs together is contra-indicated.

SSRIs such as fluoxetine may also interact with serotonin (5-HT_1) agonists with an increased risk of serotonin

syndrome (p. 443.2), and it has been suggested that *lithium* and sumatriptan may interact similarly. However, a review of the use of sumatriptan with MAOIs, SSRIs, or lithium found little evidence of an increased risk of serotonin syndrome.[1] It was concluded that most patients tolerate the combination of sumatriptan and an SSRI or lithium without incident. However, it was suggested that the use of sumatriptan with an MAOI should continue to be avoided until further data supporting safety become available. As there have since been rare reports of serotonin syndrome associated with the use of triptans with SSRIs or *serotonin and noradrenaline reuptake inhibitors (SNRIs)*, licensed product information for the triptans states that when such use is clinically warranted, appropriate observation of the patient is advised, particularly when starting treatment, with dose increases, or with addition of another serotonergic drug. Product information for zolmitriptan also advises a reduction in dosage if it is given with fluvoxamine as the latter may inhibit zolmitriptan metabolism through its effects on the cytochrome P450 isoenzyme CYP1A2. The American Headache Society has stated[2] that caution is certainly warranted but that official FDA advice should be reviewed as it is not clear what role triptans might play in contributing to serotonin syndrome with or without SSRIs or SNRIs.

Increased serotonergic effects with increased incidence of adverse effects have been reported following the use of *St John's wort* with triptans.[3] Patients should be advised to stop taking St John's wort if treatment with a serotonin (5-HT_1) agonist is necessary.

3. CSM/MCA. Reminder: St John's wort (Hypericum perforatum) interactions. *Current Problems* 2000; 26: 6–7. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON007462&RevisionSelectionMethod=LatestReleased (accessed 16/06/06)

Antimigraine drugs. Although the efficacy and tolerability of subcutaneous sumatriptan in the acute treatment of migraine did not appear to be affected in patients already taking *dihydroergotamine* orally for migraine prophylaxis,[1] the bioavailability of oral dihydroergotamine is low and it could not be assumed that it was safe to use parenteral dihydroergotamine with sumatriptan.[2] Licensed product information for sumatriptan contra-indicates its use with *ergotamine* or other related compounds and also recommend that it should not be given until at least 24 hours after stopping ergotamine or related compounds (see Interactions, p. 681.3).

Acute myocardial infarction has been reported[3] in a premenopausal woman with controlled hypertension and no known coronary artery disease after subcutaneous use of sumatriptan within a few hours of taking *methysergide* orally.

3. Liston H, *et al.* The association of the combination of sumatriptan and methysergide in myocardial infarction in a premenopausal woman. *Arch Intern Med* 1999; 159: 511–13.

Antipsychotics. For reference to a potential interaction between sumatriptan and *loxapine*, see Chlorpromazine, p. 1052.3.

Pharmacokinetics

Sumatriptan is rapidly but incompletely absorbed when given orally and undergoes first-pass metabolism, resulting in a low absolute bioavailability of about 14%. Peak plasma concentrations after oral doses occur in about 2 hours. Bioavailability is much higher (96%) after subcutaneous doses with peak concentrations occurring within 25 minutes. Bioavailability after intranasal doses is 16% of that achieved subcutaneously, with peak concentrations occurring in about 1.5 hours. Peak concentrations after iontophoretic transdermal delivery occur in about 1.1 hours; bioavailability is lower than that achieved after oral doses. Plasma protein binding is low at about 14 to 21%.

The elimination half-life of sumatriptan is about 2 hours. Sumatriptan is extensively metabolised in the liver mainly by monoamine oxidase type A and is excreted mainly in the urine as the inactive indole acetic acid derivative and its glucuronide. Sumatriptan and its metabolites also appear in the faeces. Small amounts of sumatriptan are distributed into breast milk (see Breast Feeding, p. 681.2).

Uses and Administration

Zolmitriptan is a selective serotonin (5-HT_1) agonist with actions and uses similar to those of sumatriptan (p. 679.3). It is used for the acute treatment of migraine attacks. Zolmitriptan should not be used for prophylaxis.

The licensed dose in the UK is 2.5 mg orally. A clinical response can be expected within 1 hour. If symptoms persist or return within 24 hours, a second dose may be taken not less than 2 hours after the first dose. If a patient does not achieve satisfactory relief with a dose of 2.5 mg, subsequent attacks may be treated with doses of 5 mg. The maximum dose of zolmitriptan in 24 hours is 10 mg. Licensed doses in the USA are somewhat lower; the dose is 1.25 or 2.5 mg with a maximum dose of 10 mg in 24 hours.

When used intranasally a clinical response can be expected in 15 minutes. The usual dose is 5 mg as a single dose into one nostril. If symptoms persist or return within 24 hours, a second dose may be given after at least 2 hours, up to a maximum of 10 mg daily.

Dose reductions are recommended in patients taking certain other drugs (see also Interactions, below). The maximum dose of zolmitriptan in 24 hours should be 5 mg in those receiving cimetidine or an inhibitor of monoamine oxidase type A (although use with inhibitors of monoamine oxidase type A is contra-indicated in US licensed product information). A similar reduction is also recommended in those taking drugs, such as fluvoxamine and ciprofloxacin, that inhibit the cytochrome P450 isoenzyme CYP1A2.

For dosage in children and in hepatic impairment, see below.

Administration in children. Although unlicensed for use in children in the UK, the *BNFC* suggests that zolmitriptan may be used in those aged 12 to 18 years for the treatment of acute cluster headache (intranasal route only) or migraine. Doses are similar to those used in adults (see above).

Administration in hepatic impairment. A study[1] has indicated that while there is no need to reduce the size of the initial dose of zolmitriptan in patients with moderate or severe hepatic impairment, accumulation may occur with repeated doses in patients with severe impairment and their total daily dosage should be reduced.

UK licensed product information recommends a maximum oral dose of 5 mg in 24 hours in patients with moderate to severe impairment. In the USA, a dose of 1.25 mg is recommended in those with moderate to severe impairment, with a maximum total daily dose of 5 mg in severe impairment.

Adverse Effects and Precautions

As for Sumatriptan, p. 680.2 and p. 681.2.

Zolmitriptan should also be avoided in patients with Wolff-Parkinson-White syndrome or arrhythmias associated with accessory cardiac conduction pathways. It should be given with caution in patients with moderate to severe hepatic impairment.

Ischaemia. A spinal cord lesion related to the use of zolmitriptan has been reported in a 50-year-old woman;[1] clinical features suggested that the lesion was an ischaemic infarct.

1. Vijayan N, Peacock JH. Spinal cord infarction during use of zolmitriptan: a case report. *Headache* 2000; 40: 57–60.

Medication-overuse headache. For a report of an association between zolmitriptan and medication-overuse headache, see under Adverse Effects of Sumatriptan, p. 681.2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies zolmitriptan as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/04/11)

Renal impairment. Although renal clearance of zolmitriptan and its metabolites was reduced in patients with moderate to severe impairment,[1] the resulting effect was unlikely to be of clinical importance and adjustment of zolmitriptan dosage in patients with renal impairment was considered unnecessary.

1. Gillotin C, *et al.* No need to adjust the dose of 311C90 (zolmitriptan), a novel anti-migraine treatment in patients with renal failure not requiring dialysis. *Int J Clin Pharmacol Ther* 1997; 35: 522–6.

Interactions

As for Sumatriptan, p. 681.3.

Zolmitriptan undergoes hepatic metabolism, mainly mediated by the cytochrome P450 isoenzyme CYP1A2 and also involving monoamine oxidase type A. It is recommended that the maximum dose of zolmitriptan in 24 hours should be reduced in patients receiving cimetidine, a general P450 inhibitor (see Uses and Administration, above). A similar reduction in zolmitriptan dosage is anticipated if it is given with drugs, such as fluvoxamine and ciprofloxacin, that inhibit the isoenzyme CYP1A2. Opinion varies on the use of zolmitriptan with inhibitors of monoamine oxidase type A such as moclobemide. In the UK licensed product information recommends that the maximum dose of zolmitriptan should be reduced when used with inhibitors of monoamine oxidase type A (see Uses and Administration, above), whereas US licensed product information states that such combinations are contra-indicated.

References.

Beta blockers. *Propranolol* increased plasma-zolmitriptan concentrations in a study in 12 healthy subjects, but the changes were not thought to be clinically important enough to warrant dosage adjustment during concomitant use.[1]

1. Peck RW, *et al.* The interaction between propranolol and the novel antimigraine agent zolmitriptan (311C90). *Br J Clin Pharmacol* 1997; 44: 595–9.

Pharmacokinetics

The absolute bioavailability of zolmitriptan after oral and intranasal doses is about 40%, and peak plasma concentrations occur about 1.5 to 3 hours after oral doses, depending on the formulation, and in about 3 hours with the intranasal spray. Plasma protein binding is about 25%. Zolmitriptan undergoes hepatic metabolism, mainly to the indole acetic acid, and also the *N*-oxide and *N*-desmethyl analogues. The *N*-desmethyl metabolite (183C91) was more active than the parent compound in *animal* studies, and would be expected to contribute to the therapeutic effect of zolmitriptan. The primary metabolism of zolmitriptan is mediated mainly by the cytochrome P450 isoenzyme CYP1A2 while monoamine oxidase type A is responsible for further metabolism of the *N*-desmethyl metabolite. Over 60% of a dose is excreted in the urine, mainly as the indole acetic acid, and about 30% appears in the faeces, mainly as unchanged drug. The elimination half-life is 2.5 to 3 hours, and is prolonged in patients with liver disease.

Distribution into milk has been found in studies in *rats*.

Antimyasthenics

This chapter includes those drugs used for their anticholinesterase action in the treatment of myasthenia gravis and related neuromuscular disorders. Other groups of drugs playing an important role in the management of myasthenia are the corticosteroids (p. 1597.1) and some drugs with immunosuppressant actions discussed in the chapters on Antineoplastics (p. 691.1) and Immunosuppressants (p. 1936.1).

Eaton-Lambert myasthenic syndrome

Eaton-Lambert myasthenic syndrome is a rare autoimmune disease of the neuromuscular junction. Unlike myasthenia gravis (below), in which autoantibodies affect acetylcholine receptors, antibodies in Eaton-Lambert syndrome act presynaptically to reduce release of acetylcholine. Weakness mostly affects the proximal muscles, particularly those of the limbs; respiratory and ocular muscles are usually spared. Autonomic symptoms including dry mouth, constipation, and impotence are common. Over half of patients also have underlying small cell carcinoma of the lung. Successful treatment of the tumour often leads to some improvement in symptoms.

The symptomatic treatment of Eaton-Lambert syndrome involves the use of drugs that increase the availability of acetylcholine at the neuromuscular junction.[1-8] Response to treatment with *anticholinesterases* alone is poor and treatment with *amifampridine*, which increases acetylcholine release, appears to be more effective, particularly when given with an anticholinesterase such as *pyridostigmine*. The use of drugs with a similar action such as *guanidine* and *fampridine* has been limited by severe adverse effects. Low-dose guanidine has been tried with pyridostigmine where amifampridine is not readily available;[9] although there has been some improvement with the combination, the incidence of adverse effects, especially gastrointestinal reactions, was still high. Immunosuppressants including *azathioprine* and *corticosteroids* are also used in patients who have an inadequate response to symptomatic treatment, and unlike in treatment for myasthenia gravis, corticosteroids do not appear to induce an initial exacerbation of symptoms. Plasma exchange or high-dose intravenous *normal immunoglobulin* have been tried in patients with severe weakness.

Myasthenia gravis

Myasthenia gravis is an auto-immune disorder characterised by defective neuromuscular transmission and consequent muscular weakness. It is caused by the formation of autoantibodies to elements of the neuromuscular junction. In most patients, antibodies to the postsynaptic nicotinic acetylcholine receptor are present (described as 'seropositive myasthenia'). However, about 10 to 15% of patients have so-called 'seronegative myasthenia', in whom antibodies to other elements such as muscle-specific tyrosine kinase (MuSK) may be present instead; the proportion of such patients is much higher among those with ocular myasthenia (where the disease is initially confined to the extra-ocular muscles but may progress to generalised myasthenia). The thymus appears to be involved in many patients and some have a thymoma. Classifications of the disease may be based on the distribution and severity of symptoms, on the age of onset, and on the presence or absence of thymoma. Other types of myasthenia include transient neonatal myasthenia due to transplacental passage of receptor antibodies, which may persist for 1 to 6 weeks in the infants of myasthenic mothers, penicillamine-induced myasthenia, and congenital myasthenia (see under Amifampridine, p. 685.1).

Diagnosis of myasthenia gravis.[1-7]

Antibody testing remains the gold standard for diagnosis of myasthenia gravis. Patients may often be tested first for their reaction to an anticholinesterase. Intravenous edrophonium preceded by atropine (Tensilon test) is the most commonly used anticholinesterase test because of its rapid onset and short duration of action. Severe adverse effects can occasionally occur so testing should only be undertaken when facilities for endotracheal intubation and controlled ventilation are immediately available. A positive result is considered to be a rapid but temporary increase in muscle strength. Repetitive nerve stimulation and/or single-fibre electromyography are also used as a diagnostic test but, like the anticholinesterase test, are not specific for myasthenia gravis. Computed tomography or magnetic resonance imaging may be used to detect thymoma.

Treatment of myasthenia gravis.[1-17]

- Symptomatic treatment is with an *anticholinesterase*; pyridostigmine and neostigmine are those most commonly used. Most patients prefer pyridostigmine as it produces less muscarinic adverse effects and has a longer duration of action, although the quicker onset of action of neostigmine may offer an advantage at the beginning of the day. The dose must be adjusted to give the optimum therapeutic response but muscle strength may not be restored to normal and some patients must live with a degree of disability. The effect may vary for different muscles and the dosage should be adjusted so that the bulbar and respiratory muscles receive optimum treatment. Generally, anticholinesterases only provide partial remission and their effects tend to diminish with continued treatment. Overdosage may lead to a 'cholinergic crisis' (see Adverse Effects of Neostigmine, p. 688.2). Edrophonium may be used to establish whether the patient is underdosed or overdosed.
- *Corticosteroids* are the main immunosuppressive drugs used for treatment. They are also useful in patients with ocular myasthenia, who as a group respond poorly to anticholinesterases and to thymectomy, provided that their disability is severe enough to warrant long-term corticosteroid treatment with its attendant adverse effects. Many start with low doses such as 5 to 20 mg of prednisolone daily or on alternate days, to reduce the risk of steroid-induced exacerbations of weakness, and increase the dose slowly thereafter according to response; an improvement is usually seen after a few weeks. Others use more aggressive regimens to obtain a more rapid response and start with large doses such as 60 to 80 mg of prednisolone daily. Whichever method is used, once clinical benefit has been obtained the regimen should be modified to alternate-day dosage, with the dose being slowly tapered when the patient is in remission. Patients taking corticosteroids require less anticholinesterase therapy and, if the dosage of the anticholinesterase is not reduced, an initial deterioration in the myasthenia may occur in the first few weeks of treatment (see also under Interactions of Neostigmine, p. 689.1). It is rarely possible to withdraw corticosteroids completely but some patients may be maintained satisfactorily on as little as 10 mg on alternate days. If remission cannot be maintained on low-dose prednisolone, addition of azathioprine at a dosage of 2 to 3 mg/kg daily may be considered.
- Addition of *azathioprine* to treatment may allow a reduction in the dose of both corticosteroids and anticholinesterases. Azathioprine may also be of use when corticosteroids are contra-indicated or when response to corticosteroids alone is insufficient, but it has a much slower onset of action than corticosteroids and is not usually used alone. *Ciclosporin* is effective in some patients unresponsive to standard combinations but serious adverse effects including nephrotoxicity may limit its use; the time to response is similar to that with corticosteroids. Other drugs such as *cyclophosphamide, mycophenolate mofetil,* and *methotrexate* have also been tried and benefit has been reported with *tacrolimus*. However, a systematic review[14] has found that only a small number of randomised controlled studies have been conducted on the use of immunosuppressive drugs for myasthenia gravis and most have been short-term. The review of this limited evidence concluded that, apart from cyclophosphamide used alone or ciclosporin used alone or with corticosteroids, there was no clear evidence of benefit from use of other immunosuppressants.
- Plasma exchange provides a dramatic but short-lived improvement and is useful as a short-term measure in myasthenic crisis to improve ill patients while other therapies take effect, but there is no evidence that repeated plasma exchange combined with immunosuppression is superior to immunosuppression alone. A similar short-term benefit has been seen from the use of high-dose intravenous *normal immunoglobulins*; however, a systematic review[15] considered further study to be warranted.
- Thymectomy may be offered to all patients sufficiently fit to undergo surgery unless they have minimal symptoms, purely ocular disease, or late onset or seronegative disease. Thymectomy is usually avoided in prepubertal children because of concern over the effect on growth and the developing immune system; it has been suggested that symptomatic treatment with anticholinesterases should be continued until adolescence, when the disease often improves spontaneously. After thymectomy, remission or improvement may be expected in about 80% of patients without thymomas, although this may take some years; the response is poorer in those with thymomas.

Ambenonium Chloride *(BAN, rINN)*

Ambenonii Chloridum; Ambenonio, cloruro de; Ambenonium Chlorid; Ambénonium, Chlorure d'; Ambenonlumklorid; Ambenoniumkloridi; Ambestigmini Chloridum; Cloruro d'Ambénonio; Cloruro de ambenonio; Win-8077; Амбенония Хлорид.

N,N'-Oxalylbis(*N*-2-aminoethyl-*N*-2-chlorobenzyldiethylammonium) dichloride.

$C_{28}H_{42}Cl_4N_4O_2$=608.5

CAS — 7648-98-8 (ambenonium); 115-79-7 (anhydrous ambenonium chloride); 52022-31-8 (ambenonium chloride tetrahydrate).

ATC — N07AA30.

ATC Vet — QN07AA30.

UNII — 51FOB87G3I (ambenonium chloride); 9T1OT01KW1 (ambenonium chloride tetrahydrate).

Pharmacopoeias. In *Jpn*.

Uses and Administration

Ambenonium is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase activity with actions similar to those of neostigmine (p. 687.2), but of longer duration. Ambenonium chloride is given orally in the treatment of myasthenia gravis (above) in usual doses of 5 to 25 mg three or four times daily, adjusted according to response. It may be of value in patients who cannot tolerate neostigmine or pyridostigmine.

Adverse Effects, Treatment, and Precautions

As for Neostigmine, p. 688.2.

Ambenonium produces fewer muscarinic adverse effects than neostigmine. As there is only slight warning of overdosage, routine use of atropine with ambenonium is contra-indicated because the muscarinic symptoms of overdosage may be suppressed leaving only the more

serious nicotinic effects (fasciculation and paralysis of voluntary muscle).

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies ambenonium as probably not porphyrinogenic: it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/07/11)

Pharmacokinetics

Ambenonium chloride is poorly absorbed from the gastrointestinal tract. It does not appear to be hydrolysed by cholinesterases.

Amifampridine *(BAN, rINN)*

Amifampridin; Amifampridina; Amifampridinum; 3,4-Diaminopiridina; 3,4-Diaminopyridine; Амифампридин.

Pyridine-3,4-diamine.

$C_5H_7N_3$=109.1

CAS — 54-96-6.

ATC — N07XX05.

ATC Vet — QN07XX05.

UNII — RU4S6E2G0J.

Amifampridine Phosphate *(rINNM)*

Amifampridine, Phosphate de; Amifampridini Phosphas; Fosfato de amifampridina; Амифампридина Фосфат.

$C_5H_7N_3H_3PO_4$=207.1

ATC — N07XX05.

ATC Vet — QN07XX05.

Uses and Administration

Amifampridine enhances the release of acetylcholine from nerve terminals; its actions and uses are similar to those of fampridine (p. 686.2) but it is reported to be more potent. It is used in the Eaton-Lambert myasthenic syndrome (below) and other myasthenic conditions. It has been tried in multiple sclerosis and in botulism. Amifampridine is given as the phosphate but doses are expressed as the base; 18.98 mg of amifampridine phosphate is equivalent to about 10 mg of amifampridine. The recommended oral starting dose in adults with Eaton-Lambert myasthenic syndrome is the equivalent of 15 mg daily given in 3 or 4 divided doses; the dose may be increased in steps of 5 mg every 4 or 5 days to a maximum of 60 mg daily. For doses in patients with hepatic or renal impairment see below.

Administration in hepatic or renal impairment. An oral starting dose the equivalent of amifampridine 5 mg daily is recommended in patients with moderate to severe hepatic or renal impairment; those with mild impairment may be given a starting dose of 10 mg daily. The dose may be increased in steps of 5 mg every 7 days.

Congenital myasthenia. Congenital or hereditary myasthenia[1-3] is a heterogeneous group of rare disorders associated with various defects in neuromuscular transmission including presynaptic impairment of acetylcholinesterase release, postsynaptic abnormality of acetylcholine receptors, or a deficiency of acetylcholinesterase. Consequently, for any given congenital myasthenic syndrome, the synaptic response to acetylcholine is either increased or decreased. Symptoms may be similar to those of myasthenia gravis (p. 684.1) but there are no immunological abnormalities. Treatment[2,3] is symptomatic and depends on both the structural defect of the neuromuscular junction and the underlying genetic defect. Drugs that are beneficial for one type of congenital myasthenia can be harmful for another; hence, a precise diagnosis including genetic testing is recommended for rational therapy. Anticholinesterases and amifampridine may be used when there is a decreased synaptic response to acetylcholine; up to 1 mg/kg daily of amifampridine has been given in divided doses. Quinidine sulfate and fluoxetine, both open-channel blockers of acetylcholine receptors, have been used when the synaptic response is increased, such as in the slow-channel syndromes. Initially, quinidine sulfate 200 mg may be given 3 times daily for a week, adjusted according to serum levels thereafter; when quinidine is not tolerated, fluoxetine may be given in gradual increments until a total daily dose of 80 to 100 mg is reached. Ephedrine, given in doses of 25 to 50 mg 2 or 3 times daily, has also been shown to be of benefit in certain types of congenital myasthenia although its mode of action is unclear.

2. Engel AG. The therapy of congenital myasthenic syndromes. *Neurotherapeutics* 2007; 4: 252–7.
3. Schara U, Lochmüller H. Therapeutic strategies in congenital myasthenic syndromes. *Neurotherapeutics* 2008; 5: 542–7.

Eaton-Lambert myasthenic syndrome. Oral daily doses of up to 100 mg of amifampridine have been found[1,2] to be effective in the treatment of both the motor and autonomic deficits of patients with Eaton-Lambert syndrome (p. 684.1). However, some workers have recommended limiting the dose to 80 mg daily because of the increased risk of seizures with higher doses.[3,4] (UK licensed product information recommends a maximum daily dose of 60 mg.) Amifampridine can produce mild excitatory effects and some patients may have difficulty in sleeping.

1. McEvoy KM, *et al.* 3,4-Diaminopyridine in the treatment of Lambert-Eaton myasthenic syndrome. *N Engl J Med* 1989; 321: 1567–71.

3. Sanders DB, *et al.* A randomized trial of 3,4-diaminopyridine in Lambert-Eaton myasthenic syndrome. *Neurology* 2000; 54: 603–7.
4. Oh SJ, *et al.* 3,4-Diaminopyridine is more effective than placebo in a randomized, double-blind, cross-over drug study in LEMS. *Muscle Nerve* 2009; 40: 795–800.

Multiple sclerosis. Amifampridine has been tried in the management of multiple sclerosis (p. 996.3). In a crossover study[1] involving 36 patients with multiple sclerosis, amifampridine given in a dosage of up to 100 mg daily improved symptoms of leg weakness to a greater extent than placebo but paraesthesia and abdominal pain, which occurred in most patients, were dose-limiting in some. A systematic review[2] of the use of aminopyridines for symptomatic management of multiple sclerosis was unable to come to any conclusion, and commented on the problem of publication bias in this area.

1. Bever CT, *et al.* Treatment with oral 3,4-diaminopyridine improves leg strength in multiple sclerosis patients: results of a randomized, double-blind, placebo-controlled, crossover trial. *Neurology* 1996; 47: 1457–62.
2. Solari A, *et al.* Aminopyridines for symptomatic treatment in multiple sclerosis. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2002 (accessed 15/02/06).

Adverse Effects and Precautions

The most common adverse effects with amifampridine are paraesthesias and gastrointestinal disturbances such as epigastralgia, diarrhoea, nausea, and abdominal pain. Sleep disorders, anxiety, weakness, fatigue, headache, chorea, myoclonus, Raynaud's syndrome, cough, bronchial hypersecretion, and elevated liver enzyme values have also been reported. The severity and incidence of most adverse effects are dose-dependent.

Arrhythmias have been reported with amifampridine and ECG monitoring should be performed at the start of treatment and yearly thereafter; amifampridine should not be used in patients with congenital QT interval prolongation. There have also been isolated reports of seizures and amifampridine is therefore contra-indicated in patients with epilepsy. Asthma attacks have occurred in patients with asthma or a history of the disease; amifampridine should not be used in those with uncontrolled asthma.

Blurred vision, drowsiness, and dizziness have been reported with amifampridine and may affect the ability of a patient to drive or operate machinery.

References.

1. Flet L, *et al.* 3,4-Diaminopyridine safety in clinical practice: an observational, retrospective cohort study. *J Neurol* 2010; 257: 937–46.

Overdosage. A 65-year-old woman with Eaton-Lambert myasthenic syndrome suffered a cardiac arrest 11 days after her dose of amifampridine had been mistakenly altered to 60 mg 6 times daily instead of her usual dose of 10 mg 6 times daily;[1] she had also complained of paraesthesia, nausea, vomiting, and palpitations and had suffered generalised convulsions in the days preceding the cardiac arrest. She recovered completely after amifampridine was stopped.

1. Boerma CE, *et al.* Cardiac arrest following an iatrogenic 3,4-diaminopyridine intoxication in a patient with Lambert-Eaton myasthenic syndrome. *J Toxicol Clin Toxicol* 1995; 33: 249–51.

Pregnancy. Licensed product information states that there are no adequate clinical data on the use of amifampridine during pregnancy; it is recommended that men and women of child-bearing potential use effective contraception during amifampridine treatment.

A healthy infant was born to a woman with congenital myasthenia who took pyridostigmine and amifampridine throughout her pregnancy.[1] Her dose of pyridostigmine was maintained at her pre-conception dose of 180 mg daily while her amifampridine dose was progressively reduced to about 20 mg daily which allowed an acceptable level of fatigue. The infant's weight and height were within normal limits when seen aged 5 months.

1. Pelufo-Pellicer A, *et al.* Fetal exposure to 3,4-diaminopyridine in a pregnant woman with congenital myasthenia syndrome. *Ann Pharmacother* 2006; 40: 762–6.

Interactions

Use of amifampridine with sultopride is contra-indicated due to the increased risk of ventricular tachycardia, particularly torsade de pointes. The risk of seizures is increased if amifampridine is used with other drugs that are known to lower the seizure threshold.

Pharmacokinetics

Amifampridine is rapidly absorbed after oral use and peak plasma concentrations occur after 20 to 60 minutes. Its elimination half-life is about 2 hours.

$C_{22}H_{32}Br_2N_4O_4$=576.3

CAS — 15876-67-2.

ATC — N07AA03.

ATC Vet — QN07AA03.

UNII — 750F36OP6J.

Pharmacopoeias. In *Jpn*.

Uses and Administration

Distigmine is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase activity with actions similar to those of neostigmine (p. 687.2) but more prolonged. Maximum inhibition of plasma cholinesterase occurs 9 hours after a single intramuscular dose, and persists for about 24 hours.

Although it is rarely used, distigmine bromide may be given orally with other short-acting parasympathomimetics for the treatment of **myasthenia gravis** (p. 684.1); patients being treated with parasympathomimetics tend to prefer pyridostigmine. The initial dose is 5 mg daily 30 minutes before breakfast, increased at intervals of 3 to 4 days if necessary to a maximum of 20 mg daily. For details of doses in children, see below.

Distigmine is one of several drugs that have been used in the prevention and treatment of **postoperative gastrointestinal atony** (see Decreased Gastrointestinal Motility, p. 1808.2). It has also been used in **postoperative urinary retention** (p. 2349.2), although it has been superseded by catheterisation. An oral dose of 5 mg daily 30 minutes before breakfast may be given. A similar oral dose, given daily or on alternate days, has been used in the management of **neurogenic bladder.**

Distigmine has been given by intramuscular injection.

Administration in children. Although it is rarely used, distigmine bromide may be given to children for the treatment of myasthenia gravis in oral doses of up to 10 mg daily according to age.

Adverse Effects, Treatment, and Precautions

As for Neostigmine, p. 688.2. The anticholinesterase action of distigmine, and hence its adverse effects, may be prolonged, and if treatment with atropine is required it should be maintained for at least 24 hours. Distigmine may stimulate uterine contractions and licensed product information advises that it should be avoided in pregnancy.

Interactions

As for Neostigmine, p. 688.3.

Pharmacokinetics

Distigmine is poorly absorbed from the gastrointestinal tract.

Preparations

Proprietary Preparations (details are given in Volume B)

Ethyl(3-hydroxyphenyl)dimethylammonium chloride.

$C_{10}H_{16}ClNO$=201.7

CAS — 312-48-1 (edrophonium); 116-38-1 (edrophonium chloride).

UNII — QO611KSM5P.

Pharmacopoeias. In *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Edrophonium Chloride). A white or almost white crystalline powder. Very soluble in water; freely soluble in alcohol; practically insoluble in dichloromethane. A 10% solution in water has a pH of 4.0 to 5.0. Protect from light.

USP 36: (Edrophonium Chloride). A white odourless crystalline powder. Soluble 1 in 0.5 of water and 1 in 5 of alcohol; insoluble in chloroform and in ether. A 10% solution in water is practically colourless and the pH is between 4.0 and 5.0.

Uses and Administration

Edrophonium is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase activity. It has actions similar to those of neostigmine (p. 687.2) but its effect on skeletal muscle is claimed to be particularly prominent. It has a rapid onset but short duration of action. In patients with myasthenia gravis, there is immediate subjective improvement and muscle strength increases. This effect usually lasts only for about 5 to 15 minutes, after which time the typical signs and symptoms return; because of its brief action the drug is not suitable for the routine treatment of myasthenia gravis.

Edrophonium chloride is used in **myasthenia gravis** (p. 684.1) both diagnostically and to distinguish between under- and over-treatment with other anticholinesterases.

- The usual *diagnostic procedure* is to inject 2 mg intravenously and, if no adverse reaction occurs within 30 to 45 seconds, to continue with the injection of a further 8 mg; the test may be repeated after 30 minutes if necessary.
  When intravenous injection is difficult edrophonium chloride may be given by intramuscular injection in a usual dose of 10 mg. Atropine should always be available when the test is carried out in order to treat any severe muscarinic reactions that may occur.
- To *detect under- or over-treatment*, test doses of 1 to 2 mg of edrophonium chloride are given intravenously to distinguish severe symptoms of myasthenia gravis due to inadequate therapy from the effects of overdosage with anticholinesterase drugs. If treatment has been inadequate, edrophonium chloride will produce an immediate amelioration of symptoms, whereas in cholinergic crises due to over-treatment the symptoms will be temporarily aggravated. Licensed product information suggests testing one hour after the last dose of treatment but the *BNF* recommends testing just before the next dose is due. Testing should only be undertaken when facilities for endotracheal intubation and controlled ventilation are immediately available.

Edrophonium chloride was originally introduced for the **reversal of neuromuscular blockade** in anaesthesia. In the UK, the recommended dose for the reversal of the effects of competitive neuromuscular blockers is 500 to 700 micrograms/kg given by intravenous injection over several minutes either with or after atropine sulfate 7 micrograms/kg. It has been suggested that in the presence of bradycardia atropine sulfate should be given several minutes before edrophonium. In the USA, a dose of 10 mg of edrophonium chloride is given over 30 to 45 seconds and repeated as required up to a maximum of 40 mg. The brevity of its action limits its value. Prolonged apnoea may occur in patients treated with a depolarising neuromuscular blocker, such as suxamethonium; to determine if this is caused by a phase II block (see p. 2037.2), edrophonium chloride 10 mg may be given intravenously with atropine.

For details of doses in children, see below.

Edrophonium bromide has been used similarly to edrophonium chloride.

Administration in children. The use of edrophonium chloride in children with **myasthenia gravis** is similar to that in adults (see Uses and Administration, above).

- The usual *diagnostic procedure* in the UK is to inject 20 micrograms/kg intravenously and, if no adverse reaction occurs within 30 seconds, to continue with the injection of a further 80 micrograms/kg. The *BNFC* suggests that this dose may be given to those aged from 1 month to 12 years. Older children may be given the usual adult dose. In the USA a total intravenous dose of 5 mg for children weighing less than 34 kg and 10 mg for heavier children is recommended, with one-fifth of the dose being given initially followed by increments of 1 mg every 30 to 45 seconds. Alternatively, a total of 200 micrograms/kg may be given, with one-fifth of the dose being given initially over 1 minute followed by the remainder if no adverse reactions occur within 45 seconds. The recommended total dose for infants is 500 micrograms. When intravenous injection is difficult edrophonium chloride may be given by intramuscular injection; children weighing under 34 kg may be given 2 mg and heavier children 5 mg. The recommended dose for infants is 0.5 to 1 mg given intramuscularly or subcutaneously.
- To *detect under- or over-treatment*, the *BNFC* recommends that children aged from 1 month to 12 years be given a dose of 20 micrograms/kg by intravenous injection just before the next dose of anticholinesterase. Older children may be given the usual adult dose.

For the **reversal of neuromuscular blockade** in anaesthesia, usual doses in the UK for children are as for adults; the *BNFC* suggests that these doses may be given to children as young as 1 month of age.

Reversal of neuromuscular blockade. For a discussion of whether edrophonium might be more suitable than neostigmine for reversal of residual block after the use of the shorter-acting competitive neuromuscular blockers, see under Uses and Administration of Neostigmine, p. 688.1.

Snake bite. For the use of anticholinesterases in the treatment of snake bite, see under Uses and Administration of Neostigmine, p. 688.1.

Tetrodotoxin poisoning. Management of poisoning due to tetrodotoxin, a heat stable neuromuscular blocking toxin found in various marine animals, such as puffer fish, is mainly symptomatic and supportive. Reports[1-4] on the efficacy of intravenous anticholinesterases such as edrophonium or neostigmine in reversing muscle weakness in tetrodotoxin poisoning have been conflicting. Although it appears that anticholinesterases may only be effective during partial block produced by tetrodotoxin, some consider[5] that, as there is no specific antidote, any measure that brings about improvement may be tried.

For a discussion of the general principles of the management of acute poisoning, see p. 1537.1.

Fampridine *(rINN)*

Dalfampridine (USAN); EL-970; Fampridin; Fampridina; Fampridinum; Фампридин.

4-Aminopyridine; 4-Pyridinamine.

$C_5H_6N_2$=94.12

CAS — 504-24-5.

ATC — N07XX07.

ATC Vet — QN07XX07.

UNII — BH3B64OKL9.

Uses and Administration

Fampridine is an aminopyridine that, like its derivative amifampridine (p. 685.1), enhances the release of acetylcholine from nerve terminals. It is used to improve walking in patients with multiple sclerosis (below); the licensed dose is 10 mg twice daily as an oral modified-release preparation. Fampridine has also been tried in the management of Guillain-Barré syndrome (p. 2406.1) and spinal cord injury; oral doses used in patients with spinal cord injuries have ranged from 30 to 50 mg daily. Other uses of fampridine that have been investigated include the neurological disorders Eaton-Lambert myasthenic syndrome (p. 684.1) and Alzheimer's disease (see Dementia, p. 388.1), and the reversal of neuromuscular blockade in patients with botulism (p. 2380.2) or after the use of competitive neuromuscular blockers.

Fampridine has also been considered as a specific antidote in poisoning with calcium-channel blockers (see Overdosage under Treatment of Adverse Effects of Nifedipine, p. 1452.3).

Multiple sclerosis. Fampridine has potassium-channel blocking activity and has been tried in the treatment of multiple sclerosis (p. 996.3) to improve conduction in demyelinated fibres. Improvements have been reported in walking, dexterity, and vision, but only small numbers of patients have been studied. An early systematic review[1] was unable to come to a conclusion about its safety and efficacy, noting that publication bias posed a problem in this area. However, further multicentre randomised controlled studies,[2-4] and reviews[5-7] of these studies, suggested that fampridine improved walking ability in some patients. Any benefit is generally noted within 2 weeks of starting treatment.

Adverse Effects and Precautions

The most common adverse effect with fampridine is urinary-tract infection. Other adverse effects include insomnia, dizziness, headache, gastrointestinal disturbances such as constipation, dyspepsia, and nausea, asthenia, back pain, paraesthesia, and nasopharyngitis.

A dose-dependent increase in the incidence of seizures has been noted with fampridine treatment and therefore its use is contra-indicated in patients with a history of seizures.

Fampridine is mainly eliminated unchanged by the kidneys and patients with renal impairment therefore have an increased risk of adverse effects, particularly neurological reactions. Consequently, its use is contra-indicated in patients with moderate to severe renal impairment (creatinine clearance of 50 mL/min or less). In patients with mild renal impairment (creatinine clearance of 80 mL/min or less), the risk of seizures is unknown although plasma levels of fampridine may approach those associated with an increased risk; UK licensed product information also contra-indicates fampridine use in this patient group.

Overdosage. An 8-month-old boy had dramatic opisthotonic posturing and vermiform tongue fasciculations after ingestion of up to 20 mg of fampridine;[1] the child was also noted to be tachycardic and tachypnoeic. His symptoms resolved after treatment with benzodiazepines. Choreoathetoid movements in all limbs were also reported in a 45-year-old woman with multiple sclerosis who accidentally overdosed with fampridine;[2] when rechallenged,

symptoms including confusion, opisthotonus, risus sardonicus, motor distress, and head tremor were noted instantly.

Three adult patients[3] with multiple sclerosis developed status epilepticus within minutes to hours of taking incorrectly-compounded tablets that contained between 90.1 and 125.6 mg of fampridine per tablet instead of the prescribed 10 mg. Although acute recovery was seen in all 3 patients after treatment with benzodiazepines and phenytoin, chronic neurological disabilities remained.

In another case, a 56-year-old man developed altered mental status, hypothermia, and atrial fibrillation after taking an unknown quantity of fampridine for toothache.[4] He had rubbed a large 'rock' of fampridine against his tooth in an attempt to relieve the pain, inadvertently swallowing some flakes of drug, which resulted in the overdose.

Pharmacokinetics

Fampridine is rapidly and extensively absorbed from the gastrointestinal tract after oral use. Plasma protein binding is minimal (1 to 3%). Fampridine is eliminated mostly unchanged in the urine; less than 10% of the drug is metabolised, some via the cytochrome P450 isoenzyme CYP2E1. Two major metabolites have been identified: 3-hydroxy-4-aminopyridine and 3-hydroxy-4-aminopyridine sulfate.

Profile

Ipidacrine, an analogue of tacrine (p. 396.1), is a cholinesterase inhibitor. It is used in the management of various neurological disorders including CNS and peripheral nervous system disorders, demyelinating disease, myasthenia gravis (p. 684.1) and other myasthenic syndromes, Alzheimer's disease (see Dementia, p. 388.1), and gastrointestinal atony. For myasthenic syndromes an oral dose of 20 to 40 mg has been given up to 5 times daily. A usual dosage in Alzheimer's disease is 10 to 20 mg given 2 or 3 times daily but this may be increased gradually up to 200 mg daily given in divided doses.

Ipidacrine has also been given by injection as the hydrochloride.

UNII — 98IMH7M386.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Neostigmine Metilsulfate). Hygroscopic, colourless crystals or a white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol. Store in airtight containers. Protect from light.

USP 36: (Neostigmine Methylsulfate). Store in airtight containers.

Uses and Administration

Neostigmine is a quaternary ammonium compound that inhibits cholinesterase activity and thus prolongs and intensifies the physiological actions of acetylcholine (p. 2003.2). It probably also has direct effects on skeletal muscle fibres. The anticholinesterase actions of neostigmine are reversible.

Neostigmine is used in the treatment of myasthenia gravis, and has been used as an alternative to edrophonium in the diagnosis of myasthenia gravis (p. 684.1). It is used in anaesthesia to reverse the neuromuscular blockade produced by competitive neuromuscular blockers (see p. 688.1). It is also used in the management of paralytic ileus. Neostigmine has been used in the management of postoperative urinary retention (p. 2349.2) but has generally been superseded by catheterisation. It has also been used to lower intra-ocular pressure in the management of glaucoma and to reduce rises in intra-ocular pressure associated with ophthalmic surgery, although other parasympathomimetics are usually used when such miotics are required.

Neostigmine is given as the bromide and as the metilsulfate. Neostigmine bromide is given orally and has been used topically as eye drops; the metilsulfate is given by intramuscular, intravenous, or subcutaneous injection.

Licensed product information states that 500 micrograms of neostigmine metilsulfate by intravenous injection is equivalent in effect to about 1 to 1.5 mg of neostigmine metilsulfate by intramuscular or subcutaneous injection, or 15 mg of neostigmine bromide orally.

In the treatment of **myasthenia gravis**, neostigmine bromide is given orally in a total daily dose that ranges from 75 to 300 mg, divided throughout the day, and if necessary the night, according to response; larger portions of the total dose may be given at times of greater fatigue. The *BNF* states that the maximum daily dose that most patients can tolerate is 180 mg. In patients in whom oral therapy is impractical neostigmine metilsulfate may be given in doses of 0.5 to 2.5 mg by intramuscular or subcutaneous injection at intervals, giving a total daily dose usually in the range 5 to 20 mg.

To **reverse neuromuscular blockade** produced by competitive neuromuscular blockers, the usual licensed dose in the UK is 50 to 70 micrograms/kg given by intravenous injection over a period of 60 seconds; the *BNF* suggests giving a dose of 2.5 mg. In the USA licensed doses of 0.5 to 2 mg are recommended. Additional neostigmine may be given until the muscle power is normal but a total of 5 mg should not be exceeded. The patient should be ventilated until complete recovery of normal respiration is assured. To counteract any muscarinic effects 0.6 to 1.2 mg (20 to 30 micrograms/kg) of atropine sulfate is given by intravenous injection with or before the dose of neostigmine. It has been suggested that in the presence of bradycardia atropine sulfate should be given several minutes before neostigmine. Glycopyrronium bromide has been used as an alternative to atropine sulfate.

In the treatment of paralytic **ileus** and postoperative **urinary retention**, oral doses of 15 to 30 mg of the bromide, or more usually 0.5 to 2.5 mg of the metilsulfate by subcutaneous or intramuscular injection, have been used.

For details of doses in children, see below.

Administration in children. The use of neostigmine in children is similar to that in adults (see Uses and Administration above).

For the treatment of **myasthenia gravis** UK licensed product information states that neostigmine bromide may be given orally in an initial dose of 7.5 mg to children aged under 6 years, or 15 mg to those aged 6 to 12 years. This is adjusted according to response to a usual total daily dose of 15 to 90 mg, divided throughout the day.

When oral therapy is impractical, children aged under 12 years may be given intramuscular or subcutaneous injections of neostigmine metilsulfate in doses of 200 to 500 micrograms, repeated at suitable intervals throughout the day.

For all routes of administration, children aged over 12 years may be given the usual adult dose.

In the treatment of neonatal myasthenia gravis, UK licensed product information states that neostigmine metilsulfate may be given in an initial intramuscular dose of 100 micrograms followed by a usual dose of 50 to 250 micrograms, or 30 micrograms/kg, every 2 to 4 hours. The *BNFC* recommends higher doses: an initial intramuscular or subcutaneous dose of 150 micrograms/kg every 6 to 8 hours, increased to a maximum of 300 micrograms/kg every 4 hours if necessary. Alternatively, the *BNFC* suggests that neostigmine bromide may be given in an initial oral dose of 1 to 2 mg followed by 1 to 5 mg every 4 hours. For all routes of administration, doses should be given 30 minutes before feeding. Treatment is rarely needed beyond 8 weeks of age.

To **reverse neuromuscular blockade** produced by competitive neuromuscular blockers, children may be given doses similar to those used in adults; the *BNFC* recommends an intravenous dose of 50 micrograms/kg (to a maximum of 2.5 mg) in neonates and those aged up to 18 years; a further dose of 25 micrograms/kg may be given if required. To counteract any muscarinic effects, neonates and children may be given atropine sulfate 20 micrograms/kg (to a maximum of 1.2 mg) by intravenous injection with or before the dose of neostigmine. Glycopyrronium may be used as an alternative to atropine.

For the treatment of paralytic **ileus** or postoperative **urinary retention** in children, oral doses of 2.5 to 15 mg of the bromide, or more usually 0.125 to 1 mg of the metilsulfate by subcutaneous or intramuscular injection, have been used.

Decreased gastrointestinal motility. Parasympathomimetics enhance gastric contractions and increase intestinal motility and have been used in conditions associated with decreased gastrointestinal motility (p. 1808.2). Good results have been reported with intravenous neostigmine in the treatment of acute colonic pseudo-obstruction,[1,2] a condition that appears to be due to parasympathomimetic dysfunction. These results have been confirmed in a randomised double-blind study.[3] It has therefore been suggested that parasympathomimetics should be tried before colonic decompression or surgery when conservative management has failed or a rapid resolution is required.[3] Neostigmine has also been used in the treatment of severe constipation due to disrupted intestinal motility.[4-6]

Local anaesthesia. Intrathecal neostigmine has been added to spinal local anaesthetics or opioids as an adjunct to prolong regional analgesia and improve haemodynamic stability. A systematic review[1] of studies of such use found that although neostigmine in doses up to 500 micrograms produced a very modest increase in analgesia in the perioperative and peripartum setting, it did not appear to improve haemodynamic stability and the incidence of adverse effects was greatly increased, even at low doses. The disadvantages were felt to outweigh whatever benefits such therapy might have.

Neostigmine has also been given by the epidural route as an adjunct to analgesia;[2] some adverse effects such as nausea may be less with this route.

1. Ho KM, *et al.* Use of intrathecal neostigmine as an adjunct to other spinal medications in perioperative and peripartum analgesia: a meta-analysis. *Anaesth Intensive Care* 2005; 33: 41–53.
2. Ross VH, *et al.* Neostigmine decreases bupivacaine use by patient-controlled epidural analgesia during labor: a randomized controlled study. *Anesth Analg* 2009; 109: 524–31.

Reversal of neuromuscular blockade. Anticholinesterases have often been used after surgery to antagonise residual neuromuscular block induced by long-acting competitive neuromuscular blockers. However, there has been continuing debate[1-3] on whether anticholinesterases can be used in reduced doses or even omitted for intermediate-acting blockers such as atracurium and vecuronium and shorter-acting blockers such as mivacurium.

Decreasing the anticholinesterase dose may reduce adverse effects. Although it is not clear whether omitting neostigmine reversal reduces nausea and vomiting,[3,4] it avoids any adverse effects neostigmine may have on gut anastomoses. One commentator[1] considered that the wide variation in recovery time with aminosteroid blockers such as rocuronium was an indication for always using at least a small dose of anticholinesterase when these drugs were used. However, it was suggested that, if the block was being carefully monitored and recovery was established, a reduced dose of 1.25 mg of neostigmine might be preferable after a benzylisoquinolinium blocker such as atracurium or mivacurium. In children, smaller doses of an anticholinesterase could be used, even after an aminosteroid blocker, and after a blocker such as mivacurium, they might not be needed at all.

Others have preferred to reserve neostigmine reversal for cases where it was deemed clinically necessary: in a study[4] using such a protocol, 68% of those receiving rocuronium were given neostigmine, against 10% of those receiving mivacurium.

It has been suggested that because of its shorter duration of action edrophonium might be more suitable than neostigmine to antagonise residual block for neuromuscular blockers with shorter actions and in particular, that edrophonium might be more appropriate than neostigmine for use with mivacurium. Neostigmine inhibits the plasma cholinesterase responsible for the metabolism of mivacurium and its use can in theory delay rather than speed recovery, although in practice there is considered to be little evidence for such an effect.[1] Edrophonium also has lesser effects on the vagus, a more rapid onset of action, and may be associated with a lower incidence of nausea and vomiting than neostigmine.[5] Neostigmine can cause clinically significant neuromuscular blockade if it is given to a patient who has already recovered a large degree of neuromuscular function[6,7] but edrophonium appears not to have this effect.[8] However, the antagonism produced by edrophonium is not adequately and reliably sustained especially after profound block.[9,10]

Snake bite. The general management of snake bites is discussed on p. 2419.2. Many reports from India have claimed benefit for anticholinesterases in the treatment of neurotoxic snake bites but failure to distinguish between cobra and krait bites, lack of controls, and inadequate information about other therapy weaken the claims.[1] However, edrophonium has been shown in 2 double-blind studies to be more effective than placebo[2] and antivenom[3] in the treatment of snake bite due to the Philippine cobra (*Naja naja philippinensis*). Neostigmine has also been reported[4] to have been effective in reversing paralysis in 2 patients bitten by *Micrurus frontalis* (a coral snake). Similarly, another patient made a remarkable recovery when treated with neostigmine after being bitten by an Asiatic cobra (*Naja naja kaouthia*).[5] Anticholinesterases would be expected to be of little value for bites from snakes whose venom contains neurotoxins which act presynaptically, including the Asian krait, the Australian tiger snake, and the taipan[6] and, although beneficial results have been reported in individual patients,[7] overall results are considered to be inconsistent.[2,8] However, it is recommended that a test dose of edrophonium preceded by atropine should be given to patients with neurological signs after a snake bite by any species and if improvement occurs, a longer acting anticholinesterase such as neostigmine can be given.[2,3]

Tetrodotoxin poisoning. For reference to the use of neostigmine in the treatment of tetrodotoxin poisoning caused by eating puffer fish, see under Uses and Administration of Edrophonium Chloride, p. 686.2.

Adverse Effects

The adverse effects of neostigmine are chiefly due to excessive cholinergic stimulation and most commonly include increased salivation, nausea and vomiting, abdominal cramps, and diarrhoea. Allergic reactions have been reported; rashes have been associated with the use of the bromide salt. Neostigmine penetrates the blood-brain barrier poorly and CNS effects are usually only seen with high doses.

Overdosage may lead to a 'cholinergic crisis', characterised by both muscarinic and nicotinic effects. These effects may include excessive sweating, lachrymation, increased peristalsis, involuntary defaecation and urination or desire to urinate, miosis, ciliary spasm, nystagmus, bradycardia and other arrhythmias, hypotension, muscle cramps, fasciculations, weakness and paralysis, tight chest, wheezing, and increased bronchial secretion combined with bronchoconstriction. CNS effects include ataxia, convulsions, coma, slurred speech, restlessness, agitation, and fear. Death may result from respiratory failure, due to a combination of the muscarinic, nicotinic, and central effects, or cardiac arrest.

It has been reported that a paradoxical increase in blood pressure and heart rate may result from nicotinic stimulation of sympathetic ganglia, especially where atropine has been given to reverse the muscarinic effects (see Treatment of Adverse Effects, below).

In patients with myasthenia gravis, in whom other symptoms of overdosage may be mild or absent, the major symptom of cholinergic crisis is increased muscular weakness, which must be differentiated from the muscular weakness caused by an exacerbation of the disease itself (myasthenic crisis).

The adverse effects of parasympathomimetics applied topically for their miotic action are discussed under Pilocarpine on p. 2011.2.

Treatment of Adverse Effects

If a life-threatening amount of neostigmine has been taken orally and the patient presents within 1 hour, the stomach may be emptied by lavage; giving activated charcoal to decrease absorption should also be considered. When necessary maintenance of respiration should take priority. Atropine sulfate should be given in usual doses of 1 to 2 mg, preferably intravenously, or else intramuscularly and repeated as necessary to control the muscarinic effects; single doses of up to 4 mg have also been suggested. Nicotinic effects, including muscle weakness and paralysis, are not antagonised by atropine; small doses of a competitive neuromuscular blocker have been suggested for the control of muscle twitching. Use of the cholinesterase reactivator pralidoxime as an adjunct to atropine has also been suggested (see p. 1571.2). Further supportive treatment should be given as required.

For a discussion of the general principles of the management of acute poisoning, see p. 1537.1.

Precautions

The precautions and contra-indications to be observed with neostigmine use relate mainly to its cholinergic effects.

Neostigmine is contra-indicated in patients with mechanical gastrointestinal or urinary-tract obstruction, or peritonitis. It should be used with extreme caution in patients who have undergone recent intestinal or bladder surgery and in patients with bronchial asthma. It should be used with caution in patients with cardiovascular disorders including arrhythmias, bradycardia, recent myocardial infarction, and hypotension, as well as in patients with vagotonia, epilepsy, hyperthyroidism, parkinsonism, renal impairment, or peptic ulcer disease. When neostigmine is given by injection, atropine should always be available to counteract any excessive muscarinic reactions; atropine may also be given before, or with, neostigmine to prevent or minimise muscarinic adverse effects but this may mask the initial symptoms of overdosage and lead to cholinergic crisis.

UK licensed product information states that as the severity of myasthenia gravis often fluctuates considerably during pregnancy, particular care is needed to avoid cholinergic crisis caused by overdosage; it has also been reported that neonatal myasthenia may follow large doses during pregnancy. The amount of neostigmine distributed into breast milk is very small but breast-fed infants need to be monitored.

Large oral doses of neostigmine should be avoided in conditions where there may be increased absorption from the gastrointestinal tract. It should be avoided in patients known to be hypersensitive to neostigmine; the bromide ion from neostigmine bromide may contribute to any allergic reaction.

The precautions of parasympathomimetics applied topically for their miotic action are discussed under Pilocarpine on p. 2011.2.

Neuromuscular disorders. Residual non-depolarising neuromuscular block in a patient with dystrophia myotonica was only partly reversed by neostigmine and atropine, and following a second dose of both drugs complete neuromuscular block developed.[1] In a second patient with a history of progressive muscle dystrophy, the use of neostigmine to reverse residual non-depolarising blockade gave rise to a tonic response in the indirectly stimulated muscle. The type and degree of the response to neostigmine, and probably other anticholinesterases, cannot be predicted in patients with neuromuscular disease.

A patient with sero-negative ocular myasthenia gravis had exaggerated responses to both vecuronium and neostigmine.[2] The dose of neuromuscular blockers and their antagonists used in patients with myasthenia gravis should be titrated carefully regardless of the severity of the condition.

2. Kim J-M, Mangold J. Sensitivity to both vecuronium and neostigmine in a sero-negative myasthenic patient. *Br J Anaesth* 1989; 63: 497–500.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies neostigmine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/07/11)

Renal impairment. The dosage of neostigmine may need to be adjusted in patients with renal impairment. The mean serum elimination half-life of 79.8 minutes obtained in patients with normal renal function was found to be prolonged to 181.1 minutes in anephric patients.[1]

1. Cronnelly R, *et al.* Renal function and the pharmacokinetics of neostigmine in anesthetized man. *Anesthesiology* 1979; 51: 222–6.

Interactions

Drugs with neuromuscular blocking activity, such as the aminoglycosides, clindamycin, colistin, cyclopropane, and the halogenated inhalational anaesthetics, may antagonise the effects of neostigmine. Those such as quinine, chloroquine, hydroxychloroquine, quinidine, procainamide, propafenone, lithium, and the beta blockers, that have the potential to aggravate myasthenia gravis, can reduce the efficacy of treatment with parasympathomimetics. Prolonged bradycardia has also occurred in patients receiving beta blockers when given neostigmine. Anticholinesterases, such as neostigmine, can inhibit the metabolism of suxamethonium, a depolarising neuro-

muscular blocker, and enhance and prolong its action; combined use is not recommended.

Ophthalmic use of anticholinesterases, such as ecothiopate, should be undertaken with care in patients receiving neostigmine systemically for myasthenia gravis, because of possible additive toxicity.

Antimuscarinics such as atropine antagonise the muscarinic effects of neostigmine.

Beta blockers. There have been several reports of bradycardia and hypotension when neostigmine or physostigmine were given to patients receiving beta blockers[1-4] but no significant changes in heart rate were noted in a study of pyridostigmine given to 8 patients taking beta blockers.[5] Beta blockers have the potential to aggravate the symptoms of myasthenia gravis and may therefore reduce the efficacy of parasympathomimetic treatment.

5. Arad M, *et al.* Safety of pyridostigmine in hypertensive patients receiving beta blockers. *Am J Cardiol* 1992; 69: 518–22.

Calcium-channel blockers. Use of calcium-channel blockers such as *verapamil* with neuromuscular blockers may produce an enhanced muscle block which is resistant to reversal with neostigmine[1] but which can be reversed by edrophonium.[2]

2. Jones RM, *et al.* Verapamil potentiation of neuromuscular blockade: failure of reversal with neostigmine but prompt reversal with edrophonium. *Anesth Analg* 1985; 64: 1021–5.

Corticosteroids. Although use of glucocorticoids alone may improve strength in myasthenic patients, use of *methylprednisolone* in patients receiving neostigmine or pyridostigmine has exacerbated symptoms and produced profound weakness needing assisted ventilation.[1] Since the adverse effects of combined therapy usually occur before any expected benefits it has been suggested that the glucocorticoid should be given on alternate days in small doses which are increased gradually until the optimal effect is achieved.[2]

2. Jubiz W, Meikle AW. Alterations of glucocorticoid actions by other drugs and disease states. *Drugs* 1979; 18: 113–21.

Pharmacokinetics

Neostigmine is a quaternary ammonium compound and, as the bromide, is poorly absorbed from the gastrointestinal tract. After parenteral doses as the metilsulfate, neostigmine is rapidly eliminated and is excreted in the urine both as unchanged drug and metabolites. Neostigmine undergoes hydrolysis by cholinesterases and is also metabolised in the liver. Protein binding to human serum albumin is reported to range from 15 to 25%. Penetration into the CNS is poor. Neostigmine crosses the placenta and very small amounts are distributed into breast milk.

Neostigmine appears to be poorly and variably absorbed when given orally. In 3 myasthenic patients peak plasma concentrations were obtained 1 to 2 hours after a single 30-mg oral dose and the mean plasma half-life was 0.87 hours; bioavailability was estimated to be 1 to 2%.[1] Mean plasma half-lives of 0.89 and 1.20 hours have been obtained after intravenous[1] and intramuscular[2] injections of neostigmine metilsulfate, respectively, although again only a few patients were studied. Metabolism and biliary excretion may play significant roles in the elimination of neostigmine.[2] About 80% of a dose may be excreted in the urine within 24 hours: about 50% of a dose as unchanged drug and 15% as 3-hydroxyphenyltrimethylammonium.[2] Mean plasma elimination half-lives for neostigmine have been found to be shorter in infants (0.65 hours) and children (0.80 hours) compared with adults (1.12 hours) but this does not appear to be related to its duration of effect in antagonising neuromuscular blockade.[3] For the half-life in anephric patients, see Renal Impairment, p. 688.3.

UNII — KVI301NA53.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Pyridostigmine Bromide). A white or almost white deliquescent crystalline powder. Very soluble in water and in alcohol. Store in airtight containers. Protect from light.

USP 36: (Pyridostigmine Bromide). A white or practically white, hygroscopic, crystalline powder, having an agreeable characteristic odour. Freely soluble in water, in alcohol, and in chloroform; practically insoluble in ether; slightly soluble in petroleum spirit. Store in airtight containers.

Uses and Administration

Pyridostigmine is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase activity with actions similar to those of neostigmine (p. 687.2), but is slower in onset and of longer duration. It is given as the bromide.

Pyridostigmine is mainly used in the treatment of myasthenia gravis (p. 684.1) although its use in neonatal myasthenia has declined in favour of neostigmine. It has also been used in the treatment of paralytic ileus. Pyridostigmine is sometimes used to reverse the neuromuscular blockade produced by competitive neuromuscular blockers but is generally considered less satisfactory than neostigmine. It has also been used as prophylaxis against the neuromuscular effects of nerve gas poisoning (below). Pyridostigmine has been used in the management of postoperative urinary retention (p. 2349.2) but has generally been superseded by catheterisation.

For **myasthenia gravis**, UK licensed product information states that total daily oral doses may range from 300 mg to 1.2 g; however, the *BNF* states that daily doses of 450 mg should not be exceeded in order to avoid receptor downregulation. It also noted that patients receiving pyridostigmine in doses over 360 mg daily may need more aggressive therapy. In the USA, licensed doses are somewhat higher, ranging up to 1.5 g daily.

The dose should be divided throughout the day and, if necessary, the night, according to response; larger portions of the total daily dose may be given at times of greater fatigue.

Pyridostigmine has also been given as modified-release tablets, usually once or twice daily but these offer less flexibility of dosage. If necessary it has also been given by intramuscular injection or in severe cases by very slow intravenous injection. However, the intravenous route is hazardous and, if used, atropine must be available to counteract any severe muscarinic reactions. Parenteral doses are about one-thirtieth of the usual oral dose.

To **reverse neuromuscular blockade** produced by *competitive neuromuscular blockers*, doses of 100 to 250 micrograms/kg (about 10 to 20 mg) have been given intravenously, with or preceded by intravenous atropine sulfate 0.6 to 1.2 mg to counteract any muscarinic effects. Glycopyrronium bromide has been used as an alternative to atropine.

Pyridostigmine is also used for prophylaxis against the neuromuscular effects of nerve gas poisoning, including *soman*, in military combat use only; the recommended oral dose is 30 mg every 8 hours started at least several hours before exposure. If nerve gas poisoning occurs, pyridostigmine should be stopped and the patient should be treated with atropine and pralidoxime immediately.

In the treatment of paralytic **ileus** and postoperative **urinary retention** pyridostigmine bromide has been given in oral doses of 60 to 240 mg.

For details of doses in children, see below.

Administration in children. The use of pyridostigmine in children is similar to that in adults (see Uses and Administration, above).

UK licensed product information states that children may be given pyridostigmine, as the bromide, for the treatment of **myasthenia gravis** in an initial oral dose of 30 mg for those aged under 6 years or 60 mg for those aged 6 to 12 years, repeated throughout the day. This is increased gradually by increments of 15 to 30 mg daily until a satisfactory response is obtained, which is usually within the dosage range of 30 to 360 mg daily. Alternatively, the *BNFC* suggests that children aged 1 month to 12 years may be given an initial oral dose of 1 to 1.5 mg/kg daily, increased gradually to 7 mg/kg daily in 6 divided doses, to a usual total dose of 30 to 360 mg daily. Older children may be given the usual adult dose. In the USA, an oral dose of 7 mg/kg daily in 5 or 6 divided doses has also been suggested. Those patients who require parenteral therapy have been given an intramuscular or intravenous dose of 50 to 150 micrograms/kg (up to a maximum of 10 mg) every 4 to 6 hours.

In the treatment of neonatal myasthenia doses in the range of 50 to 150 micrograms/kg by intramuscular injection or 5 mg orally have been given every 4 to 6 hours. Alternatively, the *BNFC* recommends an oral dose based on neonatal weight: initially 1 to 1.5 mg/kg, increased gradually to a maximum of 10 mg, repeated throughout the day, and given 30 to 60 minutes before feeds. Treatment is rarely needed beyond 8 weeks of age.

For the treatment of paralytic **ileus** and postoperative **urinary retention**, children have been given oral doses of 15 to 60 mg.

Decreased gastrointestinal motility. Parasympathomimetics such as pyridostigmine enhance gastric contractions and increase intestinal motility; they have been used in conditions associated with decreased gastrointestinal motility (p. 1808.2).

Pyridostigmine, generally in doses of 60 mg up to 3 times daily, has been used to relieve severe constipation in patients with impaired intestinal motility due to Parkinson's disease.[1] It has also been tried in patients with constipation due to autonomic neuropathy;[2] however, results have been equivocal.

2. Bharucha AE, *et al.* Pilot study of pyridostigmine in constipated patients with autonomic neuropathy. *Clin Auton Res* 2008; 18: 194–202.

Growth hormone deficiency. Although the value of stimulated growth hormone secretion tests in children has been questioned (see Growth Retardation, p. 1921.3), pyridostigmine with somatorelin has been found to be a potent and reproducible test for distinguishing adults with severe growth hormone deficiency from normal subjects.[1] However, the combination is not effective in patients over 55 years of age,[2] and somatorelin with arginine is generally preferred where an alternative to the gold standard of the insulin-tolerance test is required.[1]

1. Ghigo E, *et al.* Diagnostic and therapeutic uses of growth hormone-releasing substances in adult and elderly subjects. *Baillieres Clin Endocrinol Metab* 1998; 12: 341–58.
2. Vierhapper H, *et al.* The use of the pyridostigmine growth hormone-releasing hormone stimulation test to detect growth hormone deficiency in patients with pituitary adenomas. *Metabolism* 2002; 51: 34–7.

Nerve gas poisoning. Pyridostigmine has been used prophylactically to protect soldiers in the event of an attack with nerve gas agents (p. 2568.3) that inhibit acetylcholinesterase.[1] Pyridostigmine binds reversibly to acetylcholinesterase and provides a protected store from which acetylcholinesterase is later released.[1-3] Prophylaxis with pyridostigmine greatly enhances the efficacy of treatment with atropine and pralidoxime against exposure to *soman* but it is not effective alone and may not be uniformly effective against other nerve agents.[1] Giving 30 mg of pyridostigmine every 8 hours provides the optimum level of protection[2] and, although adverse effects are common at this dosage, the performance of military duties is not impaired.[4] However, neurological symptoms in veterans suffering the so-called Gulf War Syndrome appear to be

more common in those who reported exposure to a range of potentially toxic substances which include pyridostigmine.[5] It has been suggested that these symptoms may be evidence of organophosphate-induced polyneuropathy resulting from exposure to a combination of organophosphorus compounds and other cholinesterase inhibitors such as pyridostigmine.[6] A study in *hens*[7] (a species susceptible to anticholinesterases) has also found symptoms of enhanced neurotoxicity when pyridostigmine, the insect repellent diethyltoluamide, and the pyrethroid insecticide permethrin were used together.

Orthostatic hypotension. Pyridostigmine has been investigated in the treatment of orthostatic hypotension (p. 1634.3). A review[1] of 4 single-dose studies and a follow-up survey (involving a total of 106 patients and generally reporting an improvement in haemodynamic measurements) concluded that there was insufficient long-term data to support the routine use of pyridostigmine in the treatment of orthostatic hypotension.

1. Gales BJ, Gales MA. Pyridostigmine in the treatment of orthostatic intolerance. *Ann Pharmacother* 2007; 41: 314–18.

Post-poliomyelitis syndrome. Although pyridostigmine has been reported[1] in some patients to reduce fatigue associated with post-poliomyelitis syndrome, a systematic review failed to find any benefit.[2] Doses used[3] have included 30 mg daily increased gradually to about 60 mg three times daily but adverse effects are common.

Adverse Effects, Treatment, and Precautions

As for Neostigmine, p. 688.2. It has been stated that muscarinic adverse effects occur less frequently with pyridostigmine treatment than with neostigmine.

Breast feeding. Pyridostigmine was present in the breast milk of 2 nursing mothers, receiving maintenance therapy for myasthenia gravis, in a concentration between 36 and 113% of that in maternal plasma,[1] but in both cases the dose ingested per kg body-weight by the nursing infant was 0.1% or less of that ingested by the mother. Maternal medication with pyridostigmine should be no obstacle to breast feeding, at least with doses in the range of 180 to 300 mg daily.

On the basis of this study, the last available guidance from the American Academy of Pediatrics considered[2] that pyridostigmine is usually compatible with breast feeding.

1. Hardell L-I, *et al*. Pyridostigmine in human breast milk. *Br J Clin Pharmacol* 1982; 14: 565–7.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*: 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 15/02/06)

Effects on the joints. Several years after starting oral pyridostigmine bromide 60 mg five times daily, a middle-aged woman had episodes of bilateral arthralgia and hyperalgesia of her hips, knees, toes, and shoulders.[1] Symptoms resolved when pyridostigmine was stopped and rechallenge was positive on several occasions.

1. Rostedt A, Stålberg E. Joint pain and hyperalgesia due to pyridostigmine bromide in a patient with myasthenia gravis. *Neurology* 2004; 62: 835–6.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies pyridostigmine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/07/11)

Psychosis. Postoperative psychosis in a patient with myasthenia gravis who received large doses of pyridostigmine bromide was attributed to bromide intoxication,[1] but this diagnosis has been challenged.[2]

2. Senecal P-E, Osterloh J. Confusion from pyridostigmine bromide: was there bromide intoxication? *JAMA* 1990; 264: 454–5.

Renal impairment. During use of pyridostigmine for the reversal of neuromuscular blockade produced by competitive neuromuscular blockers, pyridostigmine kinetics were not significantly different after renal transplantation in 5 patients compared with those in 5 patients with normal renal function. However, in 4 anephric patients the elimination half-life was significantly increased and the plasma clearance significantly decreased.[1] It appeared that about 75% of the plasma clearance of pyridostigmine depended on renal function.

Interactions

As for Neostigmine, p. 688.3.

Pharmacokinetics

Pyridostigmine bromide is poorly absorbed from the gastrointestinal tract. It undergoes hydrolysis by cholinesterases and is also metabolised in the liver. Pyridostigmine is excreted mainly in the urine as unchanged drug and metabolites. Pyridostigmine crosses the placenta and is distributed into breast milk (see Breast Feeding, above). Penetration into the CNS is poor.

It has been suggested[1] that data from pharmacokinetic studies of pyridostigmine might have varied because of the analytical methods used or inappropriate storage conditions of plasma samples; it was recommended that samples should be acidified and stored at -75 degrees. Mean terminal elimination half-life was 200 minutes in 11 healthy subjects given 60 mg of pyridostigmine orally; peak plasma concentrations were obtained 1 to 5 hours after dosing. The mean terminal elimination half-life after a 4-mg intravenous infusion in 10 of these subjects was 97 minutes.[1] Oral bioavailability was calculated to vary from 11.5 to 18.9%. In an earlier study food did not appear to affect bioavailability but did delay the time taken to achieve peak plasma concentrations.[2] It appears that 75% of the plasma clearance of pyridostigmine depends on renal function.[3] 3-Hydroxy-*N*-methylpyridinium has been identified as one of the 3 metabolites isolated from the urine of patients taking pyridostigmine.[4]

Antineoplastic drugs are used in the treatment of malignant neoplasms
- as the primary treatment in responsive neoplasms
- when surgery or radiotherapy is not possible or has proved ineffective
- combined in different ways with surgery or radiotherapy such as concurrently, sequentially, neoadjuvant (preoperative), or adjuvant (postoperative)

Therapy with antineoplastics is notably successful in a few malignant conditions and may be used to palliate symptoms and prolong life in others.

Factors that are taken into account when prescribing chemotherapy include the type of cancer and its primary location, the general health of the patient (patient status), and the extent, or stage, of the disease. There are different staging systems; one commonly used system, the TNM staging system, describes the extent of solid cancers by numbers:
- T (tumour) refers to the size of the cancer: from 1 (small) to 4 (large)
- N (node) refers to whether the cancer has spread to the lymph nodes: from 0 (no positive nodes) to 3 (many positive nodes)
- M (metastases) refers to whether the cancer has metastasised: 0 (no metastases) or 1 (metastases)

Haematological cancers are classified differently and depend on the particular malignancy, but the extent of the disease is often described by the number and spread of affected lymph nodes and the symptoms of the patient.

The two main groups of classical cytotoxic drugs used in the treatment of malignant disease are the alkylating agents and the antimetabolites. Nitrogen mustards, ethyleneimine compounds, and alkyl sulfonates are the main **alkylating agents**. Other compounds with an alkylating action are the various nitrosoureas. Dacarbazine and the **platinum-containing complex** cisplatin appear to act similarly.

The **antimetabolites** may be subdivided into folic acid, purine, or pyrimidine antagonists.

Several natural products, or their derivatives, are used for their actions as **mitotic inhibitors**; they include the vinca alkaloids and the taxanes. Other drugs act as **topoisomerase inhibitors**, interfering with the coiling and uncoiling of DNA during replication. Drugs thought to act in this way include the podophyllotoxin derivatives such as etoposide, and camptothecin derivatives such as irinotecan and topotecan.

Some **antibiotics** such as the anthracyclines, bleomycin, and mitomycin C, also interfere with nucleic acids and are effective as antineoplastics.

Further described in this section are **other drugs** that act by various routes to affect the growth and proliferation of malignant cells. Better understanding of the biology of tumour cells has led to the development of new classes of these, including **tyrosine kinase inhibitors** such as imatinib and related drugs. Some neoplasms express receptors to endogenous sex hormones, and various **hormone antagonists**, including, notably, the **aromatase inhibitors** are used in their management. **Photosensitisers** such as porfimer sodium are used in photodynamic therapy.

In recent years considerable interest has focused on immunological approaches to the treatment of malignant disease and many **monoclonal antibodies** have been, or are being, developed. The use of **biological response modifiers** such as interleukins continues to be the subject of investigation and attempts to develop vaccines against individual neoplasms also continue.

Glucocorticoids (see Corticosteroids, p. 1597.3) are used with antineoplastics in the treatment of malignant disease, especially in acute leukaemias and lymphomas. Other agents used in antineoplastic therapy include sex hormones (p. 2231.1) and radiopharmaceuticals (p. 2222.1). Haematopoietic stem cell transplantation (p. 1937.1) is used for haematological malignancies.

Choice of Antineoplastic

The following section describes the treatment of some of the major malignant neoplasms, and in particular the role of combination chemotherapy with antineoplastics.

Table 1 (p. 719) lists published initial doses for some well-known combination chemotherapy regimens. Doses may be modified (particularly in subsequent cycles) to allow for patient status and toxic effects, although in some cases this may be at the expense of efficacy. Regimens can also vary slightly between institutions, or may be modified as part of the ongoing evolution of cancer chemotherapy; such therapy should preferably take place only in expert centres. The same acronym has sometimes been used for regimens containing different drugs, or using the same drugs in different doses or in different ways, and the reader should consult the literature for further details.

Management of malignant disease

Gestational trophoblastic tumours. The gestational trophoblastic diseases arise from the trophoblast, the first tissue to differentiate in the early embryo: they are associated with conception and pregnancy and affect women of reproductive age. They may be divided into premalignant forms such as molar pregnancy (complete or partial hydatidiform mole) and malignant forms (gestational trophoblastic tumours) which include invasive mole (chorioadenoma destruens), choriocarcinoma, and placental site trophoblastic tumour.[1-6] Hydatidiform moles are abnormal conceptions with excessive placental and some or no fetal development. Complete and partial hydatidiform moles have distinctive histological and genetic features, but both overexpress paternal genes.[1,2,7] Gestational trophoblastic neoplasia can develop after any type of pregnancy,[1,2,6] although the incidence is greater after premalignant complete or partial molar pregnancies;[3] the risk of malignancy after a complete or partial hydatidiform mole is about 15% and 0.5%, respectively.[3,5,7]

All these tumours secrete human chorionic gonadotrophin (hCG), and measurement of the urinary or serum concentrations is important in diagnosis of disease and monitoring of treatment.[1,4,5,7]

The trophoblastic tumours vary in aggressiveness but some, such as choriocarcinoma, are highly invasive; however, appropriate **treatment**, based on the perceived risk category, can result in an excellent prognosis. Prognostic factors for increased risk include high titres of hCG, liver or brain metastases, and failure of previous single-agent chemotherapy as well as greater age.[3-5,8] With current treatment, including local irradiation for metastases, virtually 100% of patients with localised disease should be cured, as are over 80% of patients with more advanced stages.

Prophylactic chemotherapy has been used in women considered at particular risk of persistent gestational trophoblastic tumour after evacuation of a complete molar pregnancy, but the practice is controversial, with anecdotal reports of fatalities; most consider the risk to be too high, especially given the low morbidity and mortality achieved with monitoring.[1,4]

In patients with ***low-risk disease***, the treatment of choice is single-agent therapy with methotrexate or dactinomycin.[1-3,5,6,9] The choice of regimen usually depends on geographical location and local experience,[9,10] as comparative data are lacking.[3] Intramuscular methotrexate is often given on alternate days, or weekly, with or without folinic acid rescue.[3-6,9,10] Several intravenous dactinomycin schedules have been used; there is some suggestion that a daily regimen may be more effective than pulsed treatment.[3,5] A systematic review that included 4 randomised studies concluded that pulsed dactinomycin was superior to weekly methotrexate.[10] However, while dactinomycin may provide slightly higher remission rates, toxicity may be greater,[4] and since methotrexate is easier to give some favour methotrexate with folinic acid as first-line treatment.[5] Alternating cycles or sequential use of both drugs have also been tried.[4,9]

Irrespective of which drug is used first-line, a switch to the alternate drug is considered appropriate in cases of resistance.[3,5] If this also fails, then combination chemotherapy is indicated; regimens are similar to those used in high-risk disease.[4]

The combination EMA-CO (etoposide, methotrexate, dactinomycin, cyclophosphamide, and vincristine) is the preferred treatment in ***high-risk*** patients.[2-6,8,11] Methotrexate, dactinomycin, and etoposide is also used.[2,3,5] Triple therapy with methotrexate, dactinomycin, and either cyclophosphamide or chlorambucil was the standard regimen for many years in the USA,[1,4] but was associated with toxicity and poor survival.[2,4] However, comparative data are lacking, and the superiority of any individual combination regimen remains to be established.[1,4,8] In

refractory disease, the salvage regimen EMA-EP uses etoposide and cisplatin in place of cyclophosphamide and vincristine in EMA-CO.[3,5,11,12] Other regimens have used etoposide and cisplatin with either bleomycin (BEP) or ifosfamide (VIP).[3,11,12]

Brain *metastases* are generally treated by local irradiation, given with systemic chemotherapy. Modified EMA-CO, using a higher dose of systemic methotrexate and adding intrathecal methotrexate, is also used.[1,2,4,5,11] Liver metastases have been treated with irradiation, local chemoembolisation, or surgical resection.[2,4,11]

Patients with placental site trophoblastic tumour, which is relatively insensitive to chemotherapy, may be best treated by hysterectomy in the early stages.[2,5] In patients with metastatic or recurrent disease, EMA-EP may be more effective than EMA-CO.[13] For further information on these and other common chemotherapy regimens, see Table I, p. 719.

Histiocytic syndromes. Histiocytic syndromes cover a broad range of proliferative disorders of histiocytes (such as macrophages and dendritic cells).[1] Langerhans-cell histiocytosis is one such disorder characterised by proliferation of CD1a-positive Langerhans cells (a form of dendritic cell).[2] Terms that were formerly used for different clinical manifestations of Langerhans-cell histiocytosis include histiocytosis X, type II histiocytosis, eosinophilic granuloma, Hand-Schüller-Christian syndrome, and Letterer-Siwe disease, but these are considered obsolete.[3] Langerhans-cell histiocytosis mainly presents in childhood, and is of uncertain aetiology: it is not clear whether it should be considered a malignancy.[2,4,5]

The clinical presentation of Langerhans-cell histiocytosis is highly variable and can include bone pain, weight loss, fever, skin rash, dyspnoea or tachypnoea, polydipsia and polyuria, lymphadenopathy, gingival hypertrophy, ataxia, and memory problems.[2,5] Depending on the organs involved, it has been categorised into localised or single-system disease, and disseminated or multisystem disease.[1,4,5] Single-system disease can be further categorised based on the number of sites involved (unifocal or multifocal).[1] Multisystem disease may be further subdivided into low-risk and high-risk groups depending upon which organs are involved; risk organs include the haematopoietic system, lungs, liver, and spleen.[1,5,6] Sequelae to the disease include diabetes insipidus, growth retardation, cognitive dysfunction, and orthopaedic handicap.[1,2,4] The morbidity and prognosis depends upon the number of organ systems involved, and whether normal function of these organs is affected.[1] Patients with **single-system disease** have a generally benign course, and single lesions often regress spontaneously. However, if a bone lesion does not resolve, or risks causing fracture or deformity before it resolves, or is causing disabling symptoms, it may be treated with curettage, intralesional corticosteroids, or radiotherapy.[1,4,5] Systemic chemotherapy may be suitable in some patients with multifocal bone disease; vinblastine with prednisone or prednisolone is a suggested regimen,[2,4,6] and may also be used for high-risk single lesions.[6] Similarly, single skin lesions may be allowed to resolve without treatment or treated with surgery, topical corticosteroids, methoxsalen plus UV light (PUVA), or topical chlormethine.[1,4,5,7]

Treatment for **multisystem disease** is controversial. Some advocate high-dose prednisone or single-agent chemotherapy as first-line options. Combination chemotherapy regimens may give greater response rates with fewer recurrences.[1] Corticosteroids and vinblastine for about 6 to 12 months are the most commonly used drugs; mercaptopurine and methotrexate have also been used with reports of efficacy.[4] A comparative study in children with multisystem disease found treatment with vinblastine or etoposide for 6 months to be equally effective.[8] Subsequent study showed that vinblastine with etoposide was not superior to vinblastine alone (when combined with corticosteroids and mercaptopurine).[2,4,6] Systemic corticosteroids have also been used for recalcitrant skin disease or multisystem disease in children[7] and for pulmonary Langerhans-cell histiocytosis in adults.[9] In patients who have not responded to combination chemotherapy, a number of treatments may be considered including ciclosporin,[4,7] thalidomide,[7] and high-dose chemotherapy with haematopoietic stem cell transplantation.[2,4,5] Cladribine has been used for multisystem disease with varying results;[5,7] an intensive regimen of cladribine and high-dose cytarabine may be effective for recurrent or refractory disease.[2] Anti-CD1 monoclonal antibodies[1,5] may offer improved therapeutic or diagnostic options in the future.

Leukaemias, acute. The acute leukaemias are malignancies affecting haematopoietic precursor cells. They are relatively rare (about 1 to 3 cases per 100 000 of population), and of uncertain cause in the majority of cases, although radiation, carcinogenic substances, or oncogenic retroviruses have been implicated in some types, and certain individuals appear to have a genetic predisposition to these diseases.

After the initiating event or events the progeny of the affected cell do not differentiate normally but proliferate in an uncontrolled fashion. The result is the accumulation in the blood and bone marrow of immature cell types (blasts) at the expense of normal functional blood cells.

The acute leukaemias may be broadly divided into **acute lymphoblastic leukaemia** (ALL), in which the neoplastic proliferation affects lymphoid cell lines, and the **acute myeloid leukaemias** (AML), variously known as acute myelogenous leukaemias or acute non-lymphoblastic leukaemias, which affect myeloid cell lines. These broad groups can be divided in various ways. ALL is subdivided by an immunophenotypic classification that distinguishes disease of B- and T-cell lineage; it was formerly divided morphologically into L1, L2, and L3 subtypes. For AML the French-American-British (FAB) classification has been widely used. This distinguishes, by lineage and estimated degree of differentiation:

- M0, undifferentiated AML
- M1, AML with minimal maturation
- M2, AML with maturation
- M3, acute promyelocytic leukaemia
- M4, acute myelomonocytic leukaemia
- M5, acute monocytic leukaemia
- M6, erythroid leukaemia
- M7, megakaryocytic leukaemia.

However, knowledge of the genotype, via cytogenetic or molecular analysis, is becoming increasingly important in the treatment of leukaemia. Consequently, a revised classification system has been proposed under the auspices of WHO, which uses a combination of morphology, immunophenotype, genetic, biological, and clinical features. In this classification,[1,2] AML is divided into 4 main groups:

- AML with recurrent cytogenic translocations
- AML with myelodysplasia-related features
- AML, therapy-related
- AML not otherwise specified.

The terms *de novo* and secondary AML are widely used but are without standardised definitions. It has been proposed that *de novo* AML should refer to AML in patients with no clinical history of myelodysplastic syndrome, myeloproliferative disorder, or exposure to potentially leukaemogenic agents; secondary AML should refer to patients with AML secondary to these disorders or proven leukaemogenic exposure.[3]

In the WHO classification of lymphoid neoplasms, the Revised European-American Lymphoma (REAL) classification has been adopted, in which acute lymphoblastic leukaemias and lymphoblastic lymphomas are considered to be a single disease with different presentations.[1]

Acute leukaemia usually presents with fatigue, anaemia, infection (due to granulocytopenia), and easy bruisability or bleeding (mainly due to thrombocytopenia). Onset is usually rapid with ALL, although AML may be preceded by myelodysplasia lasting months or years. Bone pain, and enlargement of liver, spleen and lymph nodes (due to infiltration of leukaemic cells may occur. Other organs may also be affected, and various metabolic disturbances, including hyperuricaemia, hyponatraemia, and hypokalaemia may be present.

If untreated the acute leukaemias are normally fatal, usually within months. However, these malignancies are among those in which medical treatment can make a substantial difference to life expectancy, and in some cases a permanent remission may be effected.

3. Cheson BD, *et al.* Revised recommendations of the International Working Group for Diagnosis, Standardization of Response Criteria, Treatment Outcomes, and Reporting Standards for Therapeutic Trials in Acute Myeloid Leukemia. *J Clin Oncol* 2003; 21: 4642–9.

ACUTE LYMPHOBLASTIC LEUKAEMIA. Treatment of acute lymphoblastic leukaemia (ALL) is usually stratified according to risk, with the intensity of therapy tailored to the predicted risk of relapse. Factors associated with a poor prognosis or high risk include age (infant or age greater than 10 years), high white cell count at diagnosis, poor response to induction therapy, and some genetic abnormalities such as the Philadelphia chromosome.[1-5]

Standard chemotherapy treatment regimens for T-cell and precursor B-cell ALL generally consist of 2 to 3 years of therapy divided into several phases:

- **Remission induction**
  Induction regimens are typically based around a regimen that includes vincristine, a corticosteroid (dexamethasone, prednisolone, or prednisone), an anthracycline (doxorubicin or daunorubicin), with or without asparaginase or pegaspargase, and/or cyclophosphamide.
- **Consolidation (intensification)**
  Although the importance of this phase is rarely disputed, consensus is lacking on the best regimens and duration of treatment. Drugs used include high-dose cytarabine, high-dose methotrexate, mercaptopurine, vincristine, and other antineoplastics used in induction regimens; often 4- to 5-drug combinations are used. Re-induction can further improve outcomes.
- **Maintenance (continuation)**
  Maintenance therapy is generally given for some 2 to 3 years after remission. The standard combination of drugs consists of daily mercaptopurine and weekly methotrexate.

In order to clear leukaemic cells from harbour sites, **CNS-directed therapy** is given throughout the course of ALL treatment, and may include:

- intrathecal chemotherapy (methotrexate either alone or as part of triple therapy with cytarabine and corticosteroids)
- systemic chemotherapy (high-dose methotrexate)
- cranial irradiation (usually reserved for high-risk adult patients)

Targeted drug therapy may be used in patients with specific genetic abnormalities in addition to chemotherapy regimens and CNS prophylaxis. In patients with Philadelphia chromosome-positive ALL, the addition of a tyrosine kinase inhibitor, such as imatinib or dasatinib, to standard chemotherapy regimens has greatly enhanced remission-induction rates and duration of disease-free survival. In Philadelphia chromosome-negative disease that is CD20-positive, the monoclonal antibody rituximab can be included in the treatment regimen.

In **relapsed/refractory** Philadelphia chromosome-negative ALL, second-line therapy with an induction regimen not previously used, or salvage regimens containing clofarabine or cytarabine, alkylator combinations, or liposomal vincristine may be considered; nelarabine may be used in T-cell ALL. In Philadelphia chromosome-positive disease, targeted therapy with dasatinib, nilotinib, or ponatinib can be considered, with or without chemotherapy or a corticosteroid.

Allogeneic **haematopoietic stem cell transplantation** may be a treatment option in adults who are in remission after initial induction therapy, or for relapsed or refractory disease.

Treatments that are **under investigation** include novel monoclonal antibodies, the proteasome inhibitor bortezomib, and inhibitors of the mammalian target of rapamycin, such as sirolimus and temsirolimus.

ACUTE MYELOID LEUKAEMIAS. Treatment of acute myeloid leukaemias (AML) is problematic because normal stem-cell precursors are sensitive to the drugs used, and therapy aimed at myeloid leukaemic clones results in destruction of part of the normal stem-cell pool. Wherever possible, treatment of AML should be in the context of clinical studies.[1-3] Treatment consists of induction and consolidation chemotherapy. Candidates for haematopoietic stem cell transplantation should be identified as early as possible.[3]

Induction of remission is usually possible with intensive chemotherapy. Complete remission has been stated to be achievable in up to 80% of younger patients and about 50% of older patients (who form the majority of those with AML), but patients suffer severe neutropenia during induction and remission rate is to some extent dependent upon the standard of supportive care. Remission rates are lower in those with adverse prognostic factors such as poor performance status, AML secondary to myelodysplasia or antineoplastics, high white cell count, features of multidrug resistance, and unfavourable cytogenetics.[4,5] Established regimens are based on cytarabine with an anthracycline, usually daunorubicin.[1-4,6-9] Although idarubicin may be preferred to daunorubicin,[10] especially in younger adult patients,[8] in children it is no more effective but may be associated with more toxicity.[11,12] Mitoxantrone is another alternative to daunorubicin,[8,10] and there is little evidence[1,4,10,12] that one anthracycline is better than another for induction protocols. Addition of etoposide or tioguanine to induction protocols of cytarabine and daunorubicin appears to be equally effective in younger adults and children,[13,14] but in older patients an induction regimen which added tioguanine was found to be more effective than one with etoposide.[15]

As in acute lymphoblastic leukaemia (see p. 692.3) there is a trend towards the use of more intensive induction regimens.[6,14] Use of high-dose cytarabine compared with standard doses potentially improves survival in younger patients with favourable cytogenetics, but in the elderly neurotoxicity outweighs any benefit;[10] a combination of cytarabine with fludarabine may be an alternative in these patients.[5] Some guidelines include low-intensity (with subcutaneous cytarabine, azacitidine, or decitabine) or intermediate-intensity induction therapy (with clofarabine) as treatment options for patients older than 60 years.[8] The use of haematopoietic growth factors is controversial; some allow for their use as an optional adjunct to intensive chemotherapy,[3,8] while others recommend against their routine use in AML.[1]

Once remission is induced, consolidation or **postremission therapy** is essential in preventing relapse.[1,6,10] Options include further chemotherapy, or allogeneic or autologous bone marrow transplantation (see Haematopoietic Stem Cell Transplantation, p. 1937.1).[1,3,7-9] There is no consensus on the best postremission therapy.[3,7,8] Some advocate the use of high-dose cytarabine in those with favourable or intermediate risk; others are candidates for allogeneic stem cell transplantation.[3,7,8] Non-myeloablative chemotherapy with allogeneic transplantation may be an alternative in older patients.[3,5,7-9,16]

Patients who relapse or who fail to achieve complete remission will require **salvage** therapy. Standard salvage regimens can include high-dose cytarabine or fludarabine plus cytarabine.[7,8] Allogeneic stem cell transplantation can also be used for salvage therapy or for those in second or subsequent remission.[3,7,8] Decitabine may be an alternative for elderly patients who are not candidates for standard remission induction chemotherapy.[17] Investigational therapy is also an option.[7,8] Gemtuzumab ozogamicin has been used in elderly patients,[1,9] but is now withdrawn from the US market. Low-dose **maintenance** chemotherapy (with cytarabine and tioguanine) may improve disease-free survival but not overall survival,[8] and prolonged maintenance therapy is generally considered unnecessary in patients with AML.[1,6,12,14] Where debility or other medical conditions make standard or investigational therapy impossible in the elderly, **palliative** treatment with oral hydroxycarbamide is often given; low-dose cytarabine may also be of benefit.[1,2,7-9] Good results have been reported with a combination of idarubicin and etoposide in elderly patients.[5]

Other experimental therapies under investigation for AML include clofarabine, azacitidine, and imatinib.[2,7-9,12,14] The ciclosporin analogue valspodar, an inhibitor of multidrug resistance, has been investigated, but was associated with excessive early mortality.[18]

Acute promyelocytic leukaemia (APL) is a subtype of AML accounting for 10% of AML cases in adults.[19] It is important to distinguish APL from other forms since appropriate treatment is curative in most patients.[10] Most patients with APL can achieve complete remission after treatment with tretinoin alone, but remission durations are short and most patients relapse.[20] *Induction* therapy with tretinoin and chemotherapy (an anthracycline and cytarabine) improved event-free survival compared with chemotherapy alone.[19,21] It was also shown that cytarabine could be omitted for most patients,[20,22] and standard induction for low- and intermediate risk disease consists of concomitant tretinoin and an anthracycline.[8,10,23] There are few data to suggest that one anthracycline is vastly superior to another.[20,23] The addition of cytarabine can still be considered for high-risk patients.[8]

Consolidation therapy is given after complete remission,[8,20,21] and is usually anthracycline-based. Again, although most studies have included cytarabine, its role has been questioned,[19,20,22] and standard consolidation consists of concomitant tretinoin and an anthracycline.[8] As with induction, cytarabine may be added for high-risk disease.[8,23] Arsenic trioxide has been successfully combined with tretinoin for induction and consolidation,[8,10] and this combination is an alternative for those who cannot tolerate anthracyclines.[8,23] Arsenic trioxide has also been used alone as first-line therapy, but such use tends to be restricted to patients for whom chemotherapy is contra-indicated.[21]

For those in molecular remission after consolidation therapy, *maintenance* therapy with up to 2 years of tretinoin, with or without continuous low-dose chemotherapy (mercaptopurine plus methotrexate), is recommended.[8,21,22] Maintenance therapy is particularly beneficial for those at high risk of recurrence, such as those with a high leucocyte count and older adults.[20,22] Arsenic trioxide is recommended for those who remain molecularly positive at the end of consolidation.[8,21] It is also the treatment of choice for patients who relapse,[8,19-23] particularly those treated with tretinoin within the previous year. Patients who then achieve a second remission may be considered for autologous or allogeneic haematopoietic stem cell transplantation.[8,19,20,22,24] Gemtuzumab ozogamicin may also be an option for relapsed patients, although its precise role has not been determined,[21,24] and it should be used with caution in potential transplant candidates.[8] The synthetic retinoid, tamibarotene (AM-80), has been used to induce remission in patients who relapsed after successful remission induction with tretinoin.[25]

The efficacy of tretinoin appears to be achievable only because the characteristic chromosomal abnormalities in APL result in an abnormal retinoic acid receptor. The development of drugs that can effect differentiation in other forms of AML, and indeed in other neoplasms, seems likely to be a long and difficult task.

Leukaemias, chronic. The chronic leukaemias may be broadly divided into those in which the neoplastic proliferation affects lymphoid cell lines, and those affecting the myeloid cell lines.

Chronic leukaemias affecting the *lymphoid cell lines* include chronic lymphocytic leukaemia (CLL), which is B-cell in about 95% of cases and T-cell in about 5%, and hairy-cell leukaemia, which affects B-cells. The revised European-American lymphoma classification,[1] and a proposed WHO classification of haematologic malignancies,[2] consider lymphoid leukaemias and lymphomas of the same cell type to be one disease with different clinical presentations. Thus B-cell CLL is the same disease as B-cell small lymphocytic lymphoma.

Chronic neoplasms affecting the *myeloid cell lines* include the myeloproliferative disorders chronic myeloid leukaemia (CML), polycythaemia vera, and primary (essential) thrombocythaemia, and the myelodysplastic syndromes. All of these may undergo transformation to acute myeloid leukaemia.

CHRONIC LYMPHOCYTIC LEUKAEMIA. Chronic lymphocytic leukaemia (CLL) typically occurs in people over 60 years of age, and accounts for about 30% of leukaemias in the West although it is rarer in the Far East. CLL and small lymphocytic lymphoma (SLL) have been described as the same disease manifesting in different ways.[1] Stages of CLL are defined according to the American Rai system or the European Binet system, with both having prognostic value.[1-8] The clinical course is variable: low-risk patients (Rai stage 0; Binet stage A) have a median survival of about 10 years, while high-risk patients (Rai stage III/IV; Binet stage C) have a median survival of about 1.5 years; median survival in the intermediate stages is about 6 years.[2,3,9] The mutational status of the immunoglobulin IGHV gene also affects prognosis; attempts to use surrogate markers of this status included CD38 and ZAP-70, and these have assisted in further risk stratification.[7,10-13]

In patients at low risk and those at intermediate risk with indolent disease cytotoxic chemotherapy is usually deferred until signs and symptoms of disease progression occur.[2,3,5-10,13] In these patient groups, studies of immediate versus deferred chemotherapy for early-stage CLL have shown no significant advantage, or disadvantage, for immediate chemotherapy in terms of 10-year survival.[14] Patients with high-risk or progressive disease are usually treated with immediate chemotherapy.

When **treatment** is required, several options exist. For many years, chlorambucil, given either continuously or intermittently, and with or without prednisone, was the mainstay of chemotherapy for CLL, with response rates ranging from about 40 to 70%.[10,12,15] Alkylator-based combination regimens such as COP or CVP (cyclophosphamide, vincristine, and prednisone or prednisolone), CAP (cyclophosphamide, doxorubicin, and prednisone or prednisolone), or CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone or prednisolone) were found to have no advantage over chlorambucil alone.[4,6,15]

Subsequent study with fludarabine found response rates to be higher than with alkylator-based therapy, although no overall survival advantage was shown.[6-8,10-12,15] Fludarabine has been studied in combination with other agents. Use with chlorambucil showed excessive toxicity.[1,7,15] Fludarabine plus cyclophosphamide was found to have higher remission rates and longer progression-free survival than either chlorambucil or fludarabine monotherapy,[8,11,13,15] and as such this combination is often recommended as the initial treatment of choice,[10] especially in fitter patients. Chlorambucil or fludarabine monotherapy are still considered appropriate first-line options[1,9,12,13] in those with comorbidities or poorer performance status, and CVP

or CHOP regimens are still alternatives for those unable to tolerate fludarabine-based therapy.[1]

Bendamustine, an alkylating agent, produced better response rates and progression-free survival compared with chlorambucil, and is approved in some countries as initial monotherapy; efficacy compared with other first-line therapies has not been established.[1] Other purine analogues have been investigated for CLL. Cladribine, with or without corticosteroids, achieved comparable results to those with fludarabine monotherapy.[11] Cladribine plus cyclophosphamide was found to have similar results to cladribine alone.[11] However, some do not recommend cladribine as a routine alternative to fludarabine for initial therapy.[6]

The monoclonal antibodies alemtuzumab and rituximab have been studied with other drugs for the treatment of CLL.[5,6,10,11,16] The use of rituximab with fludarabine (FR regimen) especially has shown marked clinical efficacy,[7,10,12,15] and the FCR regimen (fludarabine, cyclophosphamide, and rituximab) has shown high overall response rates;[1,11,17] some consider FCR to be a suitable first-line option.[1,9,12,13] However, others have stated that the use of rituximab with fludarabine (with or without cyclophosphamide) requires further evaluation.[6] The use of the purine analogue pentostatin with cyclophosphamide and rituximab (PCR regimen) has also been shown to have high response rates and is also an option for initial therapy for CLL.[1,8,9,12,13] Although some consider rituximab monotherapy to be suitable initial therapy for older patients or for those with comorbidities,[1,12] others do not recommend it for untreated CLL.[6] Similarly, alemtuzumab may be used as first-line therapy in patients with certain cytogenetic abnormalities associated with a poor prognosis,[1,7,10] or as consolidation therapy after fludarabine-based induction therapy.[10,11,17] However, some do not recommend alemtuzumab for untreated CLL[6] and others advise against its use in the consolidative setting given the risks of infectious complications and possible CMV reactivation.[15]

There is no definitive evidence that consolidation or maintenance therapy is better than treatment at the time of relapse, although investigation is ongoing and participation in clinical studies is encouraged.[8] Treatment of relapses depends upon response to initial therapy.[6,7,11] After long remissions, patients will usually respond again to induction treatment.[7,9] Alternative agents, or combination chemotherapy with or without monoclonal antibodies may then be tried.[1,7,9,11] Monoclonal antibody monotherapy is an option,[1,9] especially in patients refractory to chemotherapy; alemtuzumab, ofatumumab, or dose-dense rituximab may be used. Alemtuzumab with rituximab is also an option.[1] For further information on common chemotherapy regimens, see Table 1, p. 719.

Haematopoietic stem cell transplantation (HSCT) has been investigated for CLL.[7] Autologous HSCT is unlikely to provide a cure[11,13,15] and relapse is inevitable.[10] The principles of allogeneic HSCT, which is potentially curative,[6,13] include the graft-versus-leukaemia effect and the absence of stem cell contamination.[11] However, transplant-related mortality has been high. Non-myeloablative conditioning protocols are under investigation.[6,7,10,11,15] Allogeneic HSCT is suggested for younger patients with non-response or early relapse after purine analogues, or those who relapse within 2 years of an initial response with purine-analogue based therapy or autologous HSCT, or in patients with certain cytogenetic abnormalities with a poor prognosis.[10]

Other drugs that have been investigated for CLL include bortezomib,[10] denileukin diftitox,[10] lenalidomide,[7,10,18] lumiliximab,[7,10] oblimersen sodium,[10] and thalidomide.[18]

CHRONIC MYELOID LEUKAEMIA. Chronic myeloid (myelogenous) or chronic granulocytic leukaemia (CML) is a rare disease, occurring usually in older patients, and representing about 15% of all adult leukaemias. It is associated in over 90% of cases with the presence in blood cells of an abnormal chromosome, the Philadelphia chromosome (Ph), which results from a reciprocal translocation between the long arms of chromosomes 9 and 22, with the fusion of the BCR gene and the ABL gene. The product of this gene, the protein BCR-ABL, is leukaemogenic. Ph-negative disease (atypical CML) carries a worse prognosis, and some classification systems consider it to be a separate disease.

CML occurs in 3 different phases. It is usually diagnosed in the chronic phase, which may last for several years, which when untreated, progresses to an advanced phase; this consists of an often rapidly fatal blastic phase (blast crisis), which is often preceded by a transition period, the accelerated phase.

The development of imatinib, an inhibitor of the BCR-ABL protein tyrosine kinase, constituted a revolutionary change in the management of CML.[1-7] The International Randomized Study of Interferon and STI571 (IRIS), found imatinib to be better than interferon alfa with low-dose cytarabine for newly diagnosed CML in **chronic phase.**[8,9] Follow-up study found responses to be durable in a high proportion of patients,[10] and a tyrosine kinase inhibitor such as imatinib has become established as standard initial therapy for chronic phase CML.[1,5,11] Since relapse is common after stopping imatinib, therapy should be continued indefinitely in responsive patients.[1,5,7] Resistance may also be a problem.[2-6,12-15] For patients who do not respond to first-line therapy or who relapse, the preferred second-line treatment is an alternative tyrosine kinase inhibitor such as dasatinib, nilotinib, bosutinib, or ponatinib. Omacetaxine mepesuccinate, allogeneic haematopoietic stem cell transplantation (HSCT), or investigational therapies (see below) are further options in patients who are resistant to or have failed treatment with tyrosine kinase inhibitors. These therapies or an alfa interferon such as peginterferon alfa may also be tried in patients who are unable to tolerate tyrosine kinase inhibitors.For patients who only partially respond or who relapse after first-line imatinib and who are not able to take an alternative tyrosine kinase inhibitor or omacetaxine mepesuccinate, high-dose imatinib may be considered.[1]

Early allogeneic HSCT (p. 1937.1) has the potential to cure CML due to a graft-versus-leukaemia effect, but it is still associated with appreciable morbidity and mortality, including graft-versus-host disease,[6] and results with imatinib have challenged the role of HSCT as first-line therapy for chronic phase CML.[1,11] While HSCT is still an option in suitable patients such as younger patients with HLA-identical sibling donors,[4,7] or those with high-risk disease and low transplantation risk,[2] most recommend an initial period of therapy with imatinib since the response can either reinforce or weaken the indication for HSCT.[5-7,16] Ongoing advances in alternative donor sources (such as the use of HLA-matched unrelated donors and cord blood), improved HLA typing techniques, and less toxic non-myeloablative regimens are broadening the use of HSCT.[1,4] Options in patients who relapse after HSCT include the use of donor lymphocyte infusions, tyrosine kinase inhibitors, or interferon alfa.[1,2,7]

Tyrosine kinase inhibitors induce favourable response rates in those with **advanced phase** CML. In those whose disease has progressed after initial tyrosine kinase inhibitor therapy, an alternative tyrosine kinase inhibitor is used, and then allogeneic HSCT can be considered. Post-transplant tyrosine kinase treatment is continued for at least 1 year. Omacetaxine mepesuccinate is an option for patients whose disease has progressed to advanced phase due to resistance and/or intolerance to 2 or more tyrosine kinase inhibitors. For those whose disease has progressed to blast-phase, treatment includes a tyrosine kinase inhibitor, either alone or with chemotherapy, followed by allogeneic HSCT.[1]

Novel therapies for CML include farnesyl transferase inhibitors such as lonafarnib and tipifarnib, hypomethylating agents such as azacitidine and decitabine, histone deacetylase inhibitors, and vaccines.[4,15,17] Combinations of imatinib with other drugs are also under investigation.[2]

HAIRY-CELL LEUKAEMIA. Hairy-cell leukaemia is a rare, chronic, B-cell lymphoproliferative disorder marked by the presence of white blood cells with prominent cytoplasmic villi, pancytopenia, and splenomegaly. Many patients are asymptomatic and there is no clear advantage to early treatment before symptoms appear.[1,2] Splenectomy was formerly used as initial therapy, but response duration tended to be short. Interferon alfa-2a or -2b given for one year produced at least a partial response in most cases but patients had a tendency to relapse once therapy was stopped.[1,3,4]

Better results were obtained with the purine analogues cladribine and pentostatin, and these are now considered first-line treatments for this disease.[1,3-8] Durable complete remission rates of 50% or more are seen after relatively short courses of therapy.[3,4,7-10] Toxicity is generally acceptable.[3] These drugs do not appear to show cross-resistance; cladribine has been used successfully in patients resistant to, or intolerant of, pentostatin,[1,3] and others[6] have used pentostatin in patients who do not respond to cladribine. Despite long disease-free survival rates associated with purine analogue therapy, they are not curative, and relapses occur in many patients, which suggests the presence of residual disease.[7,10] For patients who relapse, retreatment with initial therapy is advocated.[1,7] Interferon alfa is an option in those patients relapsing after, or refractory to, treatment with a purine analogue.[1,4] There are reports of remission after use of rituximab in patients with relapsed or refractory disease,[1,3,4,7,8,10,11] or for residual disease,[10] and it has been suggested for use in those who fail cladribine and pentostatin.[6,7] Other immunotherapy under investigation for hairy-cell leukaemia includes alemtuzumab, and the recombinant immunotoxins LMB-2 and BL22.[4,7,8,10]

MYELODYSPLASTIC SYNDROMES. Myelodysplastic syndromes are low-grade neoplasms of haematopoietic stem cells characterised by ineffective haematopoiesis that results in anaemia, neutropenia, or thrombocytopenia in various combinations. They have been described as smouldering leukaemia or preleukaemia, and transformation to acute myeloid leukaemia (AML) occurs in some patients.

The clinical course of myelodysplastic syndromes is variable, and a precise individual determination of prognostic score is important in planning **treatment.**[1,2] In the few younger patients with suitable HLA-matched

donors, allogeneic haematopoietic stem cell transplantation (HSCT) has curative potential.[1,3-8] As most patients are older, with medical conditions precluding the use of standard conditioning regimens, novel transplant conditioning regimens of reduced intensity are being investigated.[5,7-9] Autologous HSCT may be an option for those without a suitable donor.[7]

Patients who are likely to have an ***indolent*** course are best treated conservatively with observation and supportive care (transfusions, antibacterials, or epoetins plus colony-stimulating factors).[1-4,7-9] Iron chelation therapy may be needed in patients who develop iron overload (p. 1545.2) from blood transfusions.[2,7,9] Azacitidine, decitabine, or lenalidomide may be considered where a low serum-erythropoietin concentration does not respond to epoetins (with or without colony-stimulating factors). Lenalidomide is effective for patients with chromosome 5q deletions,[6,8,10-13] and is recommended as first-line therapy in these patients.[2,9] Patients with serum-erythropoietin above 500 milliunits/mL and a good probability of response to immunosuppressive therapy should be given antilymphocyte immunoglobulins with or without ciclosporin, or possibly ciclosporin alone.[2,9] Those likely to have a poor response to immunosuppressants should be given treatment with azacitidine, decitabine, lenalidomide, investigational agents, or considered for allogeneic HSCT.[2] Azacitidine or decitabine are also treatment options for patients with serious cytopenias; if not responsive, immunosuppressive therapy, investigational agents, or allogeneic HSCT can be tried.[2]

The treatment of ***progressive*** or advanced myelodysplastic syndromes or those that have transformed to AML may involve intensive chemotherapy similar to that for AML (see p. 693.1), but remission rates are lower,[1,3,4] and relapse common.[9] However, many patients are elderly with poor performance status, and are unable to tolerate intensive chemotherapy. They may be treated with supportive care and haematopoietic growth factors alone.[9] Low-intensity chemotherapy such as azacitidine or decitabine may be tried in such patients,[2] but has had limited success.[1,3] Other antineoplastics and immunomodulating agents investigated for use in myelodysplastic syndromes include histone deacetylase inhibitors such as valproic acid and vorinostat, farnesyl transferase inhibitors, amifostine, arsenic trioxide, thalidomide, and topotecan.[1,3-5,7,9,14,15] Attempts to induce cellular differentiation have generally been disappointing.[3]

MYELOFIBROSIS. Myelofibrosis is a chronic Philadelphia-negative myeloproliferative disorder, associated with a mutation in the Janus kinase 2 (JAK2) gene in over 50% of patients. Bone marrow is replaced by collagen fibrosis. The disease may present as idiopathic or primary, or as transformation of an antecedent polycythaemia vera (below) or essential thrombocythaemia (below). Median survival after diagnosis is about 5 years, although this may be longer in younger patients with good prognostic features. Older age, anaemia, leucocytosis, peripheral blasts, and the presence of constitutional symptoms are the major risk factors. Symptoms include fatigue, night sweats, pruritus, bone pain, weight loss, and fever; patients typically develop cytopenia and splenomegaly.[1-4]

Allogeneic stem cell transplantation is the only potentially curative **treatment** approach. However, many patients are ineligible.[1,2,5] Hydroxycarbamide is used to treat splenomegaly; splenectomy may be performed for painful splenomegaly in those with good performance status.[5] Anti-angiogenic therapy with thalidomide or lenalidomide, usually given with corticosteroids, has shown response rates of between 20 and 30%.[1,4,5] Pomalidomide is under investigation.[2,4] JAK2-inhibitors such as ruxolitinib are under development.[1-3]

POLYCYTHAEMIA VERA. Polycythaemia vera (polycythaemia rubra vera) is a Philadelphia-negative chronic myeloproliferative disorder,[1] associated in about 95% of patients with a mutation in the Janus kinase 2 (JAK2) gene.[1-3] It is characterised by an increased red cell mass and packed cell volume, and is often associated with increases in white cell and platelet counts and splenomegaly.[1,4] It is a disease of later life, with a median age at presentation of about 60 years.[4] The symptoms are related to hyperviscosity due to the increased number of cells in the blood; patients often present with either arterial or venous thrombosis (cerebrovascular accident, myocardial infarction, pulmonary embolism) or occasionally, with haemorrhage, particularly involving the skin and gastrointestinal tract.[1,4]

Untreated, the disease is associated with a high risk of morbidity and mortality, and patients can undergo myelofibrotic transformation into blast crisis and acute myeloid leukaemia.[1,4] The aims of **treatment** are therefore to reduce the risk of thrombosis and haemorrhage, minimise transformation risk, and manage complications, or pregnancy.[4]

The mainstay of treatment is periodic phlebotomy to maintain the haematocrit within normal values,[5,6] along with aspirin in low doses (40 to 100 mg daily)[1,7] sufficient to reduce thrombosis without increasing the risk of major bleeding.[8] This may be all that is required in younger patients at low risk of thrombosis. In patients at high risk of thrombosis, including those who have a high phlebotomy requirement, some form of myelosuppressive therapy may also be considered. Chlorambucil, which was formerly used for this purpose, has largely been stopped because of a high incidence of leukaemia in patients so treated.[4-6] In patients with a life expectancy of less than 10 years, radioactive phosphorus-32 is probably appropriate, and produces good results with few immediate adverse effects.[5] However, like the alkylating agents it is associated with an increased risk of secondary malignancies.[6] In younger patients hydroxycarbamide,[1,4,6] busulfan,[5,6] or in some countries pipobroman,[5] have been preferred because they were considered to have lower risk of inducing leukaemia. However, there is some evidence[9] that they too may have leukaemogenic potential, especially when used in combination,[7,10] and some recommend that busulfan and pipobroman be reserved for elderly patients.[1,4] Non-cytotoxic therapies that have been shown to be effective include interferon alfa.[1,4-7,9] This may be preferred in younger patients requiring treatment.[4,5] Anagrelide, another antiplatelet drug, has also been tried in polycythaemia vera. It is effective in controlling the platelet count, but does not control progression of polycythaemia vera, and its adverse effects may make it difficult for some patients to tolerate.[4]

PRIMARY THROMBOCYTHAEMIA. Primary thrombocythaemia (essential thrombocythaemia) is a rare Philadelphia-negative myeloproliferative disorder in which abnormal platelet production results in elevated platelet counts.[1] The Janus kinase 2 (JAK2) genetic mutation occurs in about 50 to 60% of patients.[2] The disorder occurs mainly during later life[3] and unlike other myeloproliferative disorders, is associated with generally near-normal life expectancy.[3,4] However, microvascular occlusion marked by conditions such as erythromelalgia (burning pain and erythema of the hands and feet), paraesthesia, or migraine, and arterial or venous thrombosis (e.g. cerebrovascular accident, myocardial infarction, pulmonary embolism) may occur. The risk for thrombosis is highest in patients with a history of thrombosis and in those aged over 60 years. In less than 10% of patients the disease eventually enters a spent phase marked by fibrosis and marrow hypoplasia, or transforms to acute leukaemia.

Asymptomatic patients and those at low risk of thrombosis are generally not treated,[5] but when to begin **treatment** is controversial.[6] Some consider that primary antithrombotic prophylaxis seems rational even in asymptomatic patients if there are no contra-indications to this therapy. Low-dose aspirin (40 to 100 mg daily) is considered to be effective, without increasing the risk of major bleeding. Acute microvascular symptoms may be managed with higher doses of aspirin (100 to 300 mg daily).[1] In patients at risk of thrombosis, drugs that lower platelet counts are used, including cytotoxics.[1,4,7] Phosphorus-32 and alkylating agents such as busulfan or pipobroman are little used now because of their known potential to induce leukaemia.[1,3,7] Hydroxycarbamide can reduce thrombotic events,[3,7,8] and has tended to be preferred because it was thought to have lower risk of inducing leukaemia, but it too appears to have leukaemogenic potential.[3,4,6-9] The increased risk of leukaemia from therapy is particularly relevant in younger patients, for whom non-cytotoxic drugs may be preferred. Some non-cytotoxic therapies have also been shown to reduce platelet counts. Anagrelide[3,4] is often substituted for hydroxycarbamide,[1,5-8] but its value has been questioned by a comparison[10] of 2 regimens using aspirin with either anagrelide or hydroxycarbamide. Although the reductions in platelet count were similar for both groups, patients taking anagrelide were found to be at greater risk of arterial thrombosis, serious haemorrhage, and transformation to myelofibrosis (but the rate of venous thromboembolism was lower). Interferon alfa can also effectively reduce platelet counts;[4-7] it is a good alternative for younger patients who face lifelong treatment,[1] and is the treatment of choice in pregnant women.[1,3,5,6,8] Haematopoietic stem cell transplantation may be considered in younger patients who have advanced, complicated disease.[6]

Lymphomas. The malignant lymphomas are neoplastic disorders of the lymphoreticular cells. These cells are primarily located in the lymph nodes, but because of their wide distribution in the body lymphomas may arise in extranodal and extralymphatic tissues such as lung, gastrointestinal tract, and skin.

The term covers a heterogeneous group of diseases, comprising two main subgroups: Hodgkin's disease, and the non-Hodgkin's lymphomas (NHL). The cellular origin of Hodgkin's disease is uncertain; the NHL are monoclonal malignancies arising from B cells in about 80% of cases, with the remainder from cells of T lineage and from undifferentiated cells.

Management of patients with malignant lymphoma is largely determined by interpretation of histological features, and, especially for NHL, by an allocation of subtype and grade. Various classification systems have been proposed for NHL of which the National Cancer Institute Working Formulation has been widely used.[1] Under the Working Formulation, NHL are divided into:

- *low grade*, including small lymphocytic, follicular small cleaved cell, and follicular mixed small cleaved and large cell lymphoma
- *intermediate grade*, including follicular large cell, diffuse large cell, diffuse small cleaved cell, and diffuse mixed types

- *high grade*, including large cell immunoblastic, lymphoblastic, and small non-cleaved cell (including Burkitt's) lymphomas

The International Lymphoma Study Group has proposed a revised European-American lymphoma (REAL) classification,[2] and this has subsequently also been published under the auspices of WHO.[3] It is based on a division into B-cell, T-cell and natural killer cell, and Hodgkin's neoplasms. In this classification, B-cell lymphomas include B-cell small lymphocytic lymphoma, MALT lymphoma, follicular lymphoma (35% of adult NHL, rare in children), diffuse large B-cell lymphoma (30% of adult NHL, 5% of NHL in children), and Burkitt's lymphoma (rare in adults; 30% of NHL in children) and Waldenström's macroglobulinaemia (lymphoplasmacytic lymphoma). Plasma-cell myeloma (multiple myeloma) is also a B-cell neoplasm. T-cell lymphomas include precursor T-cell lymphoblastic lymphoma (rare in adults; 45% of NHL in children) and mycosis fungoides; and Hodgkin's lymphoma is subdivided into nodular lymphocyte-predominant and classical (nodular sclerosis and mixed cellularity) forms.

HODGKIN'S DISEASE. Hodgkin's disease (Hodgkin's lymphoma) is characterised histologically in most cases by the presence of a particular type of giant cell, the Reed-Sternberg cell. It is more common in males than in females, and in the West is seen particularly in young adults and in the elderly, although the age distribution differs elsewhere.

It usually presents as painless enlargement of one or more lymph nodes, particularly in the neck or axillae. About a third of all patients also have constitutional symptoms of fever, weight loss, and night sweats, which indicate poorer prognosis. In advanced disease, signs of organ infiltration may occur, as may infectious complications. The mass of the tumour may result in compression of vital organs.

Hodgkin's disease can be treated by radiotherapy or chemotherapy or both, and the choice of treatment depends on the volume and histological subtype of the tumour, the age of the patient, and, particularly, the stage of the disease.[1] The Ann Arbor classification (with Cotswold modifications) recognises 4 stages:

- Stage I, with involvement of a single lymph node region or extralymphatic site
- Stage II, in which spread is restricted to lymph nodes and sites on one side of the diaphragm only
- Stage III, involving spread on both sides of the diaphragm with possible splenic and extralymphatic involvement
- Stage IV, where the patient has diffuse or disseminated disease in one or more extralymphatic organs or tissues.

Stages are subclassified A or B according to the absence or presence respectively of the aforementioned constitutional symptoms.[1-3] X indicates bulky disease and E the involvement of single extranodal sites.[2,3] Survival rates after treatment for Hodgkin's disease are generally excellent, and there is increasing emphasis on tailoring therapy to decrease early and late treatment-related morbidity while not compromising survival.[1] For prognostic and therapeutic considerations, patients are grouped into early-stage favourable (limited) disease (IA or IIA, no bulky disease); early-stage unfavourable (intermediate) disease (IB or IIB, bulky disease); and advanced disease (stages III and IV).

In the treatment of stages I, II, and IIIA disease, **radiotherapy** alone was standard therapy for adult patients with limited disease, especially in those with good prognosis. However, there have been concerns about relapse rates and an increased risk of secondary malignancy after radiotherapy. Adding chemotherapy to radiotherapy was found to reduce recurrence rates, although this does not translate to an increase in overall survival.[4] Nonetheless, **combined modality** treatment is now the preferred treatment for favourable early stage disease.[1-3,5-10] Although the optimal chemotherapy regimen and radiation dose have yet to be determined, the ABVD or Stanford V regimens (see below) are commonly used.[1,7] Chemotherapy with ABVD alone is also used[1,8,11] and radiotherapy alone is still an option for highly selected patients unable to tolerate chemotherapy due to comorbidities.[1] Combined modality treatment is also generally accepted as the treatment of choice in those with unfavourable early stage disease, again using the ABVD[1,2,5-10] or Stanford V regimens.[1]

Chemotherapy alone is generally considered to be the treatment of choice in advanced disease although radiotherapy may be added for consolidation with some regimens.[1,7] Meta-analyses or systematic reviews of combined modality therapy in advanced disease have found no survival benefit from additional radiotherapy, although it may have a role in initial bulky or residual disease.[4,7,12]

There are several 4-drug standard **regimens** available and the choice lies between one of these, alternating cycles of 2 different regimens, or a hybrid cycle that involves giving 7 or 8 drugs in the same course of treatment. However, the single most important factor governing the outcome of chemotherapy is thought to be dose intensity of the drugs given.

The earliest of the successful 4-drug regimens was MOPP combination chemotherapy (chlormethine, vincristine, procarbazine, and prednisone or prednisolone). There are several MOPP-variant regimens that may be as effective and less toxic; these include substitution of chlorambucil or cyclophosphamide for chlormethine (LOPP or COPP, respectively), vinblastine for vincristine (MVPP), and both chlorambucil and vinblastine substituted in one regimen (ChlVPP). However, an alternative to the MOPP-based regimens, a non-cross resistant combination of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) was found to be as effective as MOPP with a reduced risk of inducing sterility or secondary leukaemia. Better results were later reported with ABVD alone, or with MOPP/ABVD, than with MOPP alone, and ABVD has become the basis of standard treatment for advanced stage Hodgkin's disease.[1,3,7-11,13,14] The Stanford V regimen (doxorubicin, vinblastine, chlormethine, vincristine, bleomycin, etoposide and prednisone, with consolidative radiotherapy) is also used as primary treatment for advanced disease.[1]

Attempts to improve the results of ABVD or MOPP have centred on dose intensified hybrid regimens. The German Hodgkin's Lymphoma study group found improved results with a hybrid regimen of bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) compared with COPP/ABVD; overall survival was highest with an increased dose of BEACOPP, although toxicity was increased.[15] Escalated-dose BEACOPP may be considered for patients with high-risk disease.[1,7,11]

Salvage treatment options for patients who relapse depend on the initial treatment and the interval between treatment and relapse. Patients who are candidates for salvage therapy can be divided into 4 groups:

- those initially treated with radiotherapy who have a recurrence, in whom standard chemotherapy regimens are effective
- those who never achieve complete remission with standard chemotherapy, in whom prognosis is very poor, and who are candidates for an intensive salvage chemotherapy regimen with autologous haematopoietic stem cell transplantation (HSCT)
- those whose original remission lasted for over a year, of whom some will respond to re-treatment with standard therapy, but in whom intensive salvage chemotherapy regimens with HSCT may be considered
- and those whose remission is short, less than one year, in whom standard chemotherapy may be used to reduce tumour volume before intensive salvage chemotherapy and HSCT.[2,16]

Common salvage regimens include BEAM or mini-BEAM (carmustine, etoposide, cytarabine, and melphalan), DHAP (dexamethasone, high-dose cytarabine, and cisplatin), ESHAP (etoposide, methylprednisolone, high-dose cytarabine, and cisplatin), ICE (ifosfamide, carboplatin, and etoposide), or gemcitabine-based regimens.[1,7,11,17] For further information on common chemotherapy regimens, see Table 1, p. 719. Although intensive chemotherapy and autologous HSCT is considered by some[2,7,11,14,17] to be the treatment of choice in relapsed patients, others[4] note that benefit on overall survival remains to be established.

Immunotherapy with brentuximab vedotin (a antibody-drug conjugate consisting of a CD30-specific monoclonal antibody and a microtubule disrupting agent) may be an option when autologous haematopoietic stem cell transplantation has failed, or when other therapies have failed in those deemed unsuitable for transplantation. Other immunotherapies under investigation for Hodgkin's disease include the anti-CD20 monoclonal antibody rituximab, and other monoclonal antibodies, some radiolabelled, to CD25 and CD30.[3,5,7,11,17]

NON-HODGKIN'S LYMPHOMAS. The non-Hodgkin's lymphomas are a heterogeneous group of malignancies that vary considerably in their behaviour, prognosis, and management. Classifications have grouped them by grade (low, intermediate, or high) or cellular origin (B-cell, T-cell, or NK-cell), and histology (see Lymphomas, p. 695.3). The most recent WHO classification, while still considering cell of origin, does not group the non-Hodgkin's lymphomas into a distinct clinical framework.[1] The non-Hodgkin's lymphomas include Burkitt's lymphoma, MALT lymphoma, and mycosis fungoides, all of which are discussed separately.

The usual presentation of lymphomas is lymphadenopathy, which in low-grade lymphoma may develop insidiously over a long period. There may be constitutional symptoms of fever, night sweats, and weight loss. Extranodal involvement may occur, as may symptoms due to organ compression by the tumour mass. Lymphomas of T-cell origin have a worse prognosis than B-cell lymphomas of the same type, and excess tumour bulk, involvement of bone marrow or gastrointestinal tract, and elevated serum lactic dehydrogenase concentrations are also adverse prognostic factors. Staging is of somewhat less importance as a determinant of treatment and prognosis than in Hodgkin's disease.

Follicular lymphoma is the commonest form of *indolent* non-Hodgkin's lymphoma.[2,3] Follicular lymphomas may be subclassified histologically into 3 grades according to the number of centroblasts, and grade 3, which is more aggressive, should be treated as for diffuse large B-cell lymphoma[1,4,5] (see below). The approach to therapy of other follicular lymphoma differs dramatically in patients with localised or disseminated (advanced) disease.[1]

In the few patients with limited disease at presentation, radiotherapy is potentially curative,[2,5-10] with most patients achieving long-term freedom from disease, and low rates of relapse.[2] The addition of chemotherapy to radiotherapy has not thus far convincingly prolonged remission or improved overall survival.[1,7] Patients who do not respond after therapy should be treated as those with more disseminated disease.[1] Even in more advanced disease, which is rarely curable,[2,6,8,10] follicular lymphoma may follow a fairly chronic course, with a median survival of 8 or more years[4,6,9] although transformation to more aggressive forms may occur.[2]

Treatment in advanced disease has not been shown to affect survival, and a conservative approach of withholding treatment until symptoms require it is considered viable.[1,3,6,7,9,11] The addition of rituximab to combination chemotherapy has increased overall response rate, response duration, and progression-free survival and hence some[1,10] recommend rituximab with chemotherapy (chemoimmunotherapy) for first-line treatment; caution is advised in patients with hepatitis B.[1]

Rituximab may be combined with either bendamustine or fludarabine.[1] Established regimens to which rituximab may be added include CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), CVP (cyclophosphamide, vincristine, and prednisone), or fludarabine-based regimens such as FCM (fludarabine, cyclophosphamide, and mitoxantrone) or FND (fludarabine, mitoxantrone, and dexamethasone).[1,3,5,10] Rituximab monotherapy is also an option for patients with a low-risk profile or who cannot tolerate more intensive chemoimmunotherapy or for the elderly and infirm.[1,10] Single-agent alkylators such as chlorambucil or cyclophosphamide are an option for these patients.[1] Rituximab maintenance therapy is under investigation; although benefits have been reported, the optimal dose and duration have not been established.[12]

The use of interferon alfa with chemotherapy for first-line treatment has produced conflicting results. However, when interferon alfa was used with anthracycline-containing regimens, improvements in response rate and prolonged remission were reported;[6,11] prolonged survival has not

been proven.[7] Interferon alfa as maintenance therapy appears to improve disease-free survival, but only if complete remission has been obtained with initial chemotherapy.[2,6] Overall, a *meta-analysis*[13] of 10 studies found that the ability of interferon alfa to prolong remission duration and survival may depend on it being used with relatively intensive chemotherapy and given in unit doses of at least 5 million units (at least 36 million units/month).

Radioimmunotherapy with radiolabelled monoclonal antibodies such as tositumomab and ibritumomab may also be considered first-line,[1,3] although myelosuppression may be a problem[9,14] and there may be practical difficulties associated with their use. Some consider radioimmunotherapy as an initial option for the elderly or infirm.[1]

Relapse of indolent lymphomas is generally inevitable. Selection of salvage therapy depends on the efficacy of initial regimens.[10] Options include chemoimmunotherapy with a different chemotherapy option to that used first-line, radioimmunotherapy (as discussed above), rituximab alone, or alkylator monotherapy.[1,3,5,10] High-dose chemotherapy followed by autologous or allogeneic haematopoietic stem cell transplantation (HSCT) may be an appropriate option for relapsed patients.[1,3,4,7,10] In the case of allogeneic HSCT, nonmyeloablative approaches may be considered.[1,3,10]

Intermediate- to high-grade lymphomas, of which **diffuse large B-cell lymphoma** (DLCL) is the most common form,[1] are *aggressive*. About one third of patients with DLCL have localised disease at presentation,[15] and treatment with CHOP (see above) and rituximab with or without radiotherapy is the treatment of choice.[1,4,16,17] Many also consider CHOP plus rituximab (R-CHOP) to be the standard of care in advanced disease,[1,4,16] although other, generally anthracycline-based, regimens are also considered acceptable, such as dose-adjusted R-EPOCH (rituximab, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin).[1] High-dose chemotherapy with autologous HSCT has been tried for initial therapy in patients with diffuse aggressive non-Hodgkin's lymphoma, but remains investigational.[1,11,15,18]

On relapse, patients are treated with salvage chemotherapy regimens such as DHAP (dexamethasone, cytarabine, and cisplatin), ICE (ifosfamide, carboplatin, etoposide), ESHP or ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), GDP (gemcitabine, dexamethasone, and cisplatin), GemOx (gemcitabine and oxaliplatin), or MINE (mitoxantrone, ifosfamide, mesna, etoposide); all these regimens may be given with or without rituximab.[1] Monotherapy with pixantrone may also be considered in patients with B-cell lymphomas. Patients are then evaluated for high-dose chemotherapy and autologous HSCT, which is considered the treatment of choice in suitable patients who respond to the salvage regimens.[1,2,17,19] However, in disease resistant to salvage chemotherapy, its role has not been established,[19] and patients whose disease progresses are considered not likely to benefit from currently available standard therapy.[1] In an effort to improve outcomes after autologous HSCT, the addition of radioimmunotherapy (as above) to conditioning regimens is being investigated. Allogeneic HSCT is also under investigation.

There is no standard approach for those patients ineligible for transplant;[19] options include rituximab monotherapy, second-line chemotherapy regimens such as R-EPOCH or EPOCH, CEPP (cyclophosphamide, etoposide, prednisone, procarbazine) with or without rituximab, lenalidomide, palliative radiotherapy, or investigational treatment.[1]

For further information on common chemotherapy regimens, see Table 1, p. 719.

High-grade lymphomas such as **precursor T-lymphoblastic lymphoma** (T-LBL) and Burkitt's lymphoma (see below) are *highly aggressive* and untreated patients survive only weeks. They occur mainly in children and young adults, and are often widely disseminated with bone marrow, peripheral blood, and CNS involvement. Lymphoblastic lymphoma is generally treated with protocols based on those used for acute lymphoblastic leukaemia (see p. 692.3), including the use of CNS prophylaxis.[1]

Vaccines for B-cell lymphomas are under investigation.

AIDS-related lymphomas. Non-Hodgkin's lymphoma is often a late complication of AIDS and its incidence in HIV-infected individuals is about 60 times greater than in the general population.[1] Histologically, it is usually diffuse large cell lymphoma (see Non-Hodgkin's Lymphomas, p. 696.3) or small non-cleaved lymphoma (Burkitt's lymphoma—see below).[1-3] About 50% of these are associated with the presence of Epstein-Barr virus.[4] The other common HIV-associated lymphoma is primary CNS lymphoma (p. 698.1), which is invariably associated with Epstein-Barr virus.[1,2] More recently, primary effusion lymphoma or body cavity-based lymphoma has been identified,[1,2] which is associated with human herpes virus 8. Although Hodgkin's disease (see p. 696.1) is not considered an AIDS-defining illness, epidemiological studies have shown it to be associated with HIV infection.[2]

It was unclear if the introduction of HAART for HIV infection (p. 957.2) would reduce the risk of lymphomas by improving immune function,[5] or, conversely, increase the incidence by allowing patients to survive long enough for lymphoma to develop.[1] However, it has become apparent that the incidence of AIDS-related lymphoma has decreased with the advent of HAART.[1,3,5] There is some evidence of tumour response when antiretroviral therapy is started in a patient who already has a lymphoma.[4]

Most patients with AIDS-related non-Hodgkin's lymphomas have disseminated disease, often extranodal, at presentation.[1,2] Optimal management is not established.[3] Combination chemotherapy regimens used include CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), CDE (cyclophosphamide, doxorubicin, and etoposide) and a dose-adjusted EPOCH regimen (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin).[1,3,5,6] M-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone) has also been used;[1] a low-dose modification of this regimen produced responses comparable to the standard-dose regimen.[7] There is some controversy about whether HAART should be given with or after chemotherapy,[2,6] although most seem to recommend concomitant treatment[2,6] as it results in a more modest decrease in immune function than when chemotherapy is given alone.[5] The addition of rituximab has been investigated, but results have been disappointing and an increased risk of neutropenic sepsis and death has been reported.[3,5] However, some consider the use of rituximab with chemotherapy to be more effective than chemotherapy alone, and safe in these patients provided appropriate antibacterial prophylaxis is used.[6] The use of colony-stimulating factors with chemotherapy has reduced neutropenia and febrile episodes, but there has been no effect on remission rates or overall survival.[1] Most studies used granulocyte-macrophage colony-stimulating factor, but this may increase HIV-1 replication.[1]

Patients with relapsed AIDS-related lymphoma who are responsive to salvage chemotherapy may be treated successfully with high-dose chemotherapy and autologous haematopoietic stem cell transplantation.[6]

HIV-positive patients with Hodgkin's disease are more likely to present with constitutional symptoms, at an advanced stage, with extranodal disease, and concomitant Epstein-Barr virus infection than HIV-negative individuals. Bone marrow involvement may be found in more than 50% of patients. Before HAART, patients with Hodgkin's disease and infected with HIV had a median survival of 1 to 2 years. Outcomes in the HAART era may be improving, although optimal treatment is undecided. Regimens that have been tried include the BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) and Stanford V regimens.[2]

For further information on common chemotherapy regimens, see Table 1, p. 719.

Burkitt's lymphoma. Burkitt's lymphoma is a small non-cleaved cell lymphoma (SNCL) of B-cell origin, which is highly aggressive and with a characteristic chromosomal translocation involving the *c-myc* oncogene. The disease accounts for up to 50% of childhood non-Hodgkin's lymphoma in non-endemic areas. Three clinical variants have been described. The endemic form occurs most commonly in equatorial Africa and Papua New Guinea, in young children, and is almost always associated with Epstein-Barr virus (EBV) infection. It frequently involves the jaws and other facial bones; bone marrow and CNS involvement can occur. In contrast, the sporadic form, seen most commonly in developed countries, arises in the lymphoid tissues of the gut and upper respiratory tract. The immunodeficiency subtype is seen in the setting of HIV infection, and to a lesser extent post-transplantation. Adult patients with the latter 2 subtypes typically present with extranodal disease, and the abdomen is the most common site of involvement. Symptoms include abdominal pain, gastrointestinal bleeding, nausea, and vomiting, and may mimic appendicitis. Bone marrow and CNS involvement can occur. Jaw involvement is rare, and only about a third of patients are EBV-positive.

The main **treatment** for Burkitt's lymphoma is chemotherapy. Shorter duration, dose-intensive chemotherapy regimens have resulted in improved survival and in children complete remission is common and prognosis good: probability of long-term disease-free survival is usually greater than 80%.[1] Prognosis has been less good in adults, but with the increasing use of more intensive regimens similar to those used in children, is improving. About half of all adult cases are reported to be curable with intensive chemotherapy regimens.[2,3]

Commonly used regimens include CODOX-M (cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate) for low-risk patients; it is given in an alternating regimen with IVAC (ifosfamide, etoposide, and high-dose cytarabine) in high-risk patients.[2-5] Hyper-CVAD (cyclophosphamide, vincristine, doxorubicin, and dexamethasone, alternating with methotrexate plus cytarabine) is also given to adult patients.[2-6] A dose-adjusted EPOCH regimen (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) is also recommended for use in low-risk patients or in high-risk patients unable to tolerate more aggressive treatment.[4] Rituximab has been added to these regimens in an attempt to improve response and long-term survival;[2-7] initial results have been promising. Cytarabine and methotrexate are also given intrathecally for CNS prophylaxis.[2-4]

Relapsed or ***refractory*** Burkitt's lymphoma has not been well-studied and the optimal treatment regimen is unknown.[2,3] Drugs used for salvage chemotherapy include high-dose methotrexate and high-dose cytarabine or etoposide plus cisplatin;[2] combination regimens incorporating cisplatin, cytarabine, or ifosfamide may be of benefit, particularly if these were not used first-line.[3] Autologous or allogeneic haematopoietic stem cell transplantation may be considered for relapsed or refractory disease,[2-4] although its role in Burkitt's lymphoma remains controversial.[5,7] There are reports of improved survival with high-dose chemotherapy followed by autologous stem cell transplantation compared with chemotherapy alone. Allogeneic transplantation has been reported to lower relapse rates when compared with autologous transplantation, but transplant-related mortality is higher.[7]

Primary CNS lymphoma. Primary CNS lymphoma is an aggressive form of non-Hodgkin's lymphoma that develops in the brain, spinal cord, leptomeninges, or the eye.[1,2] It accounts for some 0.5 to 5% of all primary brain tumours (see also Malignant Neoplasms of the Brain, p. 701.2). There is a strong association with HIV infection (see AIDS-related Lymphomas, p. 697.2). Patients usually present with neurological symptoms such as hemiparesis or dysphasia, mental status changes, symptoms of increased intracranial pressure, and behavioural changes.[1,2] The ocular manifestation is termed primary intra-ocular lymphoma; it is often misdiagnosed as uveitis, and should be distinguished from systemic lymphoma with orbital involvement.[1,3,4]

Treatment options for primary CNS lymphoma include corticosteroids, radiotherapy, and chemotherapy. Corticosteroids such as dexamethasone, although the treatment of choice for short-term palliation, should be avoided before tissue biopsy since they can interfere with the histopathology.[1,2] These tumours are radiosensitive, but the timing of radiotherapy is controversial. Most recommend some form of radiation after chemotherapy; drug delivery may be optimal before radiation, when the blood-brain barrier is maximally disrupted by the tumour.[2] Others advise against first-line radiotherapy, based on limited efficacy and potential delayed neurotoxicity; consolidation radiotherapy may be beneficial in younger patients who achieve a complete response after methotrexate-based chemotherapy.[1,5]

While the optimum chemotherapy combination remains unclear,[1,5] chemotherapy has significantly improved disease-free and overall survival.[2] High-dose methotrexate appears to be the most effective drug and is recommended first-line, with or without other drugs such as cytarabine.[1,2,5] Regimens based on CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone or prednisolone) have been associated with increased neurotoxicity and found ineffective, probably due to poor penetration across the intact blood-brain barrier;[1,2] as a consequence, CHOP-like chemotherapy is considered to have no role in the treatment of primary CNS lymphoma.[1]

In patients who relapse after a relatively long-term response (longer than 1 year), then re-treatment with a methotrexate-based regimen is considered reasonable. For those who do not respond to initial chemotherapy or who relapse quickly, recommendations include radiotherapy with or without chemotherapy.[2] Alternative agents include rituximab, temozolomide, topotecan, and the combination regimen of cisplatin, cytarabine, and dexamethasone.[2] High-dose chemotherapy followed by autologous haematopoietic stem cell transplantation (HSCT) has been investigated, but evidence to support its use first-line is considered to be lacking.[1] However, it has been reported as being an effective treatment for relapsed and refractory disease.[6]

Optimal treatment for primary intra-ocular lymphoma is not known,[3] and recommendations for therapy remain controversial.[1] Options include ocular radiotherapy, intravitreal methotrexate, combined modality treatment, and systemic methotrexate-based chemotherapy.[1,3,4] High-dose chemotherapy with autologous HSCT has been tried,[1,4] and agents under investigation include rituximab and trofosfamide.[1]

MALT lymphoma. Marginal zone B-cell lymphomas of mucosa-associated lymphoid tissue (MALT) occur most commonly in the stomach, but may also occur in the salivary gland, breast, thyroid, eye, or lung. They tend to be indolent and remain localised for long periods of time, but can transform to a more aggressive type. Clinical symptoms of gastric MALT lymphoma are vague and varied and include abdominal pain, dyspepsia, vomiting, and gastric bleeding.

Most gastric MALT lymphomas are associated with *Helicobacter pylori* infection.[1-4] The bacterium stimulates the formation of MALT in the stomach, which normally lacks organised lymphoid tissue, and there is evidence that it indirectly stimulates tumour growth. Eradication of *H. pylori* infection using antibacterial and antisecretory therapy, as described in Peptic Ulcer Disease, p. 1816.2, has been shown to result in regression of gastric MALT lymphoma in most patients.[1,2,4,5] Tumour response may be slow,[2] and lymphoma regression after *H.pylori* eradication is not always complete; eradication suppresses but does not necessarily eradicate the neoplastic clone. Only lymphomas limited to the mucosa or submucosa regress after eradication and lymphoma can recur.[1] Thus, patients who are *H. pylori*-positive with early stage primary gastric MALT lymphomas may be treated solely with *H. pylori* eradication regimens and long-term endoscopic follow-up.[2,4,6,7] The best treatment for patients without *H. pylori* infection, those whose tumours do not respond to eradication, and those with more advanced tumour stage at presentation remains to be established.

Radiation therapy is the treatment of choice for localised disease.[2,4,6,7] Rituximab monotherapy may be considered for early stage disease if radiation therapy is contra-indicated.[2] Surgical resection is generally limited to specific clinical situations,[2] such as the management of complications or for cases of locally persistent disease.[3,4] Single-agent or combination chemotherapy is recommended in advanced disease.[2,7] No standard chemotherapy regimen has been established.[4] Regimens that may be tried include alkylating agents such as cyclophosphamide or chlorambucil, purine analogues such as cladribine or fludarabine,[3,4,7] and occasionally anthracycline-based chemotherapy for younger patients with more aggressive disease.[3] Rituximab is also an option, given either alone or with chemotherapy.[2-4,7]

It has been suggested that screening for and eradication of *H. pylori* is worth investigating as a means of preventing gastric cancer.[8]

Non-gastrointestinal low-grade MALT lymphomas have been treated with surgery or radiation therapy if localised, and with single-agent or combination chemotherapy (similar to that used for other low-grade non-Hodgkin's lymphomas—see p. 696.3) if advanced.[2-4,6]

Mantle cell lymphoma. Mantle cell lymphoma is a rare, aggressive lymphoma of B-cell origin, characterised in most cases by a chromosomal t(11;14) translocation. Patients are often elderly and more often male. Most patients present with advanced stage disease. Clinical features include fever, weight loss, drenching night sweats, and gastrointestinal symptoms.[1,2]

There is no established standard **treatment** for mantle cell lymphoma.[3,4] For the few patients presenting with *localised* disease, radiotherapy significantly improves progression-free survival, and is recommended first-line, with or without chemotherapy.[1,3]

Systemic combination chemotherapy, although non-curative, is recommended in *advanced* disease.[1,3] Rituximab plus chemotherapy is recommended first-line.[1,3,5] Chemotherapy options include CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), HyperCVAD/MA (cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with high-dose methotrexate and cytarabine), and EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin).[1-3,5] For further information on these and other common chemotherapy regimens, see Table 1, p. 719. An alternative treatment in younger patients, without significant comorbidities, is high-dose radiochemotherapy consolidated by autologous haematopoietic stem cell transplantation (HSCT).[1,3,5,6] Allogeneic HSCT may be curative, but only a few patients are suitable and it is associated with considerable morbidity and mortality.[1,2,6] For patients who cannot tolerate more intensive therapy, some recommend CHOP with or without rituximab[3] or anthracycline- or fludarabine-containing regimens.[1]

Patients who *relapse* after initial therapy or with progressive disease may be treated with bendamustine (with or without rituximab), bortezomib, lenalidomide, purine analogue-containing regimens (with or without rituximab), temsirolimus, thalidomide (alone or with rituximab),[1,3,5,6] or ibrutinib. Radioimmunotherapy, with radiolabelled monoclonal antibodies ibritumomab and tositumomab, has also been investigated for relapsed or refractory disease.[1,2,5,6] Allogeneic HSCT may be considered in suitable patients with relapsed disease after first-line therapy.[1,2,6]

Mycosis fungoides. Mycosis fungoides is the most common of the cutaneous T-cell lymphomas. It is considered to have 3 stages which may overlap or occur simultaneously:

- a premycotic erythematous or patch phase, characterised by a pruritic rash resembling psoriasis, which may persist for years or even decades
- an infiltrative or plaque phase, in which some patches become thickened, darker plaques with marked T-cell infiltration
- a tumour phase where lesions enlarge and ulcerate. Ultimately there may be visceral involvement or potentially fatal sepsis secondary to skin breakdown

A leukaemic variant of mycosis fungoides presents as widespread pruritic erythroderma, accompanied by abnormal T-cells in the blood, and is known as the Sézary syndrome.

There are many therapeutic options for mycosis fungoides, but few have been evaluated in controlled studies. **Treatment** depends on disease stage and spread.[1-5] Patients with limited and slowly progressive *patch phase disease* have a good prognosis (median survival similar to age-matched controls) and may be managed with topical and local therapies. Topical therapies include emollients, corticosteroids, chlormethine, carmustine, the retinoids bexarotene or tazarotene, and imiquimod.[1,2,6-10] Phototherapy, using UV B light, or a psoralen plus UV A light (PUVA), is a useful alternative when topical treatments are ineffective or not tolerated.[1,2,8] Mycosis fungoides is very radiosensitive, and for clearly localised patches, or isolated patches that have failed to respond to other treatments, local x-ray or electron beam radiotherapy may be used.[2,3,6-8]

The initial therapy for patients with widespread *patch/plaque phase disease* is also topical, using chlormethine or PUVA.[1,6] Topical retinoids are not recommended for generalised skin involvement, as they can cause irritation.[6] Patients who fail to respond to a single drug may be treated with combinations such as chlormethine with phototherapy,[1] PUVA with interferon alfa,[1,3,7] or PUVA with retinoids.[7] Total skin electron beam therapy may be used, but it may not be widely available and is usually only given once;[3] it is generally used for thickened plaques or for disease that has not responded to other local therapies.[1-3]

In the *tumour phase*, combination therapy as described above is often used initially.[1,4,7] Alternatively, systemic retinoids (such as acitretin, bexarotene, isotretinoin, or tretinoin), interferons, vorinostat, romidepsin, denileukin diftitox, or low-dose methotrexate may be tried.[6] Systemic chemotherapy may be used for palliation in recalcitrant disease and advanced disease with extracutaneous involvement, but responses are often of short duration.[1,2,6] Options include single-agent liposomal doxorubicin, gemcitabine, chlorambucil, pentostatin, etoposide, cyclophosphamide, and temozolomide.[6] Combination regimens include CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone), CVP (CHOP without doxorubicin), CAVE (cyclophosphamide, doxorubicin, vincristine, etoposide),[1] or EPOCH (etoposide, prednisone, vincristine, doxorubicin, and cyclophosphamide).[8] For further information on common chemotherapy regimens, see Table 1, p. 719.

Mycosis fungoides with erythrodermic features is treated similarly except that skin irradiation tends to be avoided or used in very low doses as it causes severe desquamation.[1] Extracorporeal photopheresis may be useful for disease with erythrodermic features.[1,3,5,6,10]

Therapies for *persistent or recurrent* mycosis fungoides include denileukin diftitox, bexarotene, and vorinostat.[2,4,5] Experience with autologous haematopoietic stem cell transplantation (HSCT) is limited, but allogeneic HSCT may be considered for patients with advanced disease that is progressive or refractory to multiple treatment options.[6,7] Alemtuzumab has been used in patients with advanced or refractory mycosis fungoides or Sézary syndrome.[4,6,8]

Waldenström's macroglobulinaemia. Waldenström's macroglobulinaemia (primary macroglobulinaemia) is an uncommon B-cell lymphoproliferative disorder characterised by lymphoplasmacytic cells that infiltrate the bone marrow and by hypersecretion of immunoglobulin M (IgM). Patients are mainly elderly, and more often male. Although often asymptomatic, patients can present with weakness and fatigue, peripheral neuropathy, anaemia, hepatosplenomegaly, and lymphadenopathy. Some develop the hyperviscosity syndrome (characterised by oronasal bleeding, visual disturbances and retinal haemorrhage, neurological disturbances such as headache, vertigo, and hearing loss, and, rarely, heart failure).

Asymptomatic patients require no treatment and may remain stable for some years. Where **treatment** is required, first-line options include the use of alkylating agents, nucleoside analogues (such as cladribine or fludarabine), or the monoclonal antibody rituximab, as well as combinations of these.[1-9] Combination regimens include nucleoside analogues with either rituximab or cyclophosphamide, or a combination of all three drugs. Cyclophosphamide-based therapy with rituxumab may also be an option, such as R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone) or DRC (dexamethasone, rituximab, and cyclophosphamide). Rituximab may also be used with thalidomide, and this combination or the DRC regimen may be useful for those whose main indication for treatment is cytopenias.

Rituximab-based therapies may be the preferred ***initial therapy*** for most patients; cyclophosphamide-based regimens are appropriate if rapid disease control is needed.[7] Rituximab monotherapy is discouraged in those patients with higher IgM concentrations and at risk of hyperviscosity,[2,3,5] although it is an appropriate choice for those patients with low-risk disease and associated comorbidities.[7] The use of chlorambucil has decreased in Waldenström's macroglobulinaemia,[8] but it may also be considered as monotherapy in low-risk disease and in older patients with comorbidities.[7]

High-dose therapy followed by autologous haematopoietic stem cell transplantation (HSCT) has a role in the management of selected patients,[2,5] and non-myeloablative allogeneic HSCT has also been investigated.[2,7,9,10] Although many patients are too old to tolerate the high-dose therapy,[5,10] candidacy for autologous HSCT is a factor in the choice of initial therapy;[7] it is recommended that exposure to alkylating agents and nucleoside analogues be limited if HSCT is to be considered.[2,3,6,7,9] Alternatively, stem cells may be collected before treatment with these drugs.[2] A retrospective study[11] found that use of nucleoside analogues was associated with an increased risk of disease transformation to high-grade lymphoma.

When disease stabilises, treatment may be stopped and begun again on ***relapse***.[3] The choice of therapy depends on the first-line treatment used, the quality and duration of response, and other variables such as patient age, tolerance of therapy, and candidacy for HSCT.[7] Initial treatments that produce relatively long responses (6 to 12 months) may be repeated; alternate first-line agents or combination regimens are recommended for earlier progressions.[3,7] Appropriate second- or third-line choices include bortezomib, thalidomide (with or without dexamethasone), HSCT, or alemtuzumab,[3,7] although some consider the use of the latter unacceptable in this context because of high treatment-related mortality.[8] Lenalidomide is under investigation for Waldenström's macroglobulinaemia[3,8,9] and small studies have reported benefit with interferon alfa.[2,6,10]

Plasmapheresis is indicated for the treatment of symptomatic hyperviscosity,[1,3-6,10] and high-dose corticosteroids may be used to treat systemic vasculitis arising from deposition of paraproteins.[6] Splenectomy, although rarely indicated, may be used to manage painful splenomegaly and hypersplenic syndromes.[1,6]

PLASMA CELL NEOPLASMS. Multiple myeloma. Multiple myeloma (myelomatosis) is a lymphoproliferative disorder of B-cell origin, involving the development of an abnormal plasma-cell precursor. It occurs mainly in the elderly, and accounts for about 1% of all malignancies. It is more common in black than in white patients and in men than in women.

The proliferation of the abnormal clone tends to suppress normal haematopoiesis, resulting in anaemia and immunosuppression, with an increased risk of serious infection. Perhaps the most characteristic complication, however, is skeletal destruction, apparently due to release of an osteoclast stimulating factor, resulting in osteoporosis, lytic lesions and fractures, and bone pain, as well as consequent hypercalcaemia. In addition, the plasma cells release large quantities of monoclonal immunoglobulins, known as paraproteins, which can produce a hyperviscosity syndrome and in some cases may interfere with platelet function. Renal failure of various causes and neurological problems due to compression are also common.

Multiple myeloma is not curable with presently-available treatment, and **therapy** is concerned with prolongation of survival and alleviation of symptoms.[1,2] Those patients with stable, indolent or smouldering myeloma, or benign monoclonal gammopathy, are followed carefully but not treated until overt progressive disease occurs.[1-3] Early treatment may inhibit disease progression, but overall survival and response rates are not affected.[4]

The treatment of overt disease depends on eligibility for haematopoietic stem cell transplantation (HSCT) and risk assessment.[3] High-dose chemotherapy combined with autologous HSCT improves response rate, event-free survival, and overall survival compared with standard chemotherapy.[6] Evidence for these benefits is strongest for patients younger than 55 years old.[7] Although some[8] consider standard-dose chemotherapy to be the preferred initial treatment in patients older than 70 years, other reviews[6,9] have concluded that autologous HSCT is safe for the majority of patients older than 65 years, and guidelines have suggested its consideration in this group[2] if they have good functional status and limited comorbidity. With tandem transplantation, patients receive a second planned autologous HSCT,[1,10] since it was shown that patients who did not enter remission after one transplant could achieve remission after another.[11] Some recommend tandem transplants in those who do not have at least a very good partial response after the first,[12] and as such, some centres routinely collect enough stem cells for two transplants.[1,10,13,14] However, the benefit of a second transplantation has been challenged by the high efficacy of novel induction agents followed by one autologous HSCT, with these agents then used as consolidation therapy.[15] Allogeneic HSCT has been used for multiple myeloma, sometimes after autologous HSCT, but few patients are suitable, and transplant-related morbidity and mortality are high with conventional myeloablative chemotherapy regimens; non-myeloablative regimens (miniallogeneic HSCT) are under investigation.[5,10-13]

Although the VAD regimen (vincristine, doxorubicin, and dexamethasone) was used for many years as induction therapy, newer regimens are now recommended in preference.[3,5,10,15,16] Dexamethasone, which may be used alone, forms part of most recommended regimens.[1,16] Options include thalidomide plus dexamethasone, lenalidomide plus dexamethasone, and bortezomib-based regimens.[1,3,5,10,12,15,16] Although considered by some to be less favourable than the newer regimens,[16] the DVD regimen uses liposomal doxorubicin instead of doxorubicin in the VAD regimen.[1,16]

Peripheral stem cells are collected after giving high-dose cyclophosphamide and granulocyte colony-stimulating factor.[6,8] Although some suggest the use of alkylating agents and interferon alfa after stem cell collection,[8] earlier alkylator or nitrosurea therapy interferes with stem cell mobilisation,[1,10,12,13] and can result in poor engraftment.[7,9] The standard conditioning regimen before transplantation is considered to be high-dose melphalan.[2,3,6,8-10,13] Total body irradiation is no longer recommended, as combined with lower dose melphalan, it resulted in higher toxicity and no significant survival benefit compared with high-dose melphalan alone.[6,7,9] Similarly, stem cells are not purged of contaminating myeloma cells as a randomised study[17] showed no benefit.

Where transplantation is infeasible or inappropriate, ***chemotherapy*** may be given to induce remission and prolong survival. The standard first-line regimen has long been a combination of oral melphalan and corticosteroids, usually prednisolone or prednisone.[1-3,9,10,13-16] This MP regimen produces an objective response in about half of all patients, and prolongs median survival to between 2 and 3 years.[9] The contribution of corticosteroids to the regimen has been controversial although a trend towards increased survival was noted[6] compared with melphalan alone, and high-dose dexamethasone given alone has been reported to be effective in producing remissions.[9] Cyclophosphamide is active,[6] and has been substituted for melphalan.[2] The addition of thalidomide to melphalan and prednisone (the MPT regimen) has led to better response rates and progression-free survival, and it is recommended as standard induction for elderly patients ineligible for HSCT;[3,5] however, toxicity is higher than with the MP regimen.[12,16,18] Similarly, the MPV or MPB regimen (bortezomib added to melphalan and prednisone) was found to have improved response rates and overall survival compared with MP alone,[1,5,16] and it is also a recommended induction regimen. Lenalidomide added to melphalan plus prednisone is another option.[1] Other induction regimens include bortezomib plus dexamethasone, thalidomide plus dexamethasone, lenalidomide plus dexamethasone, the VAD or DVD regimens,[1] or bendamustine plus prednisone.

Maintenance chemotherapy with thalidomide has been used after autologous HSCT,[1,19] and may be offered to patients not achieving a complete response after tandem HSCT,[15,18] although optimal duration of maintenance therapy is not known.[3,19] Bortezomib and lenalidomide can also be used for maintenance,[1,12] although there may be an increased risk of secondary cancer with the latter. Other options include thalidomide plus prednisone.[1] Corticosteroids or interferon do not appear to provide significant clinical benefit,[3,10,15,19] although some guidelines suggest second-line use.[1]

In patients who fail to respond to initial treatment, or who subsequently ***relapse***, various regimens may be tried.[1] If relapse occurs more than 6 months after initial induction therapy, re-use of the initial regimen is recommended. However, a different regimen should be considered if disease recurs within 6 months of completing induction therapy.[1,16] Good responses have been achieved with bortezomib,[1,2] and it is recommended either as monotherapy, or with dexamethasone, or liposomal doxorubicin.[1,16] Other regimens include:[1,16]

- monotherapy with either bendamustine, thalidomide, lenalidomide, pomalidomide, high-dose cyclophosphamide, or carfilzomib
- dexamethasone plus either thalidomide, lenalidomide, or pomalidomide
- dexamethasone plus bortezomib and either thalidomide or lenalidomide
- dexamethasone plus cyclophosphamide and either bortezomib or lenalidomide
- dexamethasone plus lenalidomide and bendamustine
- bortezomib plus vorinostat
- cyclophosphamide-VAD
- DCEP (dexamethasone, cyclophosphamide, etoposide, and cisplatin)
- DT-PACE (dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, and etoposide)

For further information on common chemotherapy regimens, see Table 1, p. 719.

Although chemotherapy aimed at the myelomatous clone will produce symptomatic relief as disease is brought under control, ***supportive and symptomatic care*** is also important. Bisphosphonates such as clodronate, pamidronate, and zoledronate have been found to be effective in reducing skeletal complications,[20,21] and are recommended in those patients with bone disease.[1,2,14,22] Some recommend that bisphosphonate therapy be stopped after 2 years in patients with responsive or stable disease.[22,23] (For further discussion, see Malignant Neoplasms of the Bone, under Bisphosphonates, p. 1174.1.) Radiotherapy is used for impending fracture or impending spinal cord compression, and is often effective in relieving uncontrolled bone pain.[1,9]

Erythropoietin therapy can improve anaemia and reduce the need for transfusion.[1,6,8,9] A high fluid intake is essential in patients with renal dysfunction or hypercalcaemia (for the appropriate management of the latter, see p. 1778.1). Vigorous antibacterial treatment may be needed if infection occurs (see Infections in Immunocompromised Patients, p. 186.3) and plasma exchange may alleviate the hyperviscosity syndrome.[1,8,10]

Drugs under investigation for the treatment of multiple myeloma include oblimersen, vorinostat, and arsenic trioxide.[13,14]

Malignant effusions. The amount of interstitial fluid is normally regulated by a complex equilibrium between capillary filtration, osmotic pressure, and physical hydrostatic or hydraulic forces. Malignant neoplasms can disturb this equilibrium by obstruction of capillary or lymphatic drainage as well as causing active exudation of additional fluid after metastatic implantation. Malignant effusions are associated most often with lung, breast, and ovarian malignancies and lymphomas. Symptoms vary, and the fluid build-up may be asymptomatic; both pleural and pericardial effusions can produce cough, pleuritic chest pain, and dyspnoea and pericardial effusions may progress to cardiac tamponade. Peritoneal effusions may lead to malignant ascites.

The main aim of **treatment** for malignant effusions is effective palliation of symptoms, and depends in part on the tumour type, patient performance status, and prognosis.[1-4] If the tumour is chemosensitive, systemic chemotherapy may resolve the effusion.[1,4,5] Similarly, radiotherapy can be effective for pericardial effusions associated with radiosensitive tumours.[3] Simple fluid drainage (thoracentesis, paracentesis, or pericardiocentesis) will relieve symptoms until fluid build-up recurs,[2,3] and in patients with very poor prognosis and a limited life expectancy, may suffice for palliation.[4] Use of an indwelling pleural catheter allows convenient and minimally invasive fluid drainage in patients with pleural effusions, and may result in spontaneous pleurodesis.[4] In malignant ascites, paracentesis is usually effective temporarily; evidence for the value of diuretics is weak, but spironolactone may be of benefit in some patients, either alone or with a loop diuretic.[6] In other patients with refractory tumours, fluid drainage followed by sclerotherapy is likely to be preferred.

The principle of *sclerotherapy* is the instillation of an irritant agent into the pleural or pericardial cavity to promote inflammatory and fibrotic changes which result in the membranes adhering together and abolition of the space between the membranes in which fluid accumulates. When this is done to treat pleural effusions (pleurodesis) success is dependent on adequate fluid drainage beforehand and full re-expansion of the lung to bring the pleural surfaces together. Intrapleural thrombolytics such as streptokinase have been used to improve fluid drainage in cases of loculation of the effusion.[1,7]

Many drugs have been used for sclerotherapy, and the most common are a tetracycline (doxycycline or tetracycline), bleomycin, or talc. The choice between these three remains controversial, and opinions on the preferred option differ.[1,2,4,7,8] However, a systematic review[9] found talc to be the sclerosant of choice for malignant pleural effusions. Other sclerosants that have been used, with varying reported rates of success, include interferon alfa, mepacrine, mitoxantrone, picibanil, povidone-iodine, silver nitrate, *Corynebacterium parvum*, and *Staphylococcus aureus* superantigen.[8] After drainage of the effusions the sclerosant is instilled in a small volume (50 to 100 mL) of liquid through the drainage tube.[5] Talc may also be given as a powder insufflation (rather than slurry), but this involves a surgical procedure under general anaesthesia. Sclerotherapy results in painful inflammation, and local anaesthetics or analgesics should be given.[2,7] For patients who fail sclerotherapy, or for whom this is not considered suitable, there are various surgical options to manage effusions.[1,3,6]

Malignant neoplasms of the bladder. Cancer of the bladder is the fourth or fifth most common cancer in Europe and the USA, where over 90% of bladder cancers are transitional cell in type. About two-thirds of all cases occur in men, and the median age at diagnosis is 65 years. Known risk factors include tobacco smoking, exposure to chemicals such as aniline dyes, and previous radiotherapy; in countries where it is endemic, schistosomiasis is also an important cause of squamous cell bladder cancer. Most patients present with haematuria; there may also be urinary frequency or dysuria.

Urothelial tumours fall into 3 major groups, non-invasive, invasive, and metastatic, which differ in prognosis and management.[1] About 70% of cases are non-muscle-invasive (superficial), 25% are muscle-invasive, and 5% are metastatic.[2]

The **non-muscle invasive** tumours are divided into low-grade carcinomas or papillomas confined to the mucosa (Ta), those that have invaded the submucosa (T1), and high-grade carcinoma *in situ* (CIS).[1,2] The standard initial treatment for primary or recurrent disease is surgery, in the form of transurethral resection (TUR). In an attempt to prolong remission and reduce the recurrence rate antineoplastics are instilled into the bladder soon after TUR (prophylactic or adjuvant intravesical therapy).[1-3] Effective agents include mitomycin, doxorubicin, epirubicin, and thiotepa; efficacy is similar in terms of outcome and choice depends on adverse effects.[2,4] The immunomodulator BCG is also used intravesically, with good results.[2] A single dose of intravesical chemotherapy is usually given within 24 hours of TUR, which may be sufficient for low-grade Ta tumours.[1,3,4] The need for further adjuvant intravesical therapy depends on the patient's prognosis and risk of tumour recurrence.[3,4] The ideal duration and intensity of the schedule remains undefined.[4]

Chemotherapy reduces recurrence, but not progression,[2,4] and BCG is considered by some to be the preferred option for high-grade tumours or those at high risk of progression.[1,3] Mitomycin is an alternative.[1] BCG is also generally preferred to antineoplastics for CIS,[1,5] and may be considered as maintenance therapy in those showing a complete response.[1,5] Those with recurrent or persistent disease can be given a second course of BCG or mitomycin.

If residual disease is still present, cystectomy should be considered; intravesical therapy with a different agent (mitomycin, valrubicin, or BCG plus interferon alfa) is an alternative to cystectomy. Radical cystectomy is recommended if disease progresses.[1] Photodynamic therapy using porfimer sodium or 5-aminolevulinic acid has also been investigated.[6]

Management of **muscle-invasive** bladder cancer that has not yet metastasised is a matter of some controversy, but conventional therapy has revolved around radical surgery.[1,2,7] Patients are usually also given systemic chemotherapy before (neoadjuvant) or after (adjuvant) complete cystectomy, in an attempt to prolong survival.[1,5,7] Neoadjuvant chemotherapy apparently favours survival,[3] there is insufficient evidence for routine use of adjuvant chemotherapy,[3,5] and use of the latter usually depends on prognosis, and whether or not neoadjuvant chemotherapy was given.[1] Some recommend considering the use of adjuvant chemotherapy in node-positive patients.[3] Selected patients may be considered for bladder-sparing approaches such as partial cystectomy followed by radiotherapy, chemotherapy, or both.[1,7]

The optimal chemotherapy regimen remains to be defined but regimens incorporating cisplatin, gemcitabine, or methotrexate are usually preferred. Typical regimens include gemcitabine plus cisplatin, CMV (cisplatin, methotrexate, and vinblastine), or MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin).[1,3] For further information on common chemotherapy regimens, see Table 1, p. 719.

Patients with unresectable or **metastatic** disease, or who subsequently develop metastatic disease, are usually treated with systemic chemotherapy with or without radiotherapy.[1,3] For patients with good prognosis, a combination regimen such as MVAC or CMV may be used. Various combinations of gemcitabine, taxanes, and cisplatin have shown clinical benefit,[1,7] and gemcitabine plus cisplatin has been shown to provide similar survival advantage to MVAC with better tolerability: some now consider that it should be the preferred regimen in advanced disease.[1,8] Taxane-based regimens may be considered in patients unable to receive cisplatin.[1] No standard second-line therapy exists and participation in clinical studies is encouraged; depending on first-line therapy, palliative options include monotherapy with bleomycin, fluorouracil, cisplatin, carboplatin, docetaxel, doxorubicin, gemcitabine, ifosfamide, methotrexate, paclitaxel, pemetrexed, or vinblastine.[1] Vinflunine is an option for those who progress on first-line platinum-based therapy.[3] Newer drugs under investigation include epidermal growth factor receptor inhibitors such as cetuximab and inhibitors of angiogenesis such as bevacizumab and sunitinib.[9]

Malignant neoplasms of the bone. Skeletal complications may result from primary cancers or from bone metastases secondary to other cancers. Primary bone malignancies are rare, and are usually sarcomas (see Bone Sarcoma, p. 717.3). Multiple myeloma (p. 699.2) also produces bone involvement. Metastatic bone disease is a common problem with cancers of the breast, prostate, and lung.

Skeletal malignancies cause considerable morbidity, including cancer pain (the general management of which is discussed on p. 7.1) and also result in immobility, bone fractures, bone-marrow infiltration, spinal cord or nerve root compression, and hypercalcaemia.[1-3] The most common sites of metastasis are the axial skeleton including the spine and ribs, and the proximal ends of the long bones.

The goals of management of **bone metastases** are essentially palliative: to relieve pain, preserve and restore function, and to reduce the risk of fracture and stabilise the

skeleton. Treatment often requires a multi-disciplinary approach that includes radiation, surgery, and systemic therapy.[2,4-6]

Radiotherapy provides excellent palliation of localised metastatic bone pain,[2,3] with responses occurring in over 70% of patients treated with external beam irradiation. Radiation can also be used to prevent or treat fractures, or to prevent spinal cord compression.[2] Bone-seeking radiopharmaceuticals such as rhenium-186, phosphorus-32, samarium-153, or strontium-89 may be used as an alternative for pain palliation, or as an adjunct to external beam radiotherapy.[2,4,5,7] Radiofrequency ablation has also been reported to be effective for pain, but is contra-indicated in the spine owing to proximity of the spinal cord and nerve roots.[3]

Structural weakness due to extensive bone loss may require ***structural support***; external fixation with cast or brace immobilisation is an option. Internal surgical fixation or stabilisation can treat or prevent fractures.[2] Surgical excision and reconstruction with methylmethacrylate bone cement may also be required. Postoperative radiotherapy is used to prevent fractures[2] and improve mobility.[3]

Bone metastases cause local osteolysis and various bone-modifying agents (such as the bisphosphonates and denosumab) that ***inhibit bone resorption*** have been tried, not only to correct hypercalcaemia of malignancy (p. 1167.2), but also to relieve bone pain and reduce the risk of fractures. Bisphosphonates are of benefit in patients with severe bone pain that is too widespread for local use of radiotherapy and does not respond to other analgesics.[8] Reviews[9,10] concluded that bisphosphonates significantly decrease skeletal morbidity, except for spinal cord compression. Benefits in terms of skeletal events are only seen after about 6 months of treatment.[9] Despite the integration of bisphosphonate use into clinical practice for bone metastases, the optimal timing, schedule, or duration of treatment remains to be determined.[3,6,9,11,12] It has been suggested that bone-modifying treatment should start when bone metastases are diagnosed and continue until no longer clinically relevant; they do not affect survival.[10,13] While some continue bisphosphonate treatment despite disease progression, others advocate changing to a more potent bisphosphonate, or stopping treatment altogether.[9] There are no data about the consequences of stopping bone-modifying treatment after one or more skeletal-related events. Starting bone-modifying agents in women with breast cancer without evidence of bone metastases is not recommended.[13] There is little evidence supporting the efficacy of one bone-modifying agent over another;[13] denosumab and the bisphosphonates clodronate, ibandronate, pamidronate, and zoledronate have all been used.[1,2,6,9,12,13] Of the bisphosphonates, those given intravenously have shown a more significant reduction in skeletal-related events than those given orally.[3,10] Denosumab has shown some benefit over zoledronate at delaying or preventing skeletal events in advanced breast cancer,[14] and was noninferior to zoledronate in other cancers or multiple myeloma.[15]

There is much interest in the use of bisphosphonates to *prevent* the development of bone metastases.[11,12] However, preliminary evidence of their efficacy was conflicting.

Systemic ***antineoplastic therapy*** should also be given if the primary tumour is chemosensitive. Endocrine treatment is usually preferred for patients with breast and prostatic cancers,[2] and can produce useful control of symptoms from bone metastases.

Atrasentan is a new drug under investigation.[1,6]

Malignant neoplasms of the brain. Metastatic brain cancer is the most common cause of intracranial tumours in adults, being up to ten times more common than primary brain tumours.[1] The cancers that most often metastasise to the brain are lung cancer, breast cancer, and melanoma,[1] as well as colorectal cancer, renal cell carcinoma, and adenocarcinoma.[2,3] CNS involvement in patients with acute leukaemia (see Acute Lymphoblastic Leukaemia, p. 692.3) or lymphoma (see CNS Lymphomas, p. 698.1) is also quite common. The frequency and natural history of *primary* brain tumours differ between children and adults. In adults, they are usually gliomas,[4] which are classified histologically into astrocytomas, oligodendrogliomas, and oligo-astrocytomas.[5] Astrocytomas are defined by grades: I (pilocytic), II (diffuse), III (anaplastic astrocytoma), and IV (glioblastoma multiforme), the latter two of which are the most common and are considered malignant.[4,6] Low-grade astrocytomas[7] and malignant medulloblastomas are the commonest primary brain tumours in children.[8]

The symptoms of primary and metastatic cranial neoplasms are those of local pressure and damage to the brain (such as focal seizures and neurological defects), of displacement of brain structures (like oculomotor paresis with tentorial herniation), and of raised intracranial pressure (such as impaired consciousness and papilloedema). Memory loss and personality changes may occur, and headache, nausea and vomiting are common symptoms.

The standard therapy for **primary brain tumours** involves surgery and radiotherapy.[4,5,8,9] General medical management includes control of seizures with antiepileptics, the use of corticosteroids such as dexamethasone to control peritumoral oedema, anticoagulation to manage venous thromboembolism, and treatment for fatigue.[4,6]

Surgery is generally used to relieve compression and cerebral oedema, establish diagnosis, decrease the need for corticosteroids, and where feasible resect as much of the tumour as possible.[1,4,6,10] Progress in image-guided resection has improved safety, and although some consider it to have increased the extent of resection,[4,8] others note it has not been as beneficial as expected for gliomas.[10] The value of surgery in prolonging survival is controversial;[4,10] there is some evidence that extensive resection prolongs survival,[1,4] but this may be biased[10] by the selection of younger fitter patients for surgery.

Adjuvant *radiotherapy* is widely used after surgical resection for malignant tumours in adults and children.[1,4-6,8,10] There is no consensus on the timing of the start of radiotherapy.[10] Strategies to increase the dose of radiation delivered to the tumour by using brachytherapy (radioactive implants) or stereotactic radiosurgery (a technique using highly focused beams of radiation) have failed to improve survival.[4]

Local chemotherapy using biodegradable polymers impregnated with carmustine, placed intraoperatively into the surgical cavity, has been shown to improve survival in patients with either newly diagnosed or recurrent malignant glioma.[1,9,10] While some recommend this after maximal resection in high-grade disease,[1] others consider it to have only marginal benefit over adjuvant radiotherapy alone.[6]

The role of adjuvant *systemic chemotherapy* for primary brain malignancies has been unclear, in part because of the difficulty in finding drugs that can cross the blood-brain barrier; until the advent of temozolomide, treatment was usually based on nitrosoureas such as carmustine and lomustine.[1,3,11] The PCV regimen (procarbazine, lomustine, and vincristine) has been widely used in the treatment of gliomas after surgical resection and radiation therapy.[5,10] The value of this regimen was called into question by a large randomised study of adjuvant PCV plus radiotherapy versus radiotherapy alone in high-grade astrocytoma, in which PCV provided no additional survival benefit.[12] However, a meta-analysis including this and 11 smaller studies found that giving some form of adjuvant chemotherapy (usually based on nitrosoureas) modestly improved survival in adults with high-grade glioma.[13] Temozolomide, an oral alkylating agent, was initially used for the treatment of recurrent gliomas.[5] Its use during and after radiotherapy in newly diagnosed glioblastoma, usually after debulking surgery, has improved survival,[14] and this regimen has largely replaced the nitrosoureas in the management of glioma.[1,4,6,9-11,15,16] For patients who progress after chemotherapy, there is no established second-line regimen.[6] Second-line agents include irinotecan, cisplatin or carboplatin, and platinum-based regimens.[1,5] Bevacizumab plus irinotecan may be tried for recurrent disease.[1,16]

In *children*, the extent of resection correlates with survival and maximal safe resection is a major therapeutic goal.[17,18] The biology of brain tumours in very young children appears to differ from that seen in older children.[17,19] Chemotherapy is used to delay radiotherapy, reduce its dose or frequency, or even eliminate the need for it altogether, as it can cause neurodevelopmental damage.[7,17-21] Generally, in children older than 3 years, surgery can be followed by a reduced dose of craniospinal irradiation, while although those younger than 3 years are considered high-risk, radiotherapy is avoided if at all possible in this group.[18]

Common combination chemotherapy regimens used in children have included cisplatin or carboplatin, cyclophosphamide, etoposide, ifosfamide, lomustine, methotrexate, procarbazine, topotecan, vincristine, or vinblastine.[17,19,20] Temozolomide and oxaliplatin warrant further investigation.[19] Different tumour types vary in their sensitivity to chemotherapy.

Autologous haematopoietic stem cell transplantation (p. 1937.1) is also used for various paediatric brain tumours to limit the adverse effects of chemotherapy, and to maximise the dose of chemotherapy that can be used;[17-21] results have been conflicting and appear to depend on the type of tumour. Preparative regimens used have been based on thiotepa, busulfan, or melphalan, as well as high-dose combination chemotherapy regimens.[17,20,21] Intrathecal chemotherapy with drugs such as methotrexate, is also used.[19]

Since present regimens for primary brain tumours are far from optimal, alternatives continue to be tried.[1] Strategies include optimising current regimens, investigating different combinations of drugs, as well as methods to improve delivery across the blood-brain barrier.[5] Other treatments investigated include single or multitargeted kinase inhibitors, ligand-toxin conjugates, antisense oligonucleotides, and gene therapy.

Whole-brain radiation therapy (WBRT) is the common choice for most patients with **brain metastases**.[1,2,22] Surgery plus WBRT may be suitable for those with a single brain metastasis, especially if prognosis is favourable and systemic disease controlled.[1,2] Stereotactic radiosurgery (with or without WBRT) may be an alternative for patients with isolated metastases and for whom surgery is not an option.[1,2,22,23]

Chemotherapy has traditionally had a limited role in the treatment of brain metastases.[2,23] The blood-brain barrier was thought to limit delivery of drugs to the site of disease, especially those drugs that are large and less lipid-soluble. However, the blood-brain barrier appears to be partially dysfunctional in cerebral metastatic disease, and systemic therapy has led to responses in patients, especially in those who are chemotherapy-naive or who have not been heavily pre-treated.[2,3,22,23] It has been noted that the use of corticosteroids should be limited as they may restore an otherwise disrupted blood-brain barrier.[3] The chemosensitivity of the primary tumour may also be an important factor in determining response,[2,3,22,23] although many tumours that metastasise to the brain are not very chemosensitive.[1] In addition, metastases may progress and be resistant to further therapy simply due to prior exposure to the drugs used.[3,22] Thus the choice of drug needs to take previous treatment regimens into consideration.[3] Aside from common chemotherapy regimens used to treat the primary tumour (see Table 1, p. 719), other agents used for brain metastases include temozolomide (with or without radiotherapy), capecitabine, high-dose methotrexate, gefitinib, irinotecan, and topotecan. Radiosensitisers used include the platinum analogues and motexafin gadolinium.[1-3,22,23]

A brain cancer vaccine (DCVax-Brain) is also being investigated.

Malignant neoplasms of the breast. Cancer of the breast is the most common malignant neoplasm in women. The disease is rare under the age of 25, and increases in incidence with age, although the rate of increase slows after the menopause. Risk factors include a family history (women with inherited BRCA1 or BRCA2 mutations are at higher risk), and reproductive hormonal factors such as early menarche, late menopause, nulliparity, and older age at birth of first child. Oral contraceptives and postmenopausal HRT are also associated with a small excess risk (see Carcinogenicity, Breast, on p. 2234.2 and p. 2246.3 respectively).

Ductal carcinoma in situ (DCIS) is a tumour localised to the breast ducts with no evidence of invasion. Invasive breast cancer can be divided into three main groups:

- early breast cancer (operable, primary, stage I/II)
- locally advanced disease (inoperable local, stage III)
- advanced disease (metastatic; stage IV)

Breast cancer is an extremely heterogeneous disorder, and the clinical course is consequently very variable; such factors as patient age and menopausal status, tumour size and grade, involvement of axillary lymph nodes or skin, and presence of hormone receptors within the tumour may be a guide to the extent and aggressiveness of disease, and hence have prognostic significance for treatment.[1] Early determination of oestrogen-receptor (ER) status and for overexpression of HER2 (human epidermal growth factor receptor-2) is recommended, since they are of value in determining response to certain treatments.[1-3] Progesterone-receptor (PR) status may also be measured, although UK guidelines recommend against routine assessment in patients with early breast cancer.[2]

About 20% of all cancers of the breast detected by mammographic screening are **ductal carcinoma in situ** (DCIS),[4-7] the management of which still has some areas of controversy. Most patients with DCIS will be offered breast-conserving surgery,[1,8,9] although mastectomy, which was historically preferred, is still the treatment of choice in high-risk patients.[1,4-6] Radiotherapy is usually recommended after successful breast-conserving surgery,[1,7-9] as it reduces the rate of recurrence and the risk of developing invasive disease (although it does not affect survival); there may be a subgroup of women in whom it is unnecessary, but there is controversy as to how to define the group. Studies examining the use of adjuvant tamoxifen have produced conflicting reports of benefit on recurrence,[5,6] and again, there is no proven effect on survival. UK guidelines recommend against use of adjuvant tamoxifen in patients with DCIS,[2] but some recommend it in selected patients such as those with ER-positive DCIS,[1,9] in young patients, and in those without risk factors for potential adverse effects.[7] Adjuvant use of newer oestrogen modulators such as anastrozole is also under investigation.[5-7]

In patients with **early disease** (stage I or II; a relatively small tumour with no or limited nodal involvement) the prognosis is fairly good. ***Primary treatment*** is surgical,[1,2,9,10] using breast-conserving surgery or mastectomy.[1,9,11] Neoadjuvant chemotherapy should be considered for those women with large tumours who are otherwise suitable for breast-conserving surgery, in order to downstage the tumour; there is no evidence of a survival benefit.[1,11,12] Chemotherapy regimens are the same as those recommended for adjuvant treatment (see below).[1] Adjuvant radiotherapy is recommended after breast-conserving surgery, as it reduces local recurrence rates. Radiotherapy is generally recommended after mastectomy in women with four or more positive lymph nodes, considered to be at high risk of recurrence.[1,9,11]

Further adjuvant therapy with cytotoxic chemotherapy or hormonal therapy as well as ovarian ablation or suppression has been tried in order to eradicate the micrometastases which cause relapses. Studies by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) have confirmed the benefits of adjuvant therapy and attempted to determine which women derive most benefit and which regimens are most effective. Analyses from these[13] and the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 and B-20 studies[14] permitting up to 15 years of follow-up have shown that:

- all women with early-stage breast cancer benefit from adjuvant therapy (although the size of the benefit varies)
- the benefit continues to increase with time, suggesting that adjuvant therapy is curative in a proportion of women who would otherwise relapse
- about 6 months of anthracycline-based chemotherapy reduces the annual death rate due to breast cancer by about 38% in women under 50 years of age at diagnosis, and about 20% in those aged 50 to 69 at diagnosis (too few women over 70 were given chemotherapy to estimate benefit in this group)
- this survival advantage occurs largely independent of oestrogen receptor (ER) status, nodal status, or other tumour characteristics
- adjuvant regimens including an anthracycline are more effective than those without a drug of this class
- in women with ER-positive disease, about 5 years of treatment with adjuvant tamoxifen reduces the annual death rate due to breast cancer by around 31%, largely independent of age, other tumour characteristics, or the use of chemotherapy
- combined chemotherapy and tamoxifen therefore increases the survival benefit further: for middle-aged women with ER-positive disease the breast-cancer mortality rate over 15 years would be approximately halved by 6 months of anthracycline-based chemotherapy followed by 5 years of adjuvant tamoxifen
- ovarian ablation (by surgery or irradiation) or ovarian suppression with a gonadorelin analogue also appear to reduce the mortality due to breast cancer, but that the advantage only applies where other adjuvant therapies are not given

Although these data help in making therapeutic decisions, the size of the benefit will always be less in patients with good prognosis; in the most favourable cases (small tumours with no involved nodes) the incremental benefit may be too small to warrant adjuvant treatment.[1] Tailoring systemic adjuvant therapy to the patient is important, and age and clinical characteristics alone are not adequate grounds to make the judgement: appropriate prognostic markers should be considered.[14,15] Patients with tumours considered hormone-responsive (ER-positive or PR-positive) may receive hormonal therapy alone, or with chemotherapy. Patients with hormone non-responsive tumours (ER-negative or PR-negative) derive greater benefit from chemotherapy and should not receive hormonal therapy.[1,9] In addition, most patients with HER2 overexpression should receive adjuvant trastuzumab as well,[1,9] as studies have shown improvements in both disease-free and overall survival,[16,17] and the benefits are independent of ER status.[1] However, there are concerns about cardiotoxicity.[18,19]

Anthracycline-based regimens are widely used for adjuvant ***chemotherapy***, replacing earlier historical regimens such as CMF (cyclophosphamide, methotrexate, and fluorouracil) with those such as FAC or CAF (cyclophosphamide, doxorubicin, fluorouracil), AC (doxorubicin plus cyclophosphamide), and their many variants. Anthracycline-containing regimens appear to be superior to non-anthracycline-containing regimens for those with HER2-positive tumours.[1,19] The EBCTCG analysis could not show any difference in efficacy between anthracycline regimens,[13] but regimens based on epirubicin have gained in popularity in many centres, since its lower cardiotoxicity compared with doxorubicin means that higher doses can be given.[10] Addition of a taxane (docetaxel or paclitaxel) to an anthracycline-based regimen appears to improve disease-free and overall survival.[19-21] (UK guidelines recommend the use of docetaxel rather than paclitaxel.[2])

Reducing dose intensity of chemotherapy results in poorer survival, and this has led to the hypothesis that higher doses may offer more benefit, particularly in patients at high risk of recurrence. However, despite some positive reports of high-dose chemotherapy with stem-cell support, randomised studies have largely failed to show any benefit of high-dose over standard-dose therapy.[22,23]

Hormonal therapy is only effective in hormone-responsive disease and results of the analyses above established 5 years of tamoxifen as the standard of care in ER-positive disease.[1,10] However, in postmenopausal women, there is evidence that 5 years of anastrozole is an effective alternative to tamoxifen,[24] and treatment with letrozole was found to further reduce the risk of recurrence compared with tamoxifen after 2 years of follow-up.[25] Studies in which 2 to 3 years of tamoxifen were followed by an aromatase inhibitor (anastrozole, exemestane, or letrozole) compared with continued tamoxifen found that disease-free survival was improved with sequential therapy; overall survival was improved in some studies but unaffected in others.[1,26] In addition, although extending tamoxifen beyond 5 years is not generally advocated, there may be significant benefits to following a full course of tamoxifen with extended therapy with an aromatase inhibitor.[27] Thus, aromatase inhibitors can be recommended either as initial, sequential, or extended therapy in postmenopausal women,[1,2,9,26,28] and UK guidelines[2] suggest that tamoxifen should only be used for initial therapy in those with contra-indications to an aromatase inhibitor, although others have questioned the evidence for their routine initial use.[29]

The optimum length of extended or sequential therapy has yet to be determined, but US guidelines allow for 5 years of an aromatase inhibitor after a full course of tamoxifen.[1] Prolonged use of tamoxifen alone is considered an acceptable option by some in those women who cannot tolerate an aromatase inhibitor,[30] and there is some preliminary evidence that 10 years of tamoxifen may be superior to 5 years,[19] although women should be closely monitored for endometrial cancer development.[30] Aside from some suggestion that breast cancer may be sensitive to steroidal aromatase inhibitors (such as exemestane) even after failure of a nonsteroidal inhibitor (such as anastrozole or letrozole),[27] there is no compelling evidence for meaningful efficacy or toxicity differences between the aromatase inhibitors.[1]

Aromatase inhibitors are not effective for hormonal therapy in premenopausal women with ER-positive disease;[1,9,19] tamoxifen is either given alone or it may be combined with ovarian suppression (using a gonadorelin analogue) or ovarian ablation (via oophorectomy or irradiation).[1,2,9,31]

The optimum sequencing of surgery, radiotherapy, and chemotherapy/hormonal therapy has been investigated. Concurrent chemoradiotherapy (chemotherapy given with radiotherapy) is generally considered too toxic, although some allow for its use with the CMF regimen. Otherwise sequential therapy is preferred, with adjuvant chemotherapy given before radiotherapy.[1] Whether tamoxifen should be given concurrently or sequentially with radiotherapy remains unclear, despite several studies addressing the question;[32] US guidelines allow for either option.[1] Where both chemotherapy and hormonal therapy are given, it is recommended that chemotherapy should precede hormonal therapy.[1]

In **locally advanced** breast cancer (stage III) the few patients for whom initial surgery is feasible may be treated as those with high-risk early breast cancer (see above). However, for inoperable disease, anthracycline-based neoadjuvant chemotherapy is standard, which usually results in sufficient tumour shrinkage to allow surgical management, as well as allowing assessment of the responsiveness of the tumour to subsequent treatment.[1,8] Radiotherapy and adjuvant chemotherapy are used after surgery, followed by hormonal therapy if the disease is ER-positive. Adjuvant trastuzumab is also given for those patients with overexpression of HER2. Adjuvant chemotherapy regimens should take into account what was given neoadjuvantly. For disease that does not respond to neoadjuvant chemotherapy, thus remaining inoperable, additional systemic chemotherapy and/or radiotherapy may be tried.[1,2]

The aims of therapy in **advanced or metastatic disease** (stage IV) are palliation and prolongation of life; cure is generally not possible with current regimens,[1,33] and it is often appropriate to select therapy on the basis of previous therapy and patient factors.[19] In women with ER-positive, limited, or asymptomatic disease, ***hormonal therapy*** is preferred: US guidelines advocate an aromatase inhibitor (anastrozole, letrozole, or exemestane), or an anti-oestrogen (usually tamoxifen) for first-line hormonal therapy in postmenopausal patients; second-line therapy options include fulvestrant, toremifene, progestogens such as megestrol, androgens such as fluoxymesterone, or oestrogens such as ethinylestradiol.[1,28] Premenopausal women should undergo ovarian ablation (by surgery or irradiation) or suppression with a gonadorelin analogue, and then be treated as for postmenopausal women. Initial hormonal therapy is continued until disease progression or unacceptable adverse effects occur at which point up to 2 further hormonal regimens may be tried. If these fail, or symptomatic visceral disease develops, the patient is a candidate for chemotherapy. UK guidelines suggest similar management, with the use of an aromatase inhibitor in postmenopausal women, and tamoxifen and ovarian suppression in premenopausal women who have not previously had tamoxifen, or ovarian suppression alone in those who have.[3]

Patients with ER-negative disease, or tumours that are not localised, or who have symptomatic visceral metastasis, or women who have ER-positive tumours refractory to hormonal therapy, should receive ***chemotherapy***.[1,3,33] The taxanes, and in particular docetaxel (which is considered the reference drug in metastatic breast cancer[34]) are acknowledged to be effective,[35] and anthracyclines (doxorubicin, epirubicin, and the related drug mitoxantrone) are also widely used,[1] although a systematic review suggested that their benefits in terms of tumour response did not

extend to improved survival.[36] The benefits of platinum-based therapy have not been established.[37] Capecitabine, gemcitabine, and vinorelbine are also active single agents.[1,3,33]

There is considerable uncertainty as to whether combination regimens offer any substantial benefit over sequential use of single drugs. Although a systematic review of older regimens suggested benefit from combination chemotherapy,[38] and this is the usual standard of care where therapy has curative intent,[34] some do not consider the evidence of benefit from combination therapy persuasive, since toxicity is likely to be increased.[1,33] Nonetheless, established combination regimens, including CMF and various anthracycline- and taxane-based regimens are in use,[1,8] along with newer combinations, such as gemcitabine plus paclitaxel, vinorelbine plus epirubicin, or paclitaxel plus bevacizumab.[1,33] However, while time to progression is improved by paclitaxel plus bevacizumab,[1] no significant effect on overall survival has been shown with bevacizumab combinations, and which patients may benefit is as yet unclear.[33] Ixabepilone with or without capecitabine, is another option.[1,39] In patients with HER2-overexpressing tumours, trastuzumab may be added to chemotherapy:[1,33] the combination is markedly more effective in this group than chemotherapy alone,[34] although use with anthracyclines may be problematic because of the increased risk of cardiotoxicity.[1] Trastuzumab or lapatinib may also be added to hormonal therapy in those with hormone-receptor positive disease.[1,33] UK guidelines recommend stopping trastuzumab once disease progresses outside the CNS, although it should be continued if progression is confined to the CNS alone.[3] Capecitabine plus lapatinib is an option for those refractory to trastuzumab therapy.[1,33]

For further information on common chemotherapy regimens, see Table 1, p. 719.

Higher response rates have been achieved by intensive regimens, combined with autologous bone marrow transplants or stem cells in some studies. However, the results of randomised studies have been disappointing, and a systematic review found no improvement in overall survival with the use of stem-cell supported high-dose therapy in metastatic breast cancer.[40]

The use of bisphosphonates in women with bone metastases reduces bone pain and skeletal complications such as fracture, spinal cord compression, and hypercalcaemia (see Malignant Neoplasms of the Bone, p. 700.3). Radiotherapy is also used for bone pain, and for the treatment of brain metastases (see Malignant Neoplasms of the Brain, p. 701.2).

PROPHYLAXIS OF BREAST CANCER. The recognition of factors increasing the risk of breast cancer (p. 702.1), and particularly the identification of specific genes that confer a high risk, has spurred the search for effective ways of preventing the disease. Current options, other than regular screening to detect the cancer at early stages, include surgery, drug therapy (below), and possibly some life-style modifications.[1-7]

Prophylactic bilateral mastectomy and prophylactic salpingo-oophorectomy have both been shown to substantially decrease the incidence of breast cancer in moderate- and high-risk women and in known BRCA1/2 mutation carriers.[2,4-7] Mastectomy is recommended for women at high risk, such as those with genetic factors, or for women with a history of lobular carcinoma *in situ*, or thoracic radiation.[2] Bilateral salpingo-oophorectomy is generally limited to women with a known or strongly suspected BRCA1/2 mutation.[2,4,7]

The association between lifestyle modifications and breast cancer risk is not clear-cut,[2] and there is no evidence that specific dietary components can effectively reduce breast cancer risk.[7] Nevertheless, women judged to be at moderate or high risk may be advised to avoid alcohol or to decrease alcohol consumption, and postmenopausal women may benefit from weight loss.[2,7]

Treatment with tamoxifen as part of the adjuvant management of early breast cancer is associated with a reduced risk of developing cancer in the other breast. This led to the suggestion that prophylactic tamoxifen might prevent the development of breast cancer in women at risk, and to studies to test this hypothesis. These studies were not without controversy, since the risk/benefit for tamoxifen use in healthy women differed from that in women with breast cancer. The first study to be reported was the US National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 study,[8] which randomised 13 388 women to 5 years of treatment with tamoxifen or placebo. Participants were either aged 60 years or older, had a history of lobular carcinoma in situ, or had a 5-year predicted risk of developing breast cancer of greater than 1.66% (as assessed by number of first-degree relatives with breast cancer, number of previous breast biopsies, presence of atypical hyperplasia, and reproductive factors). In this study there was a highly significant 49% reduction in the occurrence of invasive breast cancer in women given tamoxifen (21.4 cancers prevented per 1000 women treated). The incidence of non-invasive breast cancer was reduced to a similar extent. Tamoxifen reduced the incidence of oestrogen-receptor (ER) positive, but not ER-negative, tumours. Adverse effects of tamoxifen included a modest increase in the risk of endometrial cancer and vascular events (stroke and pulmonary embolism). Although this study was prematurely unblinded, and all women were offered a 5-year course of tamoxifen, follow-up continued for 7 years and the incidence of breast cancer remained relatively constant for the 2 years after tamoxifen therapy was stopped.[9] Preliminary results from 2 smaller randomised European studies did not confirm the benefit of tamoxifen in breast cancer prevention. The Italian study[10] was in hysterectomised women with no particular risk for breast cancer, and because of its size may not have been sufficiently powered to detect an effect of tamoxifen. The full follow-up[11] of 5 years of treatment in this study found no difference in breast cancer incidence between tamoxifen and placebo groups. A subgroup analysis of women at high risk of ER-positive breast cancer did find a protective effect from tamoxifen, and there was an apparent protective effect for women in this group who used HRT. However, this group was not identified at randomisation of the study and these results need to be confirmed. The British study[12] of 8 years of tamoxifen or placebo was in women with a first-degree family history of breast cancer, and their median age was younger than in the US study. Although preliminary results showed no benefit from tamoxifen, follow-up for a median of about 13 years did find a reduction in the risk of ER-positive tumours.[13] This reduced risk also appeared to improve with longer follow-up. Initial results of a further placebo-controlled study (IBIS-I)[14] of women at increased risk of breast cancer found that during 5 years of tamoxifen use, the risk of all breast cancers was reduced by 32%. As in other studies, the reduction occurred in ER-positive tumours. Similar adverse effects were found with tamoxifen use, but there was also an unexpected increase in deaths from all causes in tamoxifen users. This may be associated with the excess in thromboembolic events reported, although statistical variability could not be ruled out. Extended follow-up[15] for a further median of 8 years found that the beneficial effect of tamoxifen was maintained, and that reduction in the risk of ER-positive tumours increased with longer follow-up. However, the rate of adverse effects of tamoxifen reduced after treatment stopped. A retrospective analysis[16] of the NSABP P-1 data for women who had developed invasive breast cancer found that in carriers of the oncogene BRCA2, but not BRCA1 carriers, there was a reduction in breast cancer similar to the reduction in ER-positive cancer among all women in the study. The numbers available, however, were too small to be statistically significant, and it is therefore still not known if tamoxifen can reduce the risk of breast cancer in patients with these mutations.

Another anti-oestrogen, raloxifene, has reportedly shown a reduction in breast cancer risk while its effects on osteoporosis were being studied.[17] A further large placebo-controlled study[18] that included the incidence of breast cancer as a primary outcome also found a reduction with about 5 years of raloxifene use. There was a 55% lower risk of invasive ER-positive cancer (absolute risk reduction of 1.2 cancers per 1000 women treated for 1 year), but there was no effect on ER-negative disease. The effect of raloxifene has also been directly compared with tamoxifen in women with a predicted increased risk of breast cancer (STAR study).[19] After up to 5 years of use, the incidence of invasive disease was similar in both groups, suggesting that raloxifene is as effective as tamoxifen in reducing the risk of developing invasive breast cancer in this group of women. The aromatase inhibitors, anastrozole and exemestane, are also under investigation.[2,4,6,20]

From these studies, tamoxifen prophylaxis has been shown to reduce the incidence of ER-positive breast cancer in women at increased risk,[21] although there are limited data for women with BRCA1 and 2 mutations.[2] Tamoxifen remains the drug of choice for premenopausal women at increased risk of breast cancer;[2,5,6,22] raloxifene is not recommended for use in this population. In postmenopausal women, treatment is influenced by age, presence of uterus, and comorbidities.[2] Either tamoxifen or raloxifene is recommended for use in women at high risk;[2] some[5,6] recommend raloxifene over tamoxifen due to its more favourable adverse effect profile.

Other candidates for the prevention of breast cancer include plant oestrogens (phytoestrogens) such as those in soya.[6] Epidemiological evidence suggests that diets high in these compounds may be protective, but there are many confounding factors and inconsistencies in the data available.[23] It was thought that retinoids might also be protective, but a secondary prevention study of fenretinide failed to show any benefit.[24] Regular use of aspirin and other NSAIDs has been reported to decrease breast cancer risk, but this has not been supported in other studies.[4,6,7] Similarly, inconsistent associations have been reported with the use of statins; some suggest that additional study of lipophilic

statins is warranted.[6] Use of luteinising hormone releasing hormone (LHRH) agonists is also under investigation, although adverse effects may pose a problem.[6]

For the suggestion that bisphosphonates may reduce the risk of breast cancer, see Malignant Neoplasms of the Breast, under Bisphosphonates, p. 1174.2.

MALIGNANT NEOPLASMS OF THE MALE BREAST. Breast cancer can occur in men, although it has a much lower incidence than in women. Risk factors are not well understood, but it may sometimes be associated with abnormalities of sex hormone metabolism, including those acquired through liver disease or testicular trauma. In addition, the inherited mutation BRCA2, which is associated with an increased risk of breast cancer in women, also increases the risk of breast cancer in men; occasionally BRCA1 mutations are seen. Men with Klinefelter's syndrome, a sex chromosome anomaly, may be predisposed to development of breast cancer. Possible environmental risk factors include industrial exposure to chronic heat. Other risk factors include smoking, obesity, and alcohol consumption.

A painless mass is the most common presentation; nipple discharge may occur. Other less common symptoms include breast tenderness, swelling, or nipple itching. Diagnosis is often at a late stage. Breast cancer in men occurs at a slightly older median age than in women (60 to 70 years), and is more likely to be oestrogen-receptor (ER) positive. Survival by stage appears to be similar to that in women, with an overall 5-year survival about 40 to 65%.

Treatment is similar to that for women (see p. 702.1).[1-4] Primary management for *early* or *localised* disease is surgical and usually involves simple or radical mastectomy with axillary lymph node dissection, although breast-conserving surgery is also used. Because of the rarity of the disease large controlled studies are lacking but studies in limited numbers of men and extrapolation from results in women suggest that neoadjuvant and adjuvant therapy should be considered on the same basis as for women. Radiotherapy may be used to reduce the rate of local recurrence in those considered at high risk. As most male breast cancers are ER-positive, adjuvant hormonal therapy with tamoxifen is commonly used.[1-4] Use of aromatase inhibitors such as anastrozole or letrozole is considered controversial, since inhibition of oestrogen may be incomplete unless orchidectomy is also performed;[3,4] use with a gonadorelin analogue has been suggested.[4] Males with ER-negative disease should be offered chemotherapy. Regimens are usually anthracycline- or taxane-based; common combination regimens include CMF (cyclophosphamide, methotrexate, and fluorouracil) and FAC (fluorouracil, doxorubicin, and cyclophosphamide).[2-4] Adjuvant trastuzumab should be considered for men with high-risk HER2-positive disease.[2-4]

In *advanced* metastatic disease tamoxifen is generally the first choice treatment for ER-positive disease, although there is evidence of benefit from aromatase inhibitors such as anastrozole or letrozole. Again, combination with gonadorelin analogues has been suggested because of the risk of incomplete oestrogen inhibition.[3] Chemotherapy is used for patients with ER-negative disease, or for those who progress on hormonal therapy.[2-4] Regimens are usually doxorubicin-based, such as FAC.[2,4] For further information on common chemotherapy regimens, see Table 1, p. 719. There are reports of response to trastuzumab in males with metastatic HER2-positive disease,[2,4] and some consider its use justified in this instance.[3] Hormonal ablation by adrenalectomy or orchidectomy is also effective, but has become less popular since the advent of tamoxifen.

Malignant neoplasms of the cervix. Cancer of the uterine cervix is one of the most common cancers in women, accounting for about 12% of all female malignancies. It is associated with early sexual activity and a high number of sexual partners, and the presence of human papillomavirus (HPV); high-risk types of the virus (HPV-16 and 18) that produce proteins E6 and E7 inactivate host tumour suppressor proteins and thus encourage malignant transformation. Smoking and long-term use of oral contraceptives (p. 2235.1) may also be risk factors. Widespread screening has meant that in many women the disease has been detected in the preinvasive or early stages, when the prognosis is excellent to good. An HPV vaccine is available in some countries for the primary prevention of cervical cancer.

Preinvasive cervical lesions (cervical intraepithelial neoplasia; CIN) may resolve spontaneously if low-grade (CIN1), and may be monitored by repeat screening or HPV testing.[1,2] High-grade CIN (CIN2; cervical dysplasia) and cervical carcinoma *in situ* (CIN3) may progress to invasive carcinoma and are usually treated by ablation or excision.[1,2] Conisation of the cervix (cone biopsy) may be used to rule out the presence of invasive disease.[3,4]

Invasive cervical cancers are mostly squamous cell in origin (about 80%), with about 20% being adenocarcinoma.[3,5] Invasive cervical cancers may be divided into early-stage, locally advanced, and metastatic. The earliest stage (IA1) may be treated by conisation of the cervix (which maintains fertility) or simple hysterectomy. Other *early-stage* cancers may be treated by surgery (radical hysterectomy) or by radiotherapy (usually brachytherapy with pelvic irradiation).[3-7] For patients at this stage who wish to preserve fertility, radical trachelectomy (removal of the cervix) with pelvic lymphadenectomy may be an option.[4-8] However, those with bulky tumours, poor prognostic factors, or high-risk features after surgery should be given postoperative pelvic radiotherapy with concurrent chemotherapy (chemoradiotherapy), which has been shown to improve survival.[3-6,9,10] Most regimens use cisplatin, either alone or with fluorouracil.[3,5,6,8-10] Hydroxycarbamide has also been used by some centres, but is less effective than cisplatin.[5]

Patients with *locally advanced* cervical cancer are also usually treated with primary chemoradiotherapy using cisplatin-based regimens,[3-5,7-9] as it improves overall and progression-free survival.[11] A meta-analysis of 13 studies (including patients at various stages, from early through to metastatic) confirmed the survival benefit of chemoradiotherapy in cervical cancer; there was no significant difference between platinum- and non-platinum-based chemoradiotherapy.[12] Neoadjuvant chemotherapy has been tried and although there is some indication that its use before surgery might be of benefit in bulky early-stage or locally advanced disease, no survival advantage has been shown and this approach remains controversial; it does not appear to be beneficial before radiotherapy.[10,13]

For local recurrence of disease, treatment options include radiotherapy if it has not already been used, more extensive surgery, or cisplatin-based chemoradiotherapy.[3-5,14] Patients with recurrence who are not candidates for surgery o radiotherapy may be offered palliative chemotherapy o best supportive care; chemotherapy regimens are the sam as those used for metastatic disease.[5]

Treatment of *metastases* is palliative; radiotherapy chemotherapy, or chemoradiotherapy can be used.[3,5,7,1 Cisplatin, carboplatin, or paclitaxel may all be considered fo first-line monotherapy; if cisplatin has previously been use as a radiosensitiser a combination regimen of cisplatin wit either paclitaxel, topotecan, or gemcitabine is preferred carboplatin plus paclitaxel is also an option.[5] Drugs tha have been tried for second-line treatment include bevacizumab, docetaxel, epirubicin, fluorouracil, gemcitabine, ifosfamide, irinotecan, liposomal doxorubicin, mitomycin, pemetrexed, topotecan, and vinorelbine.[5,14] Many combination regimens have shown higher response rates and improvements in progression-free survival but not overall survival compared with monotherapy; however, the CT regimen (cisplatin plus topotecan) has shown an improvement in overall survival.[5,15] UK guidelines[6] recommend treatment with cisplatin plus topotecan (for cisplatin-naïve patients), or cisplatin plus paclitaxel, for all women with stage IVB or recurrent disease. For further information on common chemotherapy regimens, see Table 1, p. 719.

Malignant neoplasms of the endometrium. Cancer of the endometrium is a disease primarily of postmenopausal women, and is more common in developed than developing countries. Based on aetiology and pathology, endometrial cancer is generally classified into 2 subtypes:

- type I are the most common, with an endometrioid histology, and are mostly low-grade, with a background of endometrial hyperplasia. They are usually oestrogen-receptor positive, and associated with increased oestrogen exposure. Factors resulting in increased endogenous exposure include obesity, anovulatory infertility, early menarche, and late menopause. Exogenous factors include use of oestrogens without progestogens for hormone replacement therapy (p. 2247.3), and tamoxifen therapy (see Carcinogenicity, p. 861.3). Other associated findings include nulliparity, diabetes mellitus, and hypertension
- poorly differentiated or non-endometrioid type II cancers appear, in contrast, to be unrelated to high oestrogen concentrations, are often associated with endometrial atrophy, and often develop in non-obese women. They include serous or clear-cell carcinomas which are highly aggressive with a poorer prognosis; endometrial intraepithelial carcinoma is believed to be a precursor

Abnormal uterine bleeding is the most common sign of endometrial cancer, and all postmenopausal women with vaginal bleeding and other risk factors should be evaluated for the disease. In menopausal or premenopausal women, diagnosis may be delayed because abnormal bleeding patterns may not be so obvious. Type I endometrioid carcinomas are surgically staged according to the International Federation of Gynecology and Obstetrics (FIGO) system; type II are classed as high-grade by definition.

Surgery is the primary **therapy** for operable endometrial cancer;[1-7] total hysterectomy and bilateral salpingo-oophorectomy is usually performed, with lymph node dissection in selected cases. No further treatment is required in women with FIGO stage I disease who are at low risk of recurrence. In those with stage I disease and a higher risk of recurrence, adjuvant vaginal brachytherapy or pelvic irradiation are used. In all other women, adjuvant radiotherapy is given, the field being tailored depending on the disease stage.[2-6] Adjuvant hormonal therapy with a progestogen has not been shown to be effective.[8] However, progesterone therapy has been used for young women with endometrial hyperplasia who wish to preserve their fertility, as well as for women who are poor surgical candidates.[3] There are a few studies of adjuvant chemotherapy in women with early-stage disease at high risk of recurrence, but no significant survival benefit has been seen.[1,2,4,6,9,10]

For women with advanced, recurrent, or metastatic disease, adjuvant chemotherapy or hormonal therapy may be considered as treatment options,[2-6,10,11] although response rates are only up to about 30%, and evidence for a survival benefit is questionable.[12] Progestogens such as medroxyprogesterone acetate are likely to be preferred because of their better tolerability.[2,4,5,11] Tamoxifen also produces minor benefit;[3] alternation with progestogens may prolong the response to hormonal therapy.[2] Well-differentiated tumours, long disease-free interval, and positive hormone receptor status are factors that suggest increased response to progestogens.[3,7] When progestogens are ineffective, chemotherapy may be tried. Single-agent drugs of choice include cisplatin or carboplatin, doxorubicin, and paclitaxel.[2-4,6,9,11] Response rates are slightly higher with combination regimens;[9,13] these include cisplatin plus doxorubicin, sometimes with paclitaxel (the TAP regimen), or carboplatin plus paclitaxel.[2-6,10,11,13] TAP has been found to be more effective, but also more toxic than cisplatin plus doxorubicin.[3,6,10,12,13] The combination of carboplatin and paclitaxel has become standard in many centres in the management of advanced or recurrent endometrial cancer.[2,9,10] For further information on common chemotherapy regimens, see Table 1, p. 719. Drugs that are being investigated for endometrial cancer include bevacizumab, erlotinib, everolimus, sorafenib, temsirolimus, and trastuzumab.[9]

For those with medically inoperable disease, radiotherapy is well-tolerated and can provide long-term progression-free survival.[1-3]

Malignant neoplasms of the eye. Tumours of the orbit of the eye in adults are most commonly metastases from primary lesions elsewhere in the body, usually in the breast or lung. Radiotherapy using external beam radiation or brachytherapy with iodine-125 is given for control of visual symptoms unresponsive to chemotherapeutic treatment of primary disease.[1]

Primary eye tumours are rare. In children, the most common intra-ocular tumour is retinoblastoma (see p. 717.2), and the most common orbital tumour is rhabdomyosarcoma (see Soft-tissue Sarcomas, p. 718.2). In adults, primary CNS lymphoma (see p. 698.1) can originate in the eye. However, the most common primary intra-ocular cancer in adults is **uveal melanoma**, which accounts for 80% of all primary ocular cancers.[2] The incidence is greater in Caucasians, and less common in brown-eyed individuals; average age at presentation is in the sixth or seventh decade.[2,3] About 40% of patients are asymptomatic, while others present with blurred or distorted vision, visual field loss, or seeing flashing lights.[3] Untreated, uveal melanomas result in loss of vision.[3] If metastasis occurs it is usually to the liver, and survival is poor;[2-4] factors associated with metastatic spread include large tumour size, ciliary body involvement, local tumour recurrence after conservative treatment, and rapid tumour regression after radiotherapy.[3]

The main objective of ***treatment*** is to prevent metastatic spread.[3] Treatment options for uveal melanomas include observation of indeterminate pigmented lesions, or eye-conserving therapies, which include brachytherapy (with iodine-125 or ruthenium-106), radiotherapy, local resection, or phototherapy such as photocoagulation or laser-induced hyperthermia (transpupillary thermotherapy).[2,3] Enucleation (removal of the eye) does not offer any survival advantage over conservative treatment, and is indicated only when eye-conserving therapy fails or for large tumours with extensive involvement of all uveal structures, diffuse growth, extensive retinal invasion or perforation, or bulky extra-ocular extension.[3]

Various treatments have been tried for patients with *metastatic* uveal melanoma. Surgical resection of isolated hepatic metastasis offers a survival advantage, but while there is continued interest in adjuvant therapy, metastatic disease is highly resistant to traditional systemic chemotherapy.[3,4] Most regimens have included dacarbazine, but these are considered to be ineffective.[4] Hepatic intra-arterial chemotherapy using fotemustine, or melphalan has been reported to be of benefit; carboplatin has also been used. Responses have been seen using hepatic artery chemoembolisation with cisplatin or carmustine; while local control was achieved with the latter drug, progression occurred at extra-hepatic sites. Embolisation with granulocyte-macrophage colony-stimulating factor (immunoembolisation) has also been reported to be effective, although data from large-scale studies are lacking. Targeted therapy is under investigation, using various drugs such as lenalidomide, sorafenib, sunitinib, and temozolomide, either alone or in combination chemotherapy regimens. Implantation of yttrium-90 microspheres is also under investigation.[4]

Ocular surface neoplasms (lesions of the conjunctival or corneal epithelium) may be benign or precancerous. They occur more commonly in sub-Saharan Africa, Australia, and regions where exposure to sunlight is more frequent. Exposure to solar UV radiation is a major aetiological factor, although human papillomavirus (HPV) and HIV infection may also have a role in the development of these tumours. Ocular surface neoplasms are usually treated with local excision. Because of a high recurrence rate, cryotherapy or brachytherapy is usually combined with surgery. Chemotherapy can be used where surgery is not feasible, or it may be used intra-operatively or as adjuvant treatment; some centres use chemotherapy initially for treating intra-epithelial ocular surface tumours. The most commonly used drugs are mitomycin C, applied topically in the form of eye drops (0.02% or 0.04%), fluorouracil (1%) eye drops, and interferon alfa-2b, which is used topically, subconjunctivally, or by intralesional injection. Patients who fail treatment with one drug may respond to another, and combination regimens have also led to tumour regression. Other drugs that have been reported to be effective when used topically include dinitrochlorobenzene, urea, tretinoin, and cidofovir.[5,6]

Malignant neoplasms of the gastrointestinal tract. Considered as a whole (and excluding skin cancers, which are often poorly registered) the gastrointestinal tract is the most frequent site of malignancies worldwide, although the frequencies of the various types of gastrointestinal cancer vary greatly from country to country. Genetic, environmental, and dietary factors may play a role in the aetiology of these cancers. Treatment may include surgery, radiotherapy, and chemotherapy, but the prognosis in most forms of gastrointestinal cancer is generally not encouraging.

Gastrointestinal cancers vary in their management depending on the site. Discussed in more detail below are:

- oesophageal cancer (below)
- stomach cancer (p. 706.1)
- colorectal cancer (p. 706.3) and its prophylaxis (p. 707.2)
- anal cancer (p. 708.1)

Cancers of the oral cavity are discussed under Malignant Neoplasms of the Head and Neck, p. 708.1.

Other cancers may sometimes manifest in the gastrointestinal tract, including the various endocrine neoplasms responsible for carcinoid syndrome (see Neuroendocrine Tumours, p. 716.3), and MALT lymphomas (p. 698.1). Gastrointestinal stromal tumours (GISTs) are soft-tissue sarcomas arising in the gastrointestinal tract, most commonly in the stomach and small bowel (see Soft-tissue Sarcoma, p. 718.2).

MALIGNANT NEOPLASMS OF THE OESOPHAGUS. Oesophageal cancer has perhaps the greatest variation in incidence between different geographical regions of any cancer, and is endemic in many parts of the world. The two major histological types are squamous cell carcinoma and adenocarcinoma. Squamous cell carcinoma is strongly associated with tobacco and alcohol use, and may occur as a second primary tumour in patients with tumours of the upper aerodigestive tract (see Malignant Neoplasms of the Head and Neck, p. 708.1). Adenocarcinoma is more common in non-endemic regions, including many developed countries, and is associated with Barrett's oesophagus (see Gastro-oesophageal Reflux Disease, p. 1810.2). Oesophageal cancer usually develops as a growth or ulcerative lesion of the oesophagus with extensive infiltration of the mucosa and invasion of neighbouring structures. Lymphatic and blood-borne metastasis occurs at a relatively early stage. Symptoms of pain and dysphagia due to obstruction occur late, and overall, more than half of all patients have unresectable or metastatic disease at initial presentation. Metastatic disease is associated with a median survival of less than 1 year.[1] The overexpression of epidermal growth factor receptor (EGFR), vascular endothelial growth factor receptor (VEGFR), and human epidermal growth factor receptor-2 (HER2) has been associated with a poor prognosis in patients with oesophageal and gastric cancers.

Patients with **locoregional disease** are treated with surgery if possible, or definitive chemoradiotherapy if they are not surgical candidates.[2-8] Chemoradiotherapy regimens usually include cisplatin, with a fluoropyrimidine (fluorouracil or capecitabine), or irinotecan, or a taxane. Alternatively, a fluoropyrimidine (such as fluorouracil or capecitabine) may be combined with either oxaliplatin or a taxane.[2] However, given the high rate of failure after surgery, in an attempt to improve survival rates, there has been great interest in neoadjuvant (pre-operative) or adjuvant (postoperative) therapies, incorporating radiotherapy or chemotherapy or both.[3,4,6]

There is no evidence that ***neoadjuvant*** radiotherapy alone improves survival.[1,3,6,9,10] The evidence for use of neoadjuvant chemotherapy is more conflicting.[1,3,6,11] A systematic review[12] found that it may offer a survival advantage compared with surgery alone, although the evidence was considered to be inconclusive. Meta-analysis[13] also suggested some survival benefit in those with adenocarcinoma, but not for those with squamous cell disease. Thus, some guidelines[2,8,9] consider neoadjuvant chemotherapy as a standard treatment option for localised adenocarcinoma. The ECF regimen (epirubicin, cisplatin, and fluorouracil), or one of its variants, is commonly used.[2]

Initial studies of neoadjuvant chemoradiotherapy also conflicted or were inconclusive due to small samples or inadequate dosage.[3,4,9,13,14] A systematic review[14] found that neoadjuvant chemoradiotherapy significantly improved the 3-year mortality rate compared with surgery alone, and a later meta-analysis[13] found a significant survival benefit, versus surgery alone, in patients with local operable oesophageal carcinoma, regardless of histological tumour type. However, the risk for postoperative mortality (within 90 days of surgery) was also increased by neoadjuvant chemoradiotherapy.[14] Despite this, many centres incorporate neoadjuvant chemoradiotherapy regimens for localised, resectable disease.[1,2,4,7,11] Regimens are largely cisplatin- or fluoropyrimidine-based.[2]

Studies of ***adjuvant*** radiotherapy have failed to show a survival advantage,[2] and, aside from possible benefit in certain subgroups, may actually increase mortality compared with surgery alone.[6] Adjuvant chemotherapy is generally not recommended,[5,9] except in those patients with adenocarcinoma who also received neoadjuvant chemotherapy;[2] treatment is usually with ECF. Adjuvant chemoradiotherapy has shown improved survival rates compared with surgery alone, in patients with adenocarcinoma.[2,6] However, it is not recommended,[5] except in selected high-risk adenocarcinoma patients who have not received neoadjuvant chemoradiotherapy.[2,6] Fluoropyrimidine-based regimens are preferred.[2]

Photodynamic therapy is under investigation for early-stage disease.[15]

In half to two-thirds of patients the disease is too advanced at presentation for anything but palliation. Chemotherapy, chemoradiotherapy, or best supportive care are all options for patients with **unresectable, advanced, or metastatic disease.** Chemoradiotherapy is an option in recurrent disease in those who have not had prior chemotherapy or radiotherapy; more extensive surgery is also an option.[2] Those with poor performance status should be offered supportive care.[2] This may include brachytherapy, laser therapy, stent placement, or photodynamic therapy with photosensitisers (such as porfimer sodium) to relieve obstruction.[2,3,5,9,16] Brachytherapy may be a better

primary therapy for obstruction than a stent.[8,17] In those patients with good performance status, chemotherapy or chemoradiotherapy may also offer some palliation of the disease. Standard options include cisplatin-based, fluoropyrimidine-based, irinotecan-based, oxaliplatin-based or taxane-based combinations.[2,9] In patients with advanced disease that is HER2-positive, trastuzumab may be added to systemic chemotherapy if chemoradiotherapy is not recommended.[2] For further information on common chemotherapy regimens, see Table 1, p. 719.

MALIGNANT NEOPLASMS OF THE STOMACH. Cancer of the stomach is one of the most common cancers worldwide. Geographical distribution varies greatly, with particularly high incidence in the Far East, eastern Europe, and parts of Latin America, although the incidence is declining almost everywhere. (In contrast the incidence of cancers at the gastro-oesophageal junction appears to be increasing.) Over 90% of malignant gastric neoplasms are adenocarcinomas. Less frequent gastric neoplasms include lymphomas (see MALT lymphoma, p. 698.1) and carcinoid tumours (see Neuroendocrine Tumours, p. 716.3). Histologically, tumours are divided into intestinal and diffuse forms; the latter type may have a genetic basis.

Dietary factors, such as high consumption of salted or smoked foods, are thought to play a role in the development of gastric cancer. Smoking is also considered to be an independent risk factor. *Helicobacter pylori* infection, and resultant gastritis, plays a role in gastric lymphomas, and appears to almost double the risk for the development of gastric cancer.[1-5] However, it is not yet clear if elimination of *Helicobacter pylori* infection can help prevent the development of gastric cancer.[6] It is possible that some patients will have developed irreversible mucosal changes, and that *H. pylori* eradication will be ineffective.[5,7]

Early disease is relatively asymptomatic or produces non-specific gastrointestinal symptoms such as dyspepsia. There is concern that the use of antisecretory drugs for these symptoms may delay the diagnosis of gastric cancer (see Gastric Carcinoma, under Omeprazole Precautions, p. 1873.2). Gastric epithelial dysplasia is a premalignant condition, and warrants follow-up and possible surgical intervention. Similarly, persistent gastric ulcers may be malignant. More advanced disease, which is the norm at presentation in most western countries, may produce abdominal discomfort or pain, anaemia, weight loss, and anorexia; obstruction, haemorrhage, and perforation may develop. Extension to the liver and pancreas, and lymphatic and blood-borne (portal) metastases may occur. The overexpression of epidermal growth factor receptor (EGFR), vascular endothelial growth factor receptor (VEGFR), and human epidermal growth factor receptor-2 (HER2) has been associated with a poor prognosis in patients with gastric and oesophageal cancers.

Surgery is the mainstay of treatment for **locoregional disease.**[2,4,8,10] There is some uncertainty, however, about the appropriate extent of surgery and associated lymph-node dissection.[1-4,11] Typical 5-year survival rates in western patients have ranged from about 50 to 80% in those with stage I disease to 13% in those with stage III;[11,12] although much higher survival rates (over 96% in stage I disease and nearly 45% in stage III) have been reported in Japan,[11] Japanese and western patients may not be equivalent, a fact that has made comparisons difficult.[13]

Because of the poorer survival rates in patients with more advanced locoregional disease, postoperative (adjuvant) and pre-operative (neoadjuvant) treatments have been tried.[1,4,8,11,12] Postoperative radiotherapy has not been shown to produce a survival benefit, and the value of pre-operative radiotherapy is uncertain.[11,12] However, there has been considerable interest in the possible value of chemotherapy, alone or with radiotherapy (chemoradiotherapy).[1,11,12] Postoperative chemotherapy has failed to show a significant survival benefit, except for results with tegafur (plus gimeracil and oteracil potassium) in a Japanese population; it has not become standard practice in western countries.[3,8,10,12] Postoperative intraperitoneal chemotherapy (using mitomycin, cisplatin, or fluorouracil) is under investigation.[2,4,9] Preliminary studies of pre-operative chemotherapy suggested improved survival compared with historical controls, but randomised evidence is lacking.[2] However, perioperative chemotherapy, with cycles of ECF (epirubicin, cisplatin, and fluorouracil) given pre- and postoperatively, was found to improve progression-free and overall survival in patients with operable adenocarcinomas.[14] This strategy is recommended for centres with a multi-disciplinary approach, where there is an opportunity for patients to be considered for perioperative treatment.[8] Perioperative chemotherapy with ECF, or modifications thereof, has become standard practice in the UK and Europe,[4,8,10,15] and is considered an option for patients in the USA.[3] A large US study[16] found that median survival was improved from 27 to 36 months in patients given postoperative chemoradiotherapy (using a fluorouracil and folinic acid regimen). This strategy is recommended for centres where surgery is used as the primary therapy, or where referral is made postoperatively.[8] Using a regimen based on a fluoropyrimidine (such as fluorouracil or capecitabine), postoperative chemoradiotherapy has become the standard of care in the USA.[3,4,10,11] The value of pre-operative chemoradiotherapy, in contrast, remains to be determined,[3,4,11] although it may be a potential option in medically fit patients whose disease is resectable. The recommended regimen includes a taxane (paclitaxel or docetaxel) with a fluoropyrimidine (fluorouracil or capecitabine).[3] For patients with inoperable locoregional disease, radiotherapy with concurrent fluorouracil-based radiosensitisation is used. Palliative chemotherapy with any of the regimens used for metastatic disease is also an option in these patients.[3]

Treatment for **advanced disease** is purely palliative, and options include supportive care with or without chemotherapy.[3] Supportive care includes the relief of luminal obstruction with, for example, stent placement, laser surgery, or photodynamic therapy. Chemotherapy may have substantial palliative effect and modest survival gains, and may be considered in those with good performance status.[2,3] There is no gold standard regimen, although combination therapy is preferred to single-agent therapy for palliation.[17] A systematic review[18] found that combination regimens including a fluoropyrimidine, anthracyclines, and cisplatin produced significant survival benefits; ECF was considered the regimen of choice since it was best tolerated, and it is considered standard therapy in some countries.[17] Fluorouracil, doxorubicin, and mitomycin (FAM) has been widely used;[3] other combinations include the substitution of methotrexate for mitomycin, or cisplatin for doxorubicin, in the FAM regimen (FAMTX and MFC, respectively),[3,17] and the use of docetaxel instead of epirubicin in ECF (DCF).[3,15] However, ECF has shown better response and median survival than FAMTX.[3,8,15,17] In turn, the use of EOX (epirubicin, oxaliplatin, and capecitabine) was found to be as effective as ECF, but with a more favourable toxicity profile.[4,8,17] ECF, DCF, or their modifications are usually preferred as first-line therapy.[3,9,10] Other combinations used in advanced or metastatic disease include irinotecan plus cisplatin or a fluoropyrimidine (such as fluorouracil or capecitabine), oxaliplatin plus a fluoropyrimidine, and paclitaxel-based regimens.[3,10] In those patients with advanced gastric cancer or gastro-oesophageal adenocarcinoma that is HER2-positive, trastuzumab may be added to systemic chemotherapy if chemoradiotherapy is not recommended.[3] Combination therapy using newer agents such as bevacizumab, cetuximab, and gefitinib are being investigated.[4,8,10,15,17] For further information on common chemotherapy regimens, see Table 1, p. 719.

MALIGNANT NEOPLASMS OF THE COLON AND RECTUM. Colorectal cancers are very common in developed areas such as the USA and western Europe, but rare among African and Asian populations. Genetic, environmental, lifestyle, and dietary factors are thought to contribute to development of the disease. Inherited predisposition syndromes include familial adenomatous polyposis and hereditary non-polyposis colorectal cancer. Most large bowel cancers arise within pre-existing intestinal polyps. Over 50% occur in the rectum and about 20% in the sigmoid colon. There may be direct invasion of neighbouring structures and metastatic spread to the lymph nodes, and to lung, bone, and in particular, liver. Over 50% of patients will develop metastases, and up to 25% present with metastatic disease. Signs and symptoms are non-specific and include blood in the stools, altered bowel habit, anaemia, abdominal pain, and weight loss; there may be local obstruction (depending on location) or perforation. Screening is effective in reducing mortality, although the ideal method to be used is controversial.

Pathological stage is an important prognostic factor. The Dukes classification and its modifications and in particular the tumour-node-metastasis (TNM) staging system have been widely used. The latter is based on depth of bowel wall invasion, extent of lymph node involvement, and presence of metastases. These are roughly grouped into stages; stages I and II have no lymph node involvement, stage III is lymph-node positive, and stage IV is metastatic.[1-3] About 40% of colorectal cancers are characterised by mutations in the KRAS gene, and about 5 to 8% show a specific mutation in the BRAF gene. KRAS mutations have been shown to predict for lack of response to cetuximab and panitumumab; mutated BRAF may be a marker of resistance to therapies that target the epidermal growth factor receptor, although data remain inconclusive.[1]

The first-line treatment for **early-stage** and **locally-advanced** disease (stages I to III; Dukes A to C) is surgery.[1-3] Survival in early-stage disease is good: published 5-year overall survival rates are 80 to 95% in patients with stage I disease, but fall to 25 to 60% (depending on prognostic factors such as nodal involvement and degree of tumour invasiveness) in those with stage III disease.[4] Adjuvant or neoadjuvant therapies have thus been widely investigated and incorporated into treatment.[1,2]

Adjuvant therapy for stage I *colon cancer* is considered to be unnecessary.[1,3] For stage III disease, fluoropyrimidine-based chemotherapy has been shown to have an overall survival benefit, and adjuvant therapy has become standard practice for these patients.[1,3,5-10] The evidence in favour of adjuvant therapy in stage II disease is weaker and its use has been controversial.[3,7,11] While it is not routinely recommended for all patients,[12] most consider that its use in high-risk patients with poor prognostic features is justified.[1,3,6,9,10,12,13] The FOLFOX regimen (infusional fluoro-

uracil, folinic acid, and oxaliplatin), compared with fluorouracil plus folinic acid, has been found to improve disease-free and overall survival in stage III patients.[1,10] The FLOX regimen (bolus fluorouracil, folinic acid, and oxaliplatin) also improves disease-free survival in patients with stage II and stage III colon cancer compared with fluorouracil and folinic acid.[1] Oral fluoropyrimidines have also been shown to improve survival after resection,[14] and oral capecitabine appears to be as effective as bolus fluorouracil plus folinic acid.[10] All the above are therefore options for adjuvant treatment.[1,10] Results with the IFL regimen (irinotecan, bolus fluorouracil, and folinic acid) have not proved satisfactory because of its toxicity,[4,7,9] and FOLFIRI (infusional fluorouracil, folinic acid, and irinotecan) has not been shown to be superior to fluorouracil plus folinic acid in the adjuvant setting.[1]

Neoadjuvant chemotherapy and adjuvant radiotherapy seem to play little role in the management of early colon cancer, and the latter is not generally recommended.[4] In contrast, in the management of early stage ***rectal cancer*** radiotherapy or chemoradiotherapy plays an important role, to decrease the size of the tumour pre-operatively, and to decrease the risk of recurrence.[4] Surgery alone may be sufficient for patients with early, favourable disease.[2,15] A meta-analysis[16] found that both neoadjuvant and adjuvant radiotherapy reduced the risk of recurrence compared with surgery alone, and that fewer patients who had neoadjuvant radiotherapy died from rectal cancer, although early deaths from other causes increased, and there was little impact on overall survival. Some still recommend neoadjuvant radiotherapy as a convenient, simple treatment with low toxicity for more locally advanced disease.[15] However, adjuvant chemoradiotherapy was shown to improve overall survival compared with surgery alone, and it was considered the standard of care for patients with stage II or stage III rectal cancer.[3,4,8,16] A large randomised study[17] subsequently found that neoadjuvant chemoradiotherapy significantly improved local control and was associated with less toxicity than adjuvant chemoradiotherapy, although there was no improvement in overall survival. As a result, neoadjuvant treatment has been advocated on the basis of better tumour control, lower morbidity,[3,4] and enhanced sphincter preservation.[4] Regimens are fluoropyrimidine-based, typically using infusional fluorouracil alone, or bolus fluorouracil plus folinic acid, or oral capecitabine. After surgery, adjuvant chemotherapy with a fluorouracil plus folinic acid regimen, FOLFOX, or capecitabine is recommended; the latter 2 options are extrapolations from results in colon cancer.[2] Adjuvant chemoradiotherapy is still used for patients if neoadjuvant radiotherapy or chemoradiotherapy has not been given.[2,15]

Palliative treatments for advanced colorectal cancer (stage IV; metastatic disease) include surgery, radiotherapy, chemotherapy, and chemoradiotherapy.[1,2,4,5,7,18] Genetic profiling may allow individualisation of therapy to improve efficacy and reduce toxicity.[19,20] Metastasis usually occurs first to the liver; for cases that are localised and resectable, surgery offers a chance of prolonged survival.[4,5] Systemic neoadjuvant chemotherapy can reduce tumour volume and render some previously unresectable metastases suitable candidates for surgery.[1,4,21] Another potential approach is the adjuvant use of hepatic arterial (intraportal) chemotherapy directed at the liver. However, it is unclear who should be offered such treatment, and what the survival benefits are; given the potential for biliary toxicity and the technical expertise required, hepatic arterial therapy is generally reserved for use at specialist centres.[1,2]

Conventional palliative chemotherapy is based on the use of fluorouracil, and has been shown to produce modest survival benefits.[22] Adding folinic acid improves the efficacy,[19,23] and the combination has long been regarded as standard. Although it has been suggested that regimens based on continuous infusion of fluorouracil are more effective than those using bolus dosage,[4,24] others consider that although response rates are improved, median survival is similar, and that differences in toxicity and convenience of administration are more significant in making the choice.[18] Oral fluorouracil prodrugs such as capecitabine, or tegafur with uracil, are considered valid alternatives to intravenous fluorouracil.[4,19,21,25]

Several newer drugs have now been shown to improve response rates and survival when used for chemotherapy in these patients. In particular, regimens including irinotecan or oxaliplatin, such as FOLFIRI or FOLFOX, are now considered options for first-line management of metastatic colorectal cancer.[1,2,6,8,18-21] There is also evidence for both improved response and survival when bevacizumab (an antagonist of vascular endothelial growth factor) is added to chemotherapy.[18,19] Similarly, cetuximab, a blocker of the epidermal growth factor receptor, appears to improve response rate and decrease the rate of progression if given with irinotecan,[8] and preliminary results suggest that it is effective when combined with a FOLFOX regimen.[20] As a result, currently recommended regimens combine bevacizumab with one of the first-line regimens—FOLFOX, FOLFIRI, a fluorouracil plus folinic acid regimen, or CapeOX (capecitabine plus oxaliplatin)—in patients with metastatic disease who are able to tolerate intensive therapy,[1,2,19-21] although the data to support some of these combinations are not yet available. Cetuximab or panitumumab may also be combined with FOLFIRI or FOLFOX (in those with the KRAS-wild type gene).[1,2,19] In those who fail to respond, an alternative first-line regimen may be tried (without bevacizumab). Other options include cetuximab plus irinotecan, or monotherapy with a drug not included in the original regimen (such as irinotecan, cetuximab, or panitumumab). In those in whom intensive therapy is not appropriate, options include capecitabine or fluorouracil plus folinic acid; either of these regimens may be combined with bevacizumab.[1,2,8,21] In those with the KRAS-wild type gene, the epidermal growth factor inhibitors cetuximab or panitumumab are alternatives.[1,2] The tyrosine kinase inhibitor regorafenib is an option when other treatments have failed.

For further information on common chemotherapy regimens, see Table 1, p. 719.

Other drugs and regimens continue to be investigated.

Prophylaxis of cancer of the colon and rectum. Various drugs and dietary factors have been shown in epidemiological studies to be associated with a reduced risk of colorectal cancer, and some of these have been investigated in prospective randomised studies.[1-3]

- Aspirin and NSAIDs are the most widely studied.[1-10] In short-term randomised studies, both sulindac and celecoxib have reduced the size and number of colonic polyps in patients with familial adenomatous polyposis.[4] However, prophylactic surgical removal of the colon is still considered the standard of care for these patients.[1,11] Furthermore, despite significant reductions in adenoma formation in high-risk patients, cyclo-oxygenase-2 (COX-2) inhibitors have also been associated with cardiovascular toxicity.[12] There is some evidence of a dose-response effect, since the greatest prophylactic effect of aspirin in average-risk populations appears to be associated with doses substantially greater than those required for prevention of cardiovascular disease.[5,6,8,13] The effect of aspirin may depend on COX-2 expression: it appears only to reduce the risk of colorectal cancers that overexpress COX-2.[14]
- Calcium supplementation has shown a moderate reduction in the formation of new adenomas in patients with a history of colorectal adenomas,[15] and is well tolerated, but the evidence is not strong enough to recommend general supplementation to prevent colorectal cancer.
- Despite the epidemiological evidence for dietary fibre, several large randomised studies of fibre supplements or high-fibre diets have not found any reduction in the formation of new adenomas in patients with a history of colorectal adenomas.[1,2,16]
- Antioxidant vitamins have also been investigated, but evidence for their benefit is conflicting (see Prophylaxis of Malignant Neoplasms, p. 2047.3).
- Ursodeoxycholic acid has been shown to reduce the risk of colorectal cancer in patients with ulcerative colitis and primary sclerosing cholangitis, see Inflammatory Bowel Disease, p. 1811.3.
- Epidemiological evidence[17] suggests that long-term use of statins is associated with a marked reduction in the risk of colorectal cancer. Prospective studies are required to confirm these results. A meta-analysis[18] did not support this hypothesis, although a modest reduction in risk or an effect with higher doses of statins could not be ruled out.
- Other potential chemopreventive agents on the basis of epidemiological evidence include folic acid, selenium, and menopausal HRT.[1-3] For the suggestion that folate may have dual modulatory effects on carcinogenesis, see Carcinogenicity, under Folic Acid, p. 2065.3.

An important component of the care of patients with inherited predisposition or other risk factors for colon cancer is regular screening.[2,11,19,20] Various screening methods have also been investigated for use in normal-risk individuals. US guidelines[21] recommend screening for colorectal cancer using faecal occult blood testing, sigmoidoscopy, or colonoscopy in average-risk adults, starting at 50 years of age and continuing until age 75; routine screening is not recommended for those older than this.

MALIGNANT NEOPLASMS OF THE ANUS. Anal cancer is a relatively uncommon malignancy. Tumours arising within the anal canal are most often squamous cell carcinomas.[1-5] Other types of cancer arising in the anal region include adenocarcinomas, which are managed similarly to rectal cancer (see Malignant Neoplasms of the Colon and Rectum, p. 706.3).[1,2,4] Anal intraepithelial neoplasia (AIN) is considered to be a precursor of squamous cell anal carcinoma.[5,6] Risk factors associated with anal carcinoma include immunosuppression, anal or genital human papillomavirus (HPV) infection (especially HPV-16), a history of receptive anal intercourse or sexually transmitted disease, multiple sexual partners, and a history of cervical, vulvar, or vaginal cancer. HIV infection, long-term corticosteroid use, and smoking may also be associated risk factors.[1-4,6,7] Clinical manifestations of anal carcinoma include anal bleeding, pain, or the sensation of a rectal mass; diagnosis may be delayed as bleeding is often attributed to haemorrhoids.[1,4,6]

Treatment of anal intraepithelial neoplasia includes excision for clinically definable lesions. Topical creams containing fluorouracil or imiquimod have also been used, and there is anecdotal evidence for the use of photodynamic therapy.[6] A vaccine for HPV-related AIN is under development.[5]

The primary treatment for anal canal carcinoma is combined modality treatment using chemotherapy and radiotherapy. Chemoradiotherapy with fluorouracil plus mitomycin is the regimen of choice, having been found to be superior to radiation alone.[1-8] Fluorouracil with cisplatin is also used. This regimen, when compared with fluorouracil plus mitomycin, had comparable survival and less haematological toxicity, but higher colostomy rates.[2,4,6] For persistent or locally recurrent disease, surgical resection with the formation of a colostomy is preferred.[1-6] Salvage chemoradiotherapy with a cisplatin-based regimen has also been reported to be successful in the treatment of persistent or relapsed disease.[1,4] About 12% of patients develop metastases, most commonly to the liver and lung.[6] There is no standard therapy for metastatic disease.[1,6,8] Treatment recommendations include platinum-based chemotherapy or enrolment in clinical studies.[2,4,6,8] Local chemotherapy for liver metastases using intra-arterial chemotherapy has been reported to be successful.[8]

The management of anal cancer in HIV-positive patients has improved with the advent of HAART; before this, standard chemoradiotherapy was associated with severe acute haematological toxicity.[5] HIV-positive patients should receive standard chemoradiotherapy treatment for anal squamous cell carcinoma, unless they are severely immunosuppressed (usually defined as CD4 cell count < 200 cells/mm^3), in which case monitoring and individualisation of therapy is advised.[4,6]

Malignant neoplasms of the head and neck. Cancers of the head and neck are classically defined as those of the mucosal surfaces of the upper aerodigestive tract and include neoplasms of the lip, oral cavity, pharynx, larynx, nasal cavity, paranasal sinuses, and salivary glands. Most are squamous cell carcinomas, and the highest incidence is in men aged over 50 years. Overall, cancers of the head and neck account for about 6% of all malignant neoplasms worldwide. The major risk factor for these cancers is the use of tobacco (whether chewed, inhaled, or smoked) and alcohol. Human papillomavirus (HPV) infection appears to be a risk factor for some squamous cancers of the oropharynx. HPV-positive tumours have a better prognosis than HPV-negative disease, being more responsive to therapy. Vaccination against HPV is of potential use for primary prevention. Nasopharyngeal carcinoma is a unique type of head and neck cancer. It is endemic in Alaska, China, and North Africa and is associated with Epstein-Barr virus and the consumption of salt-cured fish. It tends to metastasise early.

Clinical manifestations of head and neck cancer vary according to the location of the primary tumour, and can be non-specific. Symptoms include mouth ulceration, tongue pain, epistaxis, hoarseness, sore throat, otalgia, dysphagia, chronic cough, haemoptysis, and stridor.

Premalignant lesions include **leucoplakia** and **erythroplakia**, and these can progress to invasive cancer. About one-third of cancers are diagnosed at early stages (I and II), and the rest are usually locally advanced (stage III and IVA). Although early-stage disease can be successfully treated, there is a high incidence of second primary cancers in the head and neck, lung, or oesophagus. Therefore, there is interest in the development of chemopreventive drugs to reduce this risk. Fewer than 30% of patients with locally advanced disease are cured. The treatment of head and neck cancer is complex, and is affected by the site and extent of disease, pathological findings, lymph node involvement, the patient's functional status, and comorbidities; the experience and skill of the team carrying out surgery and radiotherapy will also influence treatment recommendations.

Patients with early-stage **nasopharyngeal** disease are treated with radiotherapy alone. Those with locally advanced disease are treated with cisplatin-based chemotherapy given concurrently with radiotherapy (chemoradiotherapy) followed by adjuvant chemotherapy with cisplatin plus fluorouracil.[1-3] For metastatic disease, palliative chemotherapy can be considered; platinum-based combination regimens are used first-line. Other active drugs, used as monotherapy or in combination, include paclitaxel, docetaxel, gemcitabine, capecitabine, irinotecan, vinorelbine, ifosfamide, doxorubicin, and oxaliplatin. Treatment is based on previous treatment and toxicity.[3]

Patients with early-stage resectable **squamous cell carcinoma** of the head and neck (excluding nasopharyngeal carcinoma) are treated with surgery or radiotherapy, with curative intent.[2,4-7] The two methods have comparable efficacy, and choice depends on the specific tumour site, resectability, and functional outcome after therapy.[2,5] For those with adverse prognostic factors such as nodal involvement, positive margins, or extracapsular spread, postoperative radiotherapy or postoperative chemoradiotherapy may be used.[4,8]

Locally advanced disease needs combined modality therapy,[2,4-6] individualised according to resectability, tumour site, the need for organ preservation, and functional outcome.[2] Historically, surgery plus radiotherapy was used for resectable disease, and radiotherapy alone for unresectable disease,[9] but combined chemoradiotherapy has proved a major advance in treatment.[5] It is superior to radiotherapy alone,[2,5-10] although toxicity is increased, and to the use of chemotherapy either before or after radiotherapy.[2,5] Resectable disease is therefore usually managed with surgery followed by adjuvant treatment with radiotherapy alone or chemoradiotherapy to reduce locoregional recurrence.[2,4,5,7,8] In resectable disease where organ preservation is important, and in unresectable disease, definitive chemoradiotherapy is the standard treatment,[2,4,5,7] unless the use of chemotherapy is contra-indicated due to poor performance status or comorbidities.[4,5] Platinum-based regimens are standard.[2,4,5,8] Use of cetuximab with radiotherapy may be considered as an alternative to chemoradiotherapy in those patients unable to tolerate chemotherapy.[2,4,5,8] While chemoradiotherapy improves locoregional control, its effect on distant recurrence or metastases is inconsistent, and induction or neoadjuvant chemotherapy has been studied in the hope of reducing metastasis. Interpretation of initial studies of induction chemotherapy (used before surgery or radiotherapy) was difficult given their heterogeneity, although a survival benefit was shown in those studies using cisplatin plus fluorouracil. The addition of docetaxel further improved survival and organ preservation in studies of induction chemotherapy (used before radiotherapy or chemoradiotherapy).[2,5,6] Induction chemotherapy is not regarded as standard treatment for locally advanced disease,[5] but its use before chemoradiotherapy (compared with chemoradiotherapy alone) is under investigation.[2,5]

Palliative chemotherapy is used in *metastatic* or *recurrent* disease.[4,5,9] Salvage surgery or a repeat course of radiotherapy are other options, depending on previous treatment. Drugs used for single-agent treatment include cisplatin, carboplatin, paclitaxel, docetaxel, fluorouracil, methotrexate, ifosfamide, bleomycin, cetuximab, and gemcitabine (for nasopharyngeal cancer). Common combination regimens such as cisplatin and fluorouracil produce more responses, but no clear improvement in survival.[4,5,9] Addition of cetuximab to this standard platinum plus fluorouracil regimen has been found to improve survival.[11] Other common combinations include cisplatin or carboplatin plus a taxane.[4] Gefitinib and erlotinib have shown modest benefit when used as monotherapy, and are under investigation in combination regimens.[2,5] The choice of best supportive care or single-agent or combination chemotherapy should be dictated by the patient's performance status, as the benefits of chemotherapy are limited.[4]

A local injection of cisplatin in a gel formulation containing adrenaline has been investigated in recurrent and refractory head and neck cancer.[12] Photodynamic therapy (see under Porfimer Sodium, p. 849.1) using temoporfin is a more recent development for palliative management. Head and neck cancers have high levels of p53 gene mutations, and gene therapy is under investigation.[13] Chemoprevention by treatment of premalignant disease is also under investigation (see Leucoplakia, p. 750.3).

Malignant neoplasms of the kidney. Cancer of the kidney is relatively uncommon, accounting for about 2% of all cancers worldwide. About 90% of renal tumours are renal cell carcinoma, of which the majority are clear cell tumours. The disease is about twice as common in men as in women. Several hereditary types of renal cell carcinoma exist, the most common being von Hippel-Lindau (VHL) disease, caused by a mutation in the VHL-gene, which predisposes to clear cell carcinoma. Aside from genetic predisposition, risk factors include smoking, obesity, hypertension, use of analgesics such as phenacetin and acquired cystic kidney disease associated with end-stage renal disease. Disease is often clinically silent; there may however be haematuria, flank and back pain, and a palpable mass in the flank or abdomen. Fatigue, anaemia, and weight loss can also occur. About one quarter of patients present with advanced disease. The most common sites for metastases are the lung, liver, and bone, although unusual sites for metastases are a known feature of renal cancer.

Radical nephrectomy is the main **treatment** for *early-stage* (stages I and II) disease although nephron-sparing partial nephrectomy may be considered in some patients.[1-4] Results achieved with nephron-sparing surgery are similar to radical nephrectomy, but recurrence rates are higher.[3] Minimally invasive procedures such as radiofrequency ablation and cryotherapy are options for treatment of small tumours, although comparisons with surgery are lacking.[2] Radical nephrectomy is also used in selected patients with *locally advanced* (stage III) disease. After surgery 20 to 30% of patients with localised tumours will relapse, usually at distant sites.[2] However, adjuvant therapy has no established role.[2] Radiotherapy is not beneficial, and no systemic therapy has been shown to reduce relapse; interferon alfa or interleukin-2 are not effective.[2,3] Standard care therefore remains close observation.[2]

Patients with *invasive* or *metastatic* (stage IV) disease are also candidates for surgery.[2,5,6] Palliative nephrectomy can be considered for alleviation of symptoms.[7] Nephrectomy and surgical removal of isolated metastases may be appropriate in some patients,[2,7] and cytoreductive nephrectomy before systemic therapy is recommended for patients with potentially resectable disease and multiple metastases,[2,8] since a small survival benefit has been shown with nephrectomy before cytokine therapy compared with cytokine therapy alone.[9,10]

Renal cell carcinoma has been largely resistant to conventional antineoplastic chemotherapy,[1,3,7,11] and cytokine therapy with either interleukin-2 or interferon alfa became a standard treatment,[2,8] despite toxicity problems and generally poor overall response rates.[5] It has usually been reserved for patients with good prognostic factors and good performance status.[8] A systematic review[12] found a modest survival benefit for interferon alfa. Higher response rates were reported with high-dose interleukin-2 than low-dose therapy,[2,13] but overall survival was not improved.[12] Attempts to improve the tolerability of interleukin-2 have

included the use of continuous infusion, lower doses given subcutaneously,[1,11,14] and inhalational use.[11,14] Attempts were made to improve the response rates to interleukin-2 and interferon alfa by combining them, or by addition of antineoplastics or retinoids. However, response was still generally poor and toxicity significant.[11,15]

The majority of patients with clear-cell renal cell carcinoma have overexpression of vascular endothelial growth factor (VEGF) in tumour tissues, and newer molecular therapies aimed at VEGF or its receptors have been developed.[5,16-18] The tyrosine kinase inhibitors sunitinib and sorafenib have respectively produced better and equivalent survival to interferon alfa treatment, and are both recommended as first-line options in stage IV disease, whether of clear cell or non-clear cell histology.[2] Some consider first-line use is appropriate only in favourable- or intermediate-risk patients, but that they are suitable in any patient who has failed cytokine immunotherapy.[6] Temsirolimus has also shown a significant overall survival benefit compared with interferon alfa; combination treatment using these 2 drugs did not, however, show any benefit over interferon alfa monotherapy.[2,5] Temsirolimus is recommended as a first-line option in patients with poor prognosis.[2,4,6] Bevacizumab, a monoclonal antibody directed against VEGF, has also shown activity in metastatic disease; addition of bevacizumab to interferon alfa significantly increased progression-free survival compared with interferon alfa, and this combination is also a first-line option for patients with mainly clear-cell histology.[2,4] Pazopanib is an alternative first-line agent in those with mainly clear-cell histology, and high-dose interleukin-2 also remains an option for selected patients with good performance status.[2] Sunitinib, sorafenib, pazopanib, and temsirolimus are all options in non-clear cell disease, as is chemotherapy with gemcitabine, capecitabine, floxuridine, fluorouracil, or doxorubicin.[2]

For *progressive* clear-cell disease, an alternative first-line may be given; supportive care remains a mainstay of therapy for all patients with metastatic renal cell carcinoma.[2] Treatment with everolimus has been found to prolong progression-free survival in patients who had disease after treatment with sunitinib, sorafenib, or both.[19] Interferon alfa may be used for progressive disease in clear cell carcinoma;[2] some consider its use in metastatic renal carcinoma to be inappropriate.[6]

Evolving therapies include vaccination therapy with autologous or allogeneic dendritic cell vaccines, or peptides, and allogeneic haematopoietic stem cell transplantation.[3,13,20,21]

WILMS' TUMOUR. In children most cases of renal tumours are due to Wilms' tumour (nephroblastoma). This is one of the most frequent solid tumours in childhood with a peak incidence between 1 and 5 years of age and accounts for about 6% of all childhood malignancies. The usual presentation is an asymptomatic abdominal mass; abdominal pain, haematuria, fever, and hypertension can occur. Metastasis in advanced disease is usually to the lungs and liver. Most primary tumours occur in one kidney, but some 5% involve both kidneys.

Unlike other forms of renal cancer, Wilms' tumour responds well to chemotherapy. The basis of **treatment** is surgery, combined with chemotherapy, and if necessary radiotherapy. Management varies with disease stage and also varies between different study groups.[1-7] The US National Wilms' Tumour Study Group (NWTSG), its successor the Children's Oncology Group (COG), and some other groups recommend initial surgery (nephrectomy) to confirm diagnosis and perform precise staging. Adjuvant chemotherapy and radiotherapy are based on stage and histology obtained at the time of surgery, which allows for accurate assessment. However, tumour spillage at the time of surgery can increase the risk of local abdominal relapse and subsequent poor outcome. In contrast, the European Société Internationale d'Oncologie Pédiatrique (SIOP) and some other groups use neoadjuvant chemotherapy to reduce the tumour size and make surgery easier. Staging is done after surgery, and adjuvant chemotherapy is given if needed. With this method, patients without a confirmed diagnosis may receive unnecessary neoadjuvant treatment, and more intensive chemotherapy regimens are needed to ensure any occult disease is treated. Although there continues to be controversy about the relative merits of the two approaches, overall survival for patients treated by either approach is very similar, being more than 90% for patients with favourable histology. The aim of the various study protocols has been to identify low-risk children who require less intensive therapy, and those with poor prognosis who require more intensive therapy or alternative investigative regimens.[1-7] It has been noted that the groups have borrowed freely from each other, with SIOP protocols advocating early surgery for infants, and COG protocols using neoadjuvant therapy for very large tumours. Neoadjuvant chemotherapy may also allow for treatment of children in developing countries in cases where surgery is not immediately feasible due to the general health status of the patient. The protocol selected should therefore be suited to the individual child and the particular patient population.[7]

SIOP *neoadjuvant* chemotherapy usually consists of dactinomycin and vincristine for clinically localised disease, with doxorubicin or epirubicin added for metastatic disease.[2,5-7] *Adjuvant* chemotherapy regimens for disease with favourable or standard histology are broadly similar between NWTS and SIOP. In early disease, chemotherapy consists of vincristine combined with dactinomycin; in more advanced disease radiotherapy, and an anthracycline (doxorubicin or epirubicin) are added.[2,5,6] The duration of adjuvant chemotherapy is dependent on the disease stage and whether or not neoadjuvant treatment was given.[2] The UK Children's Cancer Study Group found that adjuvant vincristine alone was as effective as vincristine plus dactiriomycin for patients with stage I favourable histology, although this did not apply to children aged 4 years or older.[1,4,6] Various regimens have been investigated, and the NWTSG found that pulse-intensive dactinomycin courses were as effective as standard courses, but had less haematological toxicity.[1,4,5] Adjuvant radiotherapy is given for lung metastases in both protocols, with NWTSG giving whole-lung irradiation in all cases, and SIOP not irradiating those patients whose metastases respond to chemotherapy (which may be related to the higher dose of anthracycline used in SIOP regimens).[1,2,4,7]

For patients with ***unfavourable histologies*** and a poorer prognosis such as anaplastic Wilms' tumour or clear-cell sarcoma, treatment usually consists of three-or four-agent chemotherapy with combinations of vincristine, dactinomycin, doxorubicin, and cyclophosphamide,[4,6] or vincristine, doxorubicin, cyclophosphamide, and etoposide.[1] Radiotherapy is also used.[1]

For ***relapsed disease***, the use of combination chemotherapy regimens has improved survival; drugs such as cyclophosphamide, ifosfamide, cisplatin, carboplatin, and etoposide have shown substantial activity.[1,2,4] The ICE regimen (ifosfamide, carboplatin, and etoposide) or ICED regimen (with the addition of doxorubicin) are commonly used.[2,5] For other common combination regimens used in cancer chemotherapy, see Table 1, p. 719. A small study found that a protracted schedule of topotecan was effective for recurrent disease with favourable histology.[8] Treatment with high-dose chemotherapy and autologous haematopoietic stem-cell rescue has shown promising results in relapsed disease,[1] although intensive chemotherapy alone has been shown to be equally effective.[5]

Bilateral Wilms' tumour is not usually treated with primary bilateral nephrectomy because of the need to retain renal function. It may be biopsied to assess histology and stage and then treated with neoadjuvant chemotherapy.[1,2,4-6] Surgery is then performed, preserving as much of the kidneys as is possible. Survival has been reported to be comparable with that in other patients.[2] Because of these results, some have suggested the use of partial nephrectomy in patients with small unilateral tumours. However, most tumours are too large or too centrally located for partial nephrectomy to be routinely indicated.[1]

Malignant neoplasms of the liver. Hepatocellular carcinoma (hepatoma) accounts for more than 90% of primary liver cancers. It is relatively uncommon in northern Europe and America but is the most common cancer among men in large parts of sub-Saharan Africa and Asia. The incidence in men ranges from 2 to 8 times that in women. Chronic infection with hepatitis B or hepatitis C virus is by far the most important factor associated with development of liver cancer. Other risk factors include ingestion of foodstuffs contaminated with aflatoxins (see p. 2432.2), alcoholic or non-alcoholic liver disease, haemochromatosis, and the long-term use of anabolic steroids (see Effects on the Liver, under Testosterone, p. 2308.1) and, rarely, combined oral contraceptives, (see p. 2235.3). Over 70% of patients with hepatocellular carcinoma have cirrhosis of the liver.

Clinical manifestations of liver cancer include increasing obstructive jaundice, upper abdominal pain, malaise, weight loss, and the presence of an epigastric mass; there may be metastasis to the lungs, kidney, bones, brain or other sites, or invasion of local structures. Multiple staging systems are used and there is no universally accepted method although most base liver function assessment on the Child-Pugh classification of disease severity. It has been noted that since the cause of hepatocellular carcinoma may vary geographically, different scoring systems may apply to different populations.[1,2]

Screening at-risk groups for hepatocellular carcinoma is feasible, although still controversial in terms of cost-effectiveness; the recommended surveillance interval is 6 months,[2-5] although 1 year may be equally effective.[6] Screening has led to increased detection of ***early disease***, and more than half of these cases will be suitable for potentially curative treatments such as resection, liver transplantation, or ablation.[3-7] Selection of which patients are best suited to which method is based on tumour factors such as resectability, liver function, patient comorbidities, candidacy for transplantation, and organ availability.[4,6,8,9] **Liver transplantation** (p. 1940.3) may be considered in those patients with small tumours and who have advanced cirrhosis and are therefore not suitable for surgical resection.[3-5,7,9,10] **Surgical resection** is suitable for patients without cirrhosis, or in cirrhotic patients with well-preserved liver function who are not candidates for transplantation and whose tumours are considered resectable.[3-5,7,9,10] However, recurrence rates after resection are high,[2,4,5,7,11] and 5-year survival is about 40%.[3,5,12]

As a result, **adjuvant** or **neoadjuvant chemotherapy** has been investigated in early-stage disease. Neoadjuvant chemotherapy has been used to reduce tumour burden before transplantation[7,12] or to permit resection.[13] A meta-analysis[14] of 7 studies concluded that adjuvant transcatheter arterial chemotherapy (drugs injected into the hepatic artery after curative resection, usually with embolisation which temporarily occludes the artery) significantly improved survival and decreased recurrence. However, a systematic review[11] found no clear evidence that either neoadjuvant or adjuvant regimens prolonged overall or disease-free survival; some evidence for benefit on disease-free survival was seen with adjuvant immunotherapy or iodine-131 with iodised oil. In patients who have small tumours and are not candidates for surgery or transplantation, percutaneous intratumoral alcohol injection is an option. Other ablative therapies include radiofrequency ablation and cryosurgery.[3-10,12,15,16]

For disease defined as ***intermediate*** or ***advanced***,[5,6] where tumours are large or unresectable and not amenable to local ablative therapies, transcatheter arterial chemoembolisation (TACE) is also used.[2-4,6,8,17] TACE uses substances such as gelatin foam or iodised oil to temporarily occlude the artery (the sole supply of blood to the tumour). This prolongs the duration of contact between drug and tumour and also attempts to induce tumour necrosis by ischaemia.[2,4,6,12] TACE compared with arterial embolisation

without chemotherapy was found to improve survival in one study.[18] Systematic review[19] confirmed a survival benefit with chemoembolisation, using doxorubicin or cisplatin, and suggested this method as standard therapy for selected patients with small unresectable tumours, and well-preserved liver function. Patients with severe hepatic impairment and portal vein thrombosis should not be treated with TACE as there is a risk of precipitating acute liver failure.[4,5,8,17] Other strategies to improve tumour response include the use of drug-eluting beads containing doxorubicin,[5,16] or transarterial radioembolisation (TARE), which injects radioactive isotopes such as iodine-131 or yttrium-90 into the hepatic artery, using the same principles as TACE.[2,4-6,17]

Systemic chemotherapy has been tried for the treatment of ***advanced or metastatic*** hepatocellular carcinoma, but has had no impact on survival.[1,3,8,10] The most active drug is doxorubicin, which has been associated with partial responses in about 10% of cases,[1,4,5] and has been widely used as the standard of care in disease not amenable or refractory to TACE.[17] Combination chemotherapy using a regimen of cisplatin, interferon, doxorubicin, and fluorouracil (PIAF) doubled the response rates compared with doxorubicin monotherapy, but toxicity was higher, and overall survival unaffected.[1,4,5,17] More recently, however, a survival benefit has been shown with the use of sorafenib when compared with placebo,[5,6,16] and some now consider it to be the new standard of care for patients with advanced disease,[5,10] although others consider it standard only in those who are not candidates for curative or locoregional therapies such as TACE, and have noted that it has only been studied in those with good liver function.[17] Other drugs under investigation for hepatocellular carcinoma include bevacizumab, sunitinib, and erlotinib.[1,3,5,6,10,16]

In contrast to the poor response of hepatocellular carcinoma to therapy, better progress has been made in strategies for its **prevention**. Neonatal vaccination against hepatitis B has dramatically decreased the incidence of chronic infection in children in Taiwan, and reduced the incidence of hepatocellular carcinoma[20] although some have noted that more time is needed to show the real impact of this measure.[2] Treatment of chronic hepatitis (p. 952.1) can prevent progression to liver cirrhosis and subsequent hepatocellular carcinoma.[20] There is also some suggestion of a possible inverse relation between coffee consumption and liver cancer risk.[16] Chemoprevention may also be a useful approach after surgical resection: use of a synthetic retinoid, peretinoin, was found to reduce the development of second primary tumours after resection.[21,22]

The liver is the most common site of ***metastatic disease.***[23] For most malignancies the presence of liver metastases is indicative of generalised dissemination, but isolated metastatic liver disease is common in colorectal cancer (p. 706.3) and rarer cancers such as some neuroendocrine tumours (p. 716.3).

Malignant neoplasms of the lung. Lung cancer is the most common non-skin cancer in the developed countries and the second most common overall worldwide. About 20 to 25% of all lung cancers are small cell lung cancers (SCLC) derived from endocrine cells in the bronchial mucosa; the remainder, comprising chiefly squamous cell carcinomas (40 to 45% of cases), adenocarcinoma (25 to 30%), and large-cell carcinoma (about 10%), are known collectively as non-small cell lung cancer (NSCLC). More than 80% of all lung cancers are associated with tobacco smoking, and there is also evidence that exposure to the cigarette smoke of others can increase the risk in non-smokers. Other risk factors may include occupational exposure to substances such as asbestos, and the effects of environmental toxins such as air pollutants.

Symptoms due to a lesion in a main bronchus (the most common site) include persistent cough, dyspnoea, haemoptysis, weight loss and sometimes chest pain. Metastatic spread is common, and may affect sites such as brain, liver, and bone. It occurs early with adenocarcinoma and SCLC, but late with squamous cell carcinoma.

Disease staging plays an important role in determining treatment. The management of SCLC differs significantly from that of NSCLC (see below and p. 711.1, respectively).

Given the poor prognosis of lung cancers, and the high incidence of second primaries in patients curatively treated for early-stage disease, there has been great interest in **prophylaxis.** The most important factor in primary and secondary prevention is cessation of tobacco smoking, for which a number of interventions may be tried (see Smoking Cessation, p. 2570.2). Diets rich in fruit and vegetables have been associated with a lower incidence of malignant disease, and have prompted the investigation of antoxidant vitamins. However, primary prevention studies in those at risk of lung cancer have failed to show any benefit for vitamin supplements, and in the case of betacarotene, an increase in lung cancer was seen in those most at risk (see Prophylaxis of Malignant Neoplasms, p. 2047.3). Other drugs under investigation are retinoids and NSAIDs.[1]

While a meta-analysis[2] concluded that screening of patients with chest radiography or sputum cytology was ineffective, the Early Lung Cancer Action Project found that computed tomography improves the likelihood of detection of nodules suggestive of lung cancer in high-risk patients.[3] Since most of those cancers detected were at an early stage, resection was possible, and it is theorised that this technique may reduce mortality,[4] although it remains investigational.

Metastatic lung disease. The lung is the second most frequent site for metastatic disease, occurring in about 30% of cancer patients. Surgical resection may be used to treat pulmonary metastases when there are no effective systemic therapies, no extrapulmonary metastases, the pulmonary metastasis is completely resectable, and the patient is able to undergo surgery.[5] Specific cancers for which surgical resection of pulmonary metastases is considered include soft-tissue sarcoma, osteosarcoma, and sometimes breast cancer.

SMALL CELL LUNG CANCER. The mainstay of treatment for small cell lung cancer (SCLC) is chemotherapy.[1-5] In ***limited disease*** (disease limited to one hemithorax with hilar and mediastinal lymph node involvement that can be encompassed within one tolerable radiotherapy field) the combination of chemotherapy and chest radiotherapy has been shown to improve survival[6,7] and is recommended therapy.[2-5] The most common chemotherapy regimen is 4 to 6 cycles of etoposide and cisplatin (EP or PE),[1,3-5,7,8] which offers a survival advantage over the previously used regimen of cyclophosphamide, doxorubicin, and vincristine (CAV). The optimum scheduling of chemotherapy and radiotherapy has been investigated and concurrent therapy found to be superior to sequential radiotherapy.[3] In comparing early and late concurrent therapy, a meta-analysis[9] of 7 studies found that a small improvement in overall survival at 2 years was associated with early radiotherapy (begun within 9 weeks of starting chemotherapy, or before the third cycle of chemotherapy) compared with late radiotherapy. There was also evidence that the use of hyperfractionated radiotherapy (given twice daily) and platinum-based regimens contributed to this benefit. In general, for limited disease it is recommended[2,3,5,7] that concurrent chest radiotherapy should be started with the first or second chemotherapy cycle. Response rates of 70 to 90% are reported, but median survival rates are only 14 to 20 months and the 2-year survival rate is about 40%.[5]

Only a few patients present with resectable early stage disease. Careful pre-operative staging is essential to rule out nodal involvement, and all patients should receive adjuvant chemotherapy. If nodal metastases are found, the addition of postoperative chest radiotherapy should be considered. Patients with later disease stages do not benefit from surgery.[3,5]

In ***extensive*** SCLC (spread beyond one hemithorax and thus beyond the boundaries of a single radiotherapy field; may include malignant pleural or pericardial effusion or haematogenous spread) chemotherapy alone is used to palliate symptoms and prolong survival. The combination of etoposide and cisplatin (or carboplatin) is also used in these patients[3-5,7] but response is poorer than that for limited disease, with response rates of 60 to 70% and a 2 year survival rate of less than 5%.[5] Alternative first-line regimens include irinotecan with cisplatin (or carboplatin), or the CAV regimen.[5] Other strategies that have been tried, but with little consistent evidence of improved results, include the addition of further drugs to EP (such as ifosfamide, paclitaxel, or cyclophosphamide plus an anthracycline), and the use of dose-intense or dose-dense regimens.[1,5,8]

The use of **consolidation or maintenance** chemotherapy has been studied in both limited and extensive disease. Most studies have found no improvement in progression-free or overall survival, and the general recommendation is that such extra therapy, with its associated toxicity, should not be used.[1-5,8] This view has been challenged by a meta-analysis[10] of 14 studies suggesting that there is evidence for benefit from maintenance therapy, although it is unclear which patients might benefit and which regimen would be most effective.

Patients who have responded to initial treatment still have a more than 50% risk of developing brain ***metastases.*** Prophylactic cranial irradiation reduces this risk and improves survival in patients in complete remission.[4,5,11] It is generally recommended for all patients with limited disease who achieve remission, and for those with extensive disease who achieve remission and have good prognostic factors and performance status.[2-5,7,8]

The value of chemotherapy in ***relapsed*** SCLC depends in part on the duration of remission before relapse, with greater responses the longer the remission.[3,5,7,8] In the UK, NICE guidelines recommend second-line chemotherapy only in patients whose disease responded to first-line treatment.[2] Patients who relapse within 3 months of achieving remission are considered to have refractory disease; second-line drugs include ifosfamide, paclitaxel, docetaxel, irinotecan, topotecan, and gemcitabine, although response is likely to be poor. Response rates are better if relapse occurs between 3 and 6 months after remission, and topotecan has been suggested as the best option. Other drugs that may be considered include irinotecan, gemcitabine, a taxane, oral etoposide, vinorelbine, or the CAV regimen.[5,7,8] Drugs under investigation for SCLC include amrubicin, pemetrexed, and picoplatin.[7,8] Patients may be given a repeat of initial therapy if they have relapsed after more than 6 months. Second-line chemotherapy should be given until the patient receives maximal benefit, becomes refractory, or develops unacceptable toxicity. Radiotherapy may also be given for localised symptomatic palliation.[5]

NON-SMALL CELL LUNG CANCER. Non-small cell lung cancer (NSCLC), like many malignancies, is treated according to the stage of the disease, for more information see p. 691.1.

For resectable NSCLC and locally-advanced unresectable disease, chemotherapy can be used with surgery or radiotherapy but, for advanced or metastatic disease, chemotherapy is the main treatment.[1-8] Platinum-based regimens prolong survival; cisplatin or carboplatin are effective when combined with docetaxel, etoposide, gemcitabine, irinotecan, conventional or albumin-bound paclitaxel, pemetrexed, vinblastine, or vinorelbine. Two-drug regimens are preferred although single-agent treatment is an option for those with poor performance status and the elderly; a third cytotoxic increases response but not survival. Targeted therapy may be added to chemotherapy for those whose tumours are a particular histology or have a specific genetic abnormality.

First-line options for advanced or metastatic NSCLC include:
- chemotherapy preferably with platinum-based regimens ± bevacizumab
- afatinib, erlotinib, or gefitinib in those with epidermal growth factor receptor (EGFR) mutations
- cetuximab plus cisplatin and vinorelbine in those with EGFR mutations
- crizotinib in those who are anaplastic lymphoma kinase (ALK) positive
- cisplatin plus pemetrexed for those with non-squamous histology
- cisplatin plus gemcitabine for those with squamous histology

First-line, platinum-based chemotherapy regimens are usually given for 4 to 6 cycles. For those who respond, or those with stable disease, the following options may be considered, although their relative benefits are still uncertain:
- continue first-line regimen
- continue treatment with a drug that was included in the first-line regimen (continuation maintenance). Often, targeted drug treatment or gemcitabine is continued after the initial 4 to 6 cycles of platinum-based chemotherapy
- change to a different drug that was not included first-line (switch maintenance). Second-line options (see below) are often used
- drug holiday

When disease progresses, a different regimen is started. Second-line options include:
- single-agent docetaxel
- single-agent afatinib, erlotinib, or gefitinib
- single-agent pemetrexed in those with non-squamous histology
- single-agent crizotinib in those who are ALK positive

Erlotinib may also be considered as a third-line option.

Emerging treatment options and alternative approaches for NSCLC include:[9,10]
- individualising treatment based on genetics or tumour characteristics
- drugs targeting the EGFR pathway
- vascular endothelial growth factor (VEGF) receptor kinase inhibitors
- cancer vaccines and immunotherapies
- histone deacetylase inhibitors

MALIGNANT PLEURAL MESOTHELIOMA. Malignant pleural mesothelioma is a relatively rare tumour of the lining of the lung, yet its incidence is increasing. Occupational exposure to asbestos is the causative factor in most cases, with a mean latent interval of about 40 years between first exposure and death. Typical clinical manifestations include chest pain or dyspnoea or both. Neurological entrapment and pericardial involvement may occur. The disease is progressive, and median survival is poor. Histologically, disease may be epithelioid, sarcomatoid, or a mixture of the two. The epithelioid type is the most common, and may be confused with adenocarcinoma (see Malignant Neoplasms of the Lung, p. 710.2).

In patients with potentially resectable disease, surgery may be considered. Radical surgery (extrapleural pneumonectomy, EPP) is suitable only for a few patients, such as those with epithelioid tumours, and mortality and morbidity are high, despite the use of adjuvant chemotherapy and radiotherapy.[1-5] If EPP is planned, platinum-based neoadjuvant or adjuvant chemotherapy should be considered.[6] Pleurectomy is a cytoreductive procedure used for limited disease, or as palliation. Talc pleurodesis is usually the treatment of choice in the management of pleural effusions associated with mesothelioma. Palliative radiotherapy may be effective for pain relief,[1,6,7] but is generally of limited value.[2,8]

Numerous drugs have been tried in mesothelioma, but responses to monotherapy have been in the region of 10 to 20%, with cisplatin, carboplatin and doxorubicin being the most active agents.[3,9,10] Combination chemotherapy regimens, mostly cisplatin- or doxorubicin-based, have shown higher response,[5] but with little effect on overall survival.[9,10] However, the combination of pemetrexed and cisplatin was shown to improve survival,[1-4,6,8] and it is generally considered to be standard first-line therapy in patients with good performance status and unresectable disease.[2,3,5,7] The regimen is associated with high toxicity, however, and prophylactic use of vitamin B_{12} and folate is recommended.[2,4,10] Carboplatin has been substituted for cisplatin in attempts to reduce toxicity; comparable survival has been reported[4] and some recommend carboplatin with pemetrexed as an alternative first-line treatment.[6,7] The use of raltitrexed with cisplatin has also improved response rates and overall survival, with comparatively little toxicity, and this combination is considered to be an alternative first-line regimen.[4,6,10] Gemcitabine plus cisplatin is also active;[2,4,5] some consider it suitable first-line,[7] while others recommend it for second-line use.[3] Other combinations have been investigated; early use of the MVP regimen (mitomycin, vinblastine, and cisplatin) has shown a trend towards improved survival compared with delayed use.[4] No standard second-line therapy has been defined.[10] Vinorelbine, alone or with gemcitabine, has also been tried as a salvage regimen.[5] Multimodality approaches are increasingly used; neoadjuvant therapy has shown promising results.[4,10] Gene therapy, immunomodulation, angiogenesis inhibitors, ribonuclease inhibitors, and proteasome inhibitors are also being tried.[1,2,4,5,8,10]

Malignant neoplasms of the ovary. Ovarian cancers account for about 5% of all malignancies in women. The most common form (90% of cases) is **epithelial ovarian cancer**, which ranks as fourth in the leading causes of cancer deaths in women. The lethality of this disease is related to the absence of symptoms in most women during its early stages: in about three-quarters of all patients disease is advanced at diagnosis and has spread to the peritoneum or beyond. It is mainly a disease of older women, the median age at diagnosis being 63 years. The risk of epithelial ovarian cancer appears to be related to the number of ovulatory cycles a women has in her lifetime, thus nulliparity increases the risk, whereas multiparity, breast feeding, and combined oral contraceptives (p. 2236.1) decrease the risk. Other risk factors are a family history (particularly when associated with the BRCA1 and BRCA2 genes), and possibly fertility drugs (see Clomifene, p. 2259.2), perineal talc use (p. 1722.3), and menopausal HRT (p. 2248.1).

The main *treatment* for epithelial ovarian cancer in most patients is surgical removal of womb, ovaries and fallopian tubes, and omentum, with debulking of any remaining gross disease.[1,2] For younger patients with favourable histology and disease confined to one ovary, and who wish to conserve fertility, unilateral salpingo-oophorectomy is possible.[1-4] The use of adjuvant chemotherapy depends on disease stage. Optimal surgical staging of early disease identifies those who have little or nothing to gain from adjuvant chemotherapy.[5]

For patients with *early stage* (stages IA/IB), well-differentiated (grade 1) disease, surgery alone is adequate;[1,2] more than 90% of women will have long-term (> 10 years) disease-free survival without further treatment.[4] In patients with poorly differentiated (high-grade) disease, or more extensive disease (stages IC and IIA), adjuvant chemotherapy should be considered.[1,2] Generally, 3 to 6 cycles of intravenous chemotherapy with carboplatin plus a taxane are recommended;[2,4] some recommend 6 cycles of carboplatin monotherapy.[1]

For patients with *advanced* disease (stages IIB to IV), intravenous adjuvant chemotherapy is also recommended, usually with a platinum and a taxane[1,2,4] for 6 to 8 cycles.[1,2] No difference in efficacy has been shown between cisplatin or carboplatin,[6] although carboplatin is usually preferred.[7] The amount of residual disease is an important prognostic factor[8,9] and secondary surgery (interval debulking surgery) can be considered for patients with suboptimal debulking at primary surgery who respond to chemotherapy.[1,3,8] However, a systematic review[9] found similar survival rates in patients who did and did not receive interval debulking surgery. Some recommend that this interval debulking surgery be performed after 3 cycles of chemotherapy, followed by a further 3 cycles of chemotherapy.[1] For patients who are considered initially not optimally resectable (for patient- or tumour-related factors), neoadjuvant chemotherapy followed by debulking surgery may be an option.[4,8-10] Some recommend this approach as standard for stage IV patients.[10]

Intraperitoneal chemotherapy is an option for those with *minimal residual disease* after surgery,[2,11,12] and may improve progression-free and overall survival compared with intravenous use.[4,7,13] However, it is not universally advocated,[3,4] because of adverse effects and complications, and the need for technical expertise;[4,11] some recommend it for stage III, optimally debulked patients.[1] The recommended regimen consists of intraperitoneal cisplatin and intraperitoneal paclitaxel, after an initial intravenous paclitaxel infusion.[2]

In patients with *recurrent* disease, the choice of therapy depends on the time since initial therapy and the drugs used.[1,2,14] Patients with long treatment-free intervals (more than 2 years) may be considered for secondary surgical resection of recurrent disease.[1] Relapse occurring more than 6 months after initial therapy is potentially platinum-sensitive and may be re-treated with platinum-based combination therapy.[1,2,4,15] Carboplatin or cisplatin monotherapy is used if combination therapy cannot be tolerated; oxaliplatin is also an option.[2] Those whose disease recurs in less than 6 months are considered to be platinum-resistant or platinum-refractory.[1,2,15] While re-treatment with a platinum compound is not generally recommended, some data suggest that altering the paclitaxel schedule may produce a secondary response.[2] Other drugs with activity include topotecan, liposomal doxorubicin, altretamine, capecitabine, cyclophosphamide, docetaxel, epirubicin, oral etoposide, gemcitabine, ifosfamide, irinotecan, pemetrexed, and vinorelbine.[1,2,7,8,12,14,15] Hormonal therapy is also an option; drugs include tamoxifen, anastrozole, letrozole, leuprorelin acetate, or megestrol acetate.[2] However, response rates are relatively low, and enrollment in clinical studies should be encouraged.[1,8] There has been considerable interest in the potential use of targeted therapy, but results in ovarian cancer with these drugs have generally not been favourable, except for bevacizumab.[4,12,15,16] Bevacizumab is active in both platinum-sensitive and platinum-resistant disease, and may be used in combination therapy in relapsed disease.[2] The monoclonal antibody oregovomab and ovarian cancer vaccines are under investigation.[16,17] Some success has been reported using high-dose chemotherapy followed by autologous stem cell transplantation,[18] although an improvement in survival has not been shown.[2,8]

Prophylaxis. The identification of genes conferring an inherited predisposition to ovarian cancer, and the difficulty

in identifying the disease and its poor prognosis has led to increased interest in prevention. Oral contraceptives are known to be protective in the general population, and there is growing evidence that women with mutation of the BRCA1 or BRCA2 gene might benefit similarly (see Ovary, under Carcinogenicity in Hormonal Contraceptives, p. 2236.1). Prophylactic oophorectomy may be considered in women with BRCA1 mutations after child-bearing or at age 35 years.[19,20] The risk/benefit ratio of this procedure is unknown, and a few women who undergo this procedure subsequently develop a primary peritoneal cancer.

Ovarian germ-cell cancers account for less than 3% of ovarian cancers and typically occur in women aged 20 to 30 years. Unlike epithelial ovarian cancer, most patients present with early disease, and have an excellent prognosis. Surgery is the main therapy (fertility-sparing if appropriate). Adjuvant chemotherapy is used except in those with stage I disease able to undergo frequent follow-up. Common regimens are similar to those used in male germ-cell tumours, such as bleomycin, etoposide, and cisplatin (BEP) or vinblastine, bleomycin, and cisplatin (VBP).[2,21-24]

Ovarian stromal tumours account for about 7% of ovarian cancers[25] and are mainly treated with surgery (fertility-sparing if appropriate).[2] For those with high-risk stage I tumours, recommendations include observation, radiotherapy, or platinum-based chemotherapy. For those with tumour stages II to IV, options include radiotherapy for limited disease, or platinum-based regimens such as BEP or paclitaxel plus carboplatin.[2,21,24]

Malignant neoplasms of the pancreas. Pancreatic adenocarcinoma (cancer of the exocrine pancreas) accounts for about 95% of pancreatic tumours. A very small percentage of pancreatic tumours arise in the endocrine pancreas, and have different clinical features and treatment (see under Neuroendocrine Tumours, p. 716.3). Worldwide, pancreatic adenocarcinoma accounts for about 2% of all cancers, but is the eighth leading cause of cancer deaths. Its incidence is higher in developed countries. The risk for pancreatic carcinoma increases with age, and mean onset is in the seventh or eighth decade. Pancreatic adenocarcinoma is ductal in origin and metastasises early to the lymph nodes, and about 40% of patients present with metastatic disease. The 5-year survival rate is about 5%, and most patients die within the first 2 years. The most frequent symptom at presentation in patients with cancer of the pancreatic head is jaundice, often with other symptoms indicative of obstruction of the bile duct. In lesions of the body and tail of the pancreas severe and relentless pain may develop. Other symptoms include weight loss, steatorrhoea, dyspepsia, nausea, and depression. Diabetes mellitus is a manifestation of the disease, but there is also some evidence that it may be a predisposing factor. About 30% of pancreatic cancers are probably due to tobacco smoking.

Pancreatic adenocarcinoma has a very poor prognosis because of its usually advanced stage at diagnosis and lack of effective therapies.[1,2] The only curative therapy is resection of the tumour and the surrounding pancreatic tissue.[3] In the few patients who present with ***early-stage*** disease (tumour confined to the pancreas), radical surgery results in a 5-year survival of about 20% in optimally staged patients.[1] *Adjuvant treatment* has been shown to increase disease-free and overall survival and should be offered to all curatively resected patients.[4] The choice of the most effective adjuvant regimen has been the subject of much controversy and no definitive standard exists. Adjuvant chemotherapy with either fluorouracil or gemcitabine improves survival[5] and European guidelines[6] recommend 6 cycles of either drug; US guidelines state that where chemotherapy alone is the choice of adjuvant therapy, gemcitabine is preferred over fluorouracil or capecitabine for most patients.[3] Results with adjuvant chemoradiotherapy have been conflicting.[4,5] Early evidence showed that adjuvant fluorouracil-based chemoradiotherapy improved survival.[4] However, the results of a large European randomised study[7,8] suggested that there was no benefit from adjuvant fluorouracil-based chemoradiotherapy. A subsequent review[9] that included this study concluded that chemoradiotherapy should not yet be dismissed from further study because studies to date had used radiotherapy regimens that were now considered to be suboptimal, and the possibility of benefit could not be ruled out. European guidelines[6] state that fluorouracil-based chemoradiotherapy may be suitable for some patients after resection and gemcitabine chemotherapy, and US guidelines[3] state that, where chemoradiotherapy is the adjuvant treatment of choice, systemic gemcitabine followed by fluorouracil-based chemoradiotherapy should be used. However, with the emergence of newer drugs, patient enrolment into adjuvant clinical studies is encouraged in the USA.[3] Pre-operative (*neoadjuvant*) chemoradiotherapy is also under investigation, but a survival benefit has not been proven, and toxicity can be severe.[1,10,11] However, US guidelines state that, while data are lacking, it has not been shown to be clearly disadvantageous, and that some patients may benefit: prolonged recovery after resection may delay the use of adjuvant therapy; neoadjuvant treatment may also allow for selection of patients responsive to therapy, and could convert unresectable disease to resectable status.[3] For these reasons, patients with borderline resectable disease should be considered for neoadjuvant chemoradiotherapy; regimens are usually fluorouracil-based, and patients are still candidates for adjuvant therapy after surgery.[3,6]

In patients with symptomatic localised ***unresectable disease***, chemoradiotherapy may be used.[3] Most studies have reported a modest survival benefit from the combination of radiotherapy and fluorouracil.[1-3,11] Evidence suggests that radiotherapy with gemcitabine can yield similar outcomes.[3] A period of chemotherapy followed by chemoradiotherapy may be preferable to first-line chemoradiotherapy. Chemotherapy alone is also an option in these patients;[3,6] European regimens are similar to those for resectable disease, whereas gemcitabine monotherapy or gemcitabine-based combination therapy is advocated in the USA. Studies of neoadjuvant chemoradiotherapy to improve resectability rates in locally advanced disease should be encouraged.[6]

For patients with ***advanced*** (metastatic) disease, gemcitabine is recommended as the standard of care.[3,6,11,12] There is also some evidence that its effectiveness may be improved if it is given at a fixed dose rate of 10 mg/m^2 per minute, rather than by conventional infusion.[3,13] Other options in metastatic disease include gemcitabine-based combination therapy for those with good performance status, or best supportive care.[3] A meta-analysis[14] found a survival benefit for gemcitabine-based combination therapy compared with gemcitabine alone. Combinations showing benefit in terms of progression-free survival or overall survival include gemcitabine with capecitabine (GEMCAP), cisplatin (GEMCIS), oxaliplatin (GEMOX), erlotinib, or albumin-bound paclitaxel.[3,5,13,15-17] The combination of cisplatin, epirubicin, fluorouracil, and gemcitabine (PEFG) has also shown impressive results.[13]

There is no consensus on second-line therapy for patients with *refractory* disease. Gemcitabine may offer palliation if patients have not previously been treated with this drug; there is some suggestion that fixed-dose gemcitabine plus oxaliplatin may be useful in those patients refractory to standard gemcitabine therapy. For those patients who have had gemcitabine, enrolment in clinical studies is encouraged. If investigational therapy is not possible, treatment options include capecitabine or fluorouracil, both with or without oxaliplatin.[3]

Pancreatic cancer vaccines are under investigation for pancreatic cancer.[5,18]

Malignant neoplasms of the prostate. Prostatic cancer is the most commonly diagnosed non-skin malignancy in men in the western world, and the second most common cause of cancer deaths in men in the UK and USA: about one in 6 white men can be expected to develop clinically evident carcinoma of the prostate during his lifetime. Black men are at higher risk for the disease. The incidence rises steadily with age. There is also a familial component to the disease. More than 95% of all prostate cancer is adenocarcinoma, which begins as a hard mass in the peripheral portion of the gland and infiltrates surrounding tissues slowly. Metastasis may occur in advanced disease, notably to bone. Presenting symptoms of advanced disease are usually those of urinary outflow obstruction, or pelvic or back pain due to bone metastases. However, most men are asymptomatic, and may be diagnosed as a result of screening.

Controversy exists regarding all aspects of the management of prostate cancer, from screening to the best treatment for each stage of the disease. Much of this is because of the lack of clear data to guide treatment decisions. Factors that guide treatment decisions include the extent (stage) of the tumour, tumour grade (Gleason score), baseline prostate specific antigen (PSA) levels, the patient's life expectancy (based on age and comorbid conditions), treatment morbidity, and patient preference.[1-3]

There is great controversy over the value of screening for early disease by detection of PSA. Screening increases the incidence, but may not decrease mortality, and can result in unnecessary treatment. PSA screening in the USA did not result in significant differences in mortality compared with the UK, where PSA screening was not widely adopted.[4] A large European study found that PSA screening reduced the rate of mortality from prostate cancer by 20% but was associated with a high risk of overdiagnosis.[5] European guidelines state that decisions on population screening await longer follow-up.[3] US expert groups vary in their recommendations. A large US study found that screening provided no reduction in death rates after 7 to 10 years of follow-up.[6] The US Preventive Services Task Force deemed the evidence insufficient to assess the balance of benefit and harm of screening in men younger than 75 years; men aged 75 years or older should not be

screened.[7] Others favour screening, subject to patient preference after discussing risks and benefits; the time at which they consider screening should start is based on the patient's perceived risk, and has varied from 40 to 50 years of age.[2,8,9]

In patients with **localised disease**, detected incidentally or by screening, the choices are radical prostatectomy, radical external beam radiotherapy, brachytherapy, or deferred treatment (active surveillance or watchful waiting).[1-3,10,11] There is no general consensus as to what constitutes best treatment.[3] Men may be stratified as low-, intermediate-, or high-risk, depending on stage, grade, and PSA level.[2,3] Treatment morbidity and patient preferences are particularly important. Adverse effects of surgery include impotence and incontinence, and for radiotherapy, radiation proctitis, impotence, urinary retention, or incontinence.[2,10,11] In medically fit patients with a life expectancy of 10 years or more or those with poorly differentiated tumours, many clinicians would consider radical prostatectomy or radiotherapy with curative intent.[1,2,12] In men with a life expectancy of less than 10 years and with low-grade tumours, there is a definite role for deferring treatment.[2,10,12] Use of continuous or intermittent androgen deprivation therapy (ADT) as primary treatment has increased,[11] although it does not improve survival, and some guidelines do not recommend it.[2] However, its use with other therapies may be considered. (For further discussion of ADT, see below.) A systematic review[13] concluded that neoadjuvant (given for 3 to 6 months before the primary curative therapy) or adjuvant hormonal therapies, used with prostatectomy or radiotherapy, were associated with clinical benefit in terms of local control. Use of either with prostatectomy did not affect survival, but neoadjuvant hormonal therapy before radiotherapy significantly improved disease-free survival, and adjuvant hormonal therapy after radiotherapy significantly improved disease-free and overall survival. Some US guidelines[2] recommend that where radiotherapy is used for intermediate-risk localised disease, short-term (4 to 6 months) of neoadjuvant, concomitant, or adjuvant ADT can be considered; for high-risk disease, long-term use (2 to 3 years) is recommended.

For patients with **locally advanced disease**, options include radiotherapy with neoadjuvant, concomitant, or adjuvant ADT, ADT alone, or radical prostatectomy.[2,3] There is evidence that the use of hormonal therapy before or after radiotherapy improves disease-free and overall survival.[13-15] Studies of ADT have found that treatment for 3 years[16] and 5 years[17] after radiotherapy have improved survival when compared with treatment of shorter duration. US guidelines recommend 2 to 3 years of ADT when radiotherapy is used for locally advanced disease.[2]

PSA may be used to monitor the efficacy of therapy and detect biochemical relapse.[1,2] For those thought at low risk of metastases, salvage options after surgery include radiotherapy with or without ADT, while after primary radiotherapy options include observation, salvage prostatectomy in selected cases, cryotherapy, or brachytherapy.[2]

For patients with **metastatic disease** cure is not possible and therapy is aimed at prolonging survival and palliating symptoms. The basis of therapy is hormonal manipulation: about 80% of patients will respond to such therapy, but resistance eventually develops.[1,18] Historically, oestrogens such as diethylstilbestrol were used, but these are no longer recommended due to cardiotoxicity.[1,19] Standard first-line therapy is now ADT, using a gonadorelin analogue (such as goserelin, leuprorelin, or triptorelin) to produce medical castration, or opting for surgical castration (orchidectomy);[1-3,18,19] these have been shown to be equally effective.[2] However, medical castration with a gonadorelin analogue causes an immediate increase in testosterone (flare reaction), and a short course of an anti-androgen (such as bicalutamide, flutamide, or nilutamide) is given (either before or with the LHRH agonist) to prevent this surge.[2,3,18]

Some consider that anti-androgen monotherapy (with nonsteroidal drugs) may be discussed as an alternative to medical or surgical castration,[19] but others[2] do not recommend it. There is some evidence that survival rates may be lower, and treatment withdrawals (due to gastrointestinal adverse effects) higher.[20] Steroidal anti-androgen monotherapy should not be offered.[19] The gonadorelin antagonist abarelix can also be used for ADT. It has a more rapid onset of effect than the gonadorelin analogue leuprorelin and does not stimulate tumour flare.[21,22] Abarelix may be an alternative for men who are not suitable candidates for orchidectomy or gonadorelin analogue therapy.

Combined androgen blockade (longer use of an anti-androgen with medical or surgical castration) is also an acceptable first-line option;[2,19] this blocks the action of adrenal androgens as well (total androgen blockade).[1] Early studies suggested a small survival advantage with this approach, but adverse effects are increased,[1,19] and some guidelines[2] state that combined androgen blockade provides no proven benefit over castration alone.

The timing of ADT is controversial; there is some suggestion that early ADT may be better than delayed ADT, but data are limited,[18,19] and treatment should be individualised.[2] However, in the presence of symptomatic or overt metastases, treatment should be started immediately.[2] Intermittent ADT may potentially offer improved disease control and quality of life; however, data are limited and this approach, while feasible, remains investigational.[1,18,19]

In patients who relapse after or during hormonal therapy, second-line hormonal therapy may be tried, although responses are variable. Anti-androgens may be used sequentially, particularly in men who wish to defer more aggressive approaches such as chemotherapy;[18] drugs used include bicalutamide, flutamide, ketoconazole, oestrogens, and corticosteroids.[2,3,18,23]

Patients with **hormone-refractory (castration-refractory)** disease should be offered chemotherapy as an option.[2,3,18,24] Personalised immunotherapy with sipuleucel-T is also an option in some countries; it is recommended for patients with good performance status, life expectancy of more than 6 months, and no visceral disease.[2] In those given chemotherapy, docetaxel-based regimens are considered the standard of care.[25] A schedule in which docetaxel is given every 3 weeks is advocated first-line.[2,3,24] since this has shown a survival benefit.[2] Docetaxel is used with prednisone or estramustine, although use with the latter increases adverse effects and is generally not recommended. Alternative regimens include weekly docetaxel plus prednisone, or mitoxantrone every 3 weeks plus prednisone.[2] No consensus exists for second-line chemotherapy after failure of docetaxel and enrolment into clinical studies is encouraged.[2] Combinations of docetaxel are under investigation, including with vinorelbine, capecitabine, or high-dose calcitriol.[25] Estramustine with etoposide, vinblastine, or vinorelbine has also shown favourable results.[26] Other drugs that might be used after treatment with docetaxel-based therapy include oral cyclophosphamide, alone or with vincristine and dexamethasone;[23,25] intravenous cabazitaxel with a corticosteroid or oral enzalutamide may be options in those with metastatic disease. Abiraterone acetate, an inhibitor of androgen synthesis, may be given to patients with disease progression after docetaxel-based therapy,[27] or where ADT has failed but chemotherapy is not yet indicated.[28] Drugs under investigation include satraplatin and ixabepilone.[23,25]

A herbal combination preparation, PC-SPES, had some beneficial results in androgen-dependent and androgen-independent disease and has been used widely as a complementary medicine, but there have been reports of adverse cardiovascular effects and contamination with diethylstilbestrol and warfarin, resulting in the withdrawal of this product from most markets.[29,30] Bone metastases are usually treated with palliative radiotherapy (see p. 700.3). Bone-targeted therapy with strontium-89 or samarium-153 may be beneficial;[2,3] radium-223 is also used. Combinations of radiopharmaceuticals with docetaxel are under investigation.[31] Intravenous bisphosphonates such as zoledronic acid are recommended for bone pain and to prevent skeletal complications.[2,3] Prostate cancer growth is thought to be stimulated by endothelin-1, a small peptide that acts at endothelin-A receptors; atrasentan is an endothelin-A receptor antagonist under investigation, and early studies have shown improvements in time to disease progression and markers of bone metastases.[25,26]

Prophylaxis.

Because of the difficulties involved in managing prostate cancer there has been interest in the concept of disease prophylaxis. In healthy men, a large controlled study[32] found that seven years of finasteride prophylaxis reduced the incidence of prostate cancer by about 25% compared with placebo, but this benefit was offset by an increased risk of high-grade tumours associated with finasteride. However, later studies found that finasteride increased the accuracy of PSA testing,[33] and decreased prostate gland volume,[34] which could have contributed to the greater detection of all grades of cancer with finasteride. Guidelines issued by the American Society of Clinical Oncology and the American Urological Association[35] concluded that while the higher incidence of high-grade cancer seen in the finasteride group was likely due to these confounding factors, an increased incidence of high-grade cancer could not be excluded with certainty. However, some men may benefit from 5-α-reductase inhibitor therapy. A systematic review[36] concluded that reduction of prostate cancer with 5-α-reductase inhibitors was limited to men who had a baseline PSA value of less than 4 nanograms/mL. Dutasteride is also under investigation.[35,37]

Results from a case-control study have suggested an association between warfarin use and a decreased risk of prostate cancer.[38] Suggestions that selenium (see p. 2087.2) or vitamin E (see p. 2047.3) supplementation, alone or in combination, might reduce the risk of prostate cancer have not been borne out.[39] However, interest in compounds such as vitamin D (see p. 2116.1) and soya isoflavones[40] continues.

Malignant neoplasms of the skin. Basal cell carcinoma is the most common form of skin cancer, accounting for about 80% of cases. The second most common skin cancer is squamous cell carcinoma. These 2 types of carcinoma (collectively referred to as nonmelanoma skin cancers) are the most common malignancies among white populations, but because many are not recorded the exact incidence is uncertain and they are often omitted from calculations of the relative frequency of malignancy. A small but increasing proportion of all skin cancers are melanomas, arising from melanocytes (pigment cells). Other cancers that manifest in the skin include cutaneous T-cell lymphomas (see Mycosis Fungoides, p. 698.3) and Kaposi's sarcoma (see p. 718.1).

Nonmelanoma and melanoma skin cancers are related to solar radiation, and the incidence is greatest in those regions where light-skinned populations live closest to the equator. Individuals at particular risk include those with fair skin, blue eyes, red hair, a tendency to freckle, and to burn rather than tan. Use of methoxsalen with ultraviolet light (PUVA) has also been associated with an increased incidence of skin cancers (see Effects on the Skin, under Methoxsalen, p. 1713.1). Other risk factors for nonmelanoma skin cancers include various inherited disorders such as xeroderma pigmentosum (see Photosensitivity Disorders, p. 1686.2) and albinism (see Pigmentation Disorders, p. 1687.2). Immunosuppressive therapy, as used after solid organ transplantation (see p. 1936.2 *et seq.*), is associated with a very large increase in risk of squamous cell carcinoma.

Prophylaxis. Although nonmelanoma and melanoma skin cancers are related to solar radiation, and measures to reduce sun exposure are therefore advocated for prophylaxis, the relationship appears to differ between the types.

- Squamous cell carcinoma and its precursor lesions are clearly linked to cumulative chronic sun exposure.[1,2] These lesions are more common on frequently exposed skin (head, neck, and back of hands), and are more common in individuals with outdoor occupations. In addition, there is evidence that regular sunscreen use can reduce the incidence of new actinic keratoses and increase remission of existing lesions,[3] and reduce incident squamous cell carcinomas.[4,5]
- Although basal cell carcinomas are also common on sun-exposed skin (head and neck), it appears that they may be more related to a history of severe sunburns, particularly in childhood and adolescence, rather than to cumulative sun exposure.[1] In one study,[4] there was no difference in incidence of basal cell carcinomas between sunscreen users and non-users. Long-term follow-up of another study[5] found no clear benefit of regular sunscreen use in reducing basal cell carcinomas.
- Cutaneous melanoma is more common on skin exposed to the sun occasionally (particularly the legs in women, and the back in men), and appears to be more common in indoor than outdoor workers.[1,2] Cumulative occupational exposure seems to be protective in some white populations.[6] This suggests that intermittent sun exposure may be more risky than regular exposure for this cancer.[1,2] Short, sharp bursts of acute exposure in childhood and severe sunburn are also strongly associated with melanoma risk.[6] Although the use of sunscreens is advocated for protection against melanoma, some reports have suggested that sunscreen use may actually increase the risk.[7] However, systematic reviews[8,9] have found no good evidence for an association between sunscreens and the increasing incidence of melanoma, but did find that studies varied in accounting for confounding factors such as patient complexion and recall bias. Also, people at higher risk of sunburn and melanoma may also be more likely to use sunscreens, and some people may use sunscreens to allow for prolonged sun exposure, thus receiving a higher cumulative amount of UV radiation. Sunscreen formulation (see p. 1681.3), sun protection factor (SPF) rating, and protection against UVA (see Light-induced Skin Reactions, p. 1685.3), have also changed considerably over the last few decades, making it difficult to compare study results. Sunscreens are therefore recommended as an adjunct to other measures (such as protective clothing) to prevent over exposure, especially in young children.[7]

Chemoprevention has also been investigated as a means of reducing the incidence of squamous and basal cell cancers, particularly in those most at risk. Retinoids such as acitretin, etretinate, and isotretinoin have been shown to reduce the incidence of new squamous cell carcinomas in individuals with xeroderma pigmentosum, and in renal transplant recipients.[10] Conversely, neither betacarotene (p. 2047.3) nor selenium (p. 2087.2) has reduced the incidence of squamous or basal cell carcinomas in patients previously treated for these disorders. There is some evidence that a low-fat diet may reduce the incidence of actinic keratosis in patients with a history of nonmelanoma skin cancer.[11] Certain substances such as flavonoids, curcumin, grape seeds, resveratrol, silymarin, and green tea have been proposed as having antiphotocarcinogenic properties.[12]

BASAL CELL AND SQUAMOUS CELL CARCINOMA. The great majority of skin cancers are basal cell carcinomas, which are completely curable if diagnosed early and treated appropriately. Although they rarely metastasise, they have a tendency to be locally destructive. The remainder are mainly squamous cell carcinomas, which, although curable when treated early, have a greater risk of metastatic spread. Common precursor lesions for squamous cell carcinoma are actinic keratosis (solar keratosis) and Bowen's disease (squamous cell carcinoma in situ).

- Treatments for **actinic keratosis** and **Bowen's disease** include cryosurgery, curettage, excision, radiotherapy, laser treatment, photodynamic therapy (see Porfimer Sodium, p. 849.1) using 5-aminolevulinic acid or methyl aminolevulinate, and topical fluorouracil or topical imiquimod.[1-3] Topical diclofenac or topical salicylic acid may be used for actinic keratosis.[2-4] The choice of treatment depends on the site and size of the lesion, evidence for efficacy, ease of application, and availability.[1]
- Treatment options for superficial low-risk **basal cell carcinomas** include curettage and electrodesiccation or cryosurgery.[6-9] Topical fluorouracil may be used for superficial lesions in some instances, as are topical imiquimod or photodynamic therapy using 5-aminolevulinic acid, methyl aminolevulinate, or porfimer.
- For superficial tumours at high-risk sites, and for most **squamous cell carcinomas**, excision with postoperatively determined margins or Mohs' micrographic surgery (tumour margins examined during the procedure) is more appropriate.[6-11] Radiotherapy is an alternative in patients at risk of surgical complications or where surgery would be difficult or extensive.

The prognosis with appropriate treatment is good, with 5-year disease free survival of over 90%. However, about 50% of patients will subsequently develop another skin cancer, and regular monitoring to detect this as early as possible is desirable.[7] In addition, patients should be educated about sun protection measures, and chemoprevention with retinoids may be appropriate for some high-risk patients (see Prophylaxis, in Malignant Neoplasms of the Skin, above).

MELANOMA. Although cutaneous melanoma is rare it is the most aggressive skin cancer, accounting for the majority of all skin cancer deaths. Melanoma may arise in apparently normal skin or from an existing naevus. Early signs of a naevus that may indicate development of a melanoma are change in size, shape, or colour. Other signs include itching, ulceration, and bleeding. The most common site in women is the legs, and in men the back. For a discussion of sun protection measures in the prevention of melanoma, see Prophylaxis, in Malignant Neoplasms of the Skin, above.

Surgical resection is the mainstay of **curative treatment** for primary melanomas, and the margins of excision are determined by tumour depth (Breslow thickness).[1-7] Patients with thin tumours (less than 1 mm) can be treated with wide local excision only; patients with intermediate (1 to 4 mm) or thick (more than 4 mm) melanoma are at high risk for nodal disease, and lymph node dissection may also be performed if node biopsy is positive.[1,3,8] Because of the high risk of recurrence after surgery in the latter group, there is great interest in adjuvant therapies. There is no accepted standard adjuvant therapy in the UK,[2,7] and it is not recommended for stage II and III disease other than in the context of a clinical study.[8] In the USA, the FDA has approved high-dose interferon alfa, which has shown benefit in terms of relapse-free survival, although the effects on overall survival are less apparent.[1,5,6] As toxicity is a significant problem with high-dose therapy, both low-dose and intermediate dosage regimens have been studied, but neither have shown a clear benefit in terms of overall survival.[1,5,6] Some recommend pegylated interferon, if tolerated, in patients with low tumour burden.[9] Isolated limb perfusion (ILP) with melphalan has been used as adjuvant therapy, but a review of four randomised studies failed to show any survival benefit for this compared with surgery alone[10] and it is considered to have no role in the adjuvant setting.[8] Similarly, systemic chemotherapy has not proved useful in the adjuvant setting.[11] Various melanoma vaccines (e.g. GM2 ganglioside, autologous melanoma-associated antigens) have been investigated for adjuvant use, but high-dose interferon alfa was shown to produce greater clinical benefit than vaccination with GM2.[3,4,8,12,13] Other drugs such as bevacizumab,[7] cytokines such as interleukin-2,[5,6] and newer immunotherapeutic approaches[13] are under investigation in the adjuvant setting.

Local **recurrences** and in-transit metastases are treated by surgical excision where possible.[1-3,6,7] Other options include cryotherapy, carbon dioxide laser ablation, intralesional injection with BCG or interferon alfa, or topical imiquimod.[1-3,8] Radiotherapy is also included as a treatment option in some centres,[3] although others do not recommend its use in the first instance.[2] Adjuvant radiotherapy may be considered for positive margins unsuitable for re-excision.[1] ILP with melphalan is considered the standard treatment option for patients with limb involvement,[1,2,8] and those with disease that progresses despite surgery or laser therapy,[2] and as an option for those with unresectable in-transit metastases or recurrence.[3] ILP with melphalan plus tissue necrosis factor-α may also be used[2,8] although this does not significantly improve response rate. However, there is some evidence that a second ILP using this combination may be of value after an initial ILP with a poor response.[1] The ILP procedure is complex[1,6] and should only be performed in specialist centres.[8] Isolated limb infusion (ILI) is a simpler alternative that may produce equivalent results.[1,3,6] ILI usually uses melphalan with or without dactinomycin. However, it may be less effective than ILP, and some consider it more suitable for patients with low volume disease or for those with comorbidities that prevent ILP.[2]

For patients who present with **metastatic melanoma** the 5-year survival rate is poor.[11] Median survival in disseminated disease is only 6 to 9 months.[1,7,8] There is no evidence to show that any systemic treatments are better than best supportive care in these patients.[14] Chemotherapy has been tried in disseminated disease,[4-6,13] and dacarbazine, with response rates of about 5 to 20%, is the most commonly used single agent. However, the response duration is short, and complete responses are rare.[1] The orally active analogue temozolomide produces similar responses,[1] and is an alternative first-line agent.[3] Ipilimumab may also be considered for initial therapy, although extreme caution is advised in those with serious underlying auto-immune disorders because of the possibility of immune-mediated reactions.[3] Nitrosoureas (such as carmustine and lomustine) have response rates of

around 15% as single agents.[15] Fotemustine appears to be more active, particularly in the treatment of brain metastases.[15] It has been reported to have a higher response rate compared with dacarbazine, but with only a trend towards increased overall survival.[1,16] Other drugs with a response rate of about 15% include cisplatin, vinblastine, vindesine, docetaxel, and paclitaxel;[15] response duration has generally been poor. Vemurafenib has improved overall and progression-free survival compared with dacarbazine in those with metastatic melanoma with the $BRAF^{V600E}$ mutation,[17] although its place in therapy is not yet established. Dabrafenib and trametinib are other options for those with BRAF mutations.

Combination regimens have been used, such as CVD (cisplatin, a vinca alkaloid, and dacarbazine),[15] but they do not improve survival compared with monotherapy.[1] Tamoxifen has also been added to regimens, on the hypothesis that melanoma is oestrogen-dependent; an example was the CDBT or Dartmouth regimen (cisplatin, dacarbazine, carmustine, and tamoxifen; see Table 1, p. 719).[15] However, this regimen was no more effective than dacarbazine alone,[1] and the addition of tamoxifen to chemotherapy is ineffective.[1,8]

Cytokines such as interferon alfa and interleukin-2 have similar activity to chemotherapy in metastatic melanoma;[15] high-dose intravenous interleukin-2 is used in the USA,[6] but not for patients with untreated or active brain metastases.[3] Cytotoxic chemotherapy has been given with these cytokines and there have been some reports of improved response rates, but overall survival has not been improved.[1,2,5-7] Second-line therapy may be offered to patients (with good performance status) who progress or are unresponsive to, or intolerant of, first-line therapy. Options include clinical studies, or treatment with a different first-line agent.[3] Surgical resection or radiotherapy may be used palliatively or for symptomatic control.[1-3,6,9] Melanoma vaccines are also being used or investigated in metastatic or recurrent disease,[12,13] as are gene therapy,[5] antiangiogenic agents such as thalidomide,[15,16] and the antisense oligonucleotide oblimersen.[6,16] Sorafenib monotherapy is minimally active, but results of its use with carboplatin plus paclitaxel were encouraging and combination studies continue.[6,7,16]

Malignant neoplasms of the testis. Testicular cancer only accounts for about 1% of all male malignancies but it is the most common cancer in young men. Patients with a history of cryptorchidism are at increased risk. Other risk factors include family history, infertility, and white race. About 95% of testicular tumours arise in germ cells, and 40% or so of these are pure seminomas. The remainder are collectively known as nonseminomatous germ cell tumours (NSGCT) in the WHO classification, and are commonly of mixed cell types with or without a seminoma component. Nonseminomatous tumours have been referred to as teratomas in the British classification system, but this term has a more specific meaning in the WHO classification.

Metastasis first occurs to the lymph nodes, then, in advanced disease, to distant sites such as lung, liver, brain, and bones. The leading symptom is a hard, painless swelling of the testis, but once metastasis occurs the patient may present with back pain (due to enlargement of retroperitoneal lymph nodes), cough, dyspnoea, gynaecomastia due to chorionic gonadotrophin production, or weight loss.

Surgical removal of the testis (orchidectomy) when diagnosis is confirmed is fundamental to the treatment of all types of testicular cancer, but further therapy depends upon the disease type and stage.[1-4]

In patients with **nonseminomatous** disease with the ***tumour confined to the testis*** (stage I), options after orchidectomy include surveillance, adjuvant chemotherapy, or retroperitoneal lymph-node dissection (RPLND). Overall survival rates are good, with a cure rate close to 100%.[4-6] With surveillance, about 20 to 30% of patients will relapse and it is not appropriate for patients who are unable to undergo regular follow-up.[1,4] Treatment options vary slightly between countries. In the USA, RPLND may be carried out to further stage the disease before making a decision regarding surveillance or adjuvant chemotherapy.[1] If resected nodes are clear, patients undergo surveillance, but if they involve tumour the decision to give adjuvant chemotherapy is based on the degree of nodal involvement and the ability of the patient to undergo regular follow-up.[1] In the UK and Europe, stage I patients are classified as low-risk or high-risk, based on the absence or presence, respectively, of vascular (venous or lymphatic) invasion.[3-6] The standard option for low-risk patients is surveillance, with treatment on relapse.[3,5,6] High-risk patients can also be surveyed, but relapse rates are higher, and about 50% of patients will require chemotherapy.[3,5] The usual regimen used for stage I patients is 2 cycles of BEP (bleomycin, etoposide, and cisplatin).[1,3] However, there is some suggestion that one cycle of BEP may be sufficient.[3] RPLND is considered only if surveillance or chemotherapy is declined by the patient for specific or personal reasons, as it has the highest treatment burden.[3,5]

Where ***metastasis to the lymph nodes*** (stage IIA/B) has occurred, options for management are 3 cycles of BEP, 4 cycles of EP (etoposide and cisplatin), or primary RPLND (followed by either surveillance or chemotherapy).[1,3,4] Patients with ***advanced*** nonseminoma (stage IIC and III) are treated with primary chemotherapy regimens based on risk status; extent of disease and serum tumour markers are prognostic, and patients are accordingly classified into good-, intermediate-, and poor-risk groups.[1,3] For patients with good prognosis, standard treatment regimens are 3 cycles of BEP or 4 cycles of EP.[1,3,4] Standard management for patients with intermediate- or poor-risk disease is 4 cycles of BEP.[1,3,4] For patients who may not tolerate bleomycin, ifosfamide can be substituted (VIP regimen).[1,3,4] Less than 50% of poor-prognosis patients achieve a durable response, and enrolment into clinical studies is encouraged.[1] Any residual tumour is resected after chemotherapy; further management depends on the results of the primary treatment and secondary surgery; consolidation chemotherapy with 2 cycles of EP, VIP, VeIP (vinblastine, ifosfamide, and cisplatin) or TIP (paclitaxel, ifosfamide, and cisplatin) may be given.[1,3]

Patients who fail, or who relapse after, standard chemotherapy, or who have unresectable disease, are treated with *salvage therapy*.[1] Common salvage regimens include cisplatin and ifosfamide with either vinblastine (VeIP regimen), paclitaxel (TIP regimen), or etoposide (VIP regimen).[1,3,5,7] High-dose chemotherapy with stem cell support may also be considered.[1,5,6,8,9] Drugs with activity as single agents in relapsed disease include paclitaxel, oxaliplatin, and gemcitabine.[5-7] Combinations of these have been tried as second-line salvage chemotherapy regimens for patients with cisplatin-resistant or refractory disease;[7,9,10] gemcitabine with either oxaliplatin (GEMOX regimen)[1] or paclitaxel[3] may be tried.

About 75% of patients with **seminoma** have stage I disease at diagnosis, with a cure rate close to 100%.[2,5,6] Treatment options after orchidectomy include surveillance (with treatment only in the case of relapse), adjuvant radiotherapy or adjuvant carboplatin monotherapy.[1,2,4-6] Surveillance offers the lowest burden of treatment,[2] and is an option for selected patients who are committed to long-term follow-up.[1,6] The optimum surveillance schedule is still uncertain,[4] but should include measurement of serum tumour markers, clinical examination, and imaging of the abdomen, pelvis, and thorax.[1,4] Seminomas are extremely sensitive to radiation,[4] and adjuvant radiotherapy is the treatment of choice after orchidectomy in stages IIA and IIB.[1,5,6] For those with relative contra-indications to radiotherapy, chemotherapy is recommended;[1,5] 3 cycles of BEP, or 4 cycles of EP are used. There is an increasing role for chemotherapy in stage IIB[3] and some[2] distinguish slightly between stages in terms of treatment, and advocate radiotherapy and chemotherapy as standard for stages IIA and IIB, respectively; non-candidates for either therapy may be offered the alternative. Patients with stages IIC to III seminoma have a relapse rate of 20 to 30% after adjuvant radiotherapy, and adjuvant chemotherapy is preferred.[5] Standard regimens are 3 cycles of BEP or 4 cycles of EP for good-risk patients, and 4 cycles of BEP for intermediate-risk patients;[1,2] using ifosfamide instead of bleomycin can also be an option in those at intermediate-risk.[2] About 90% of patients with advanced seminoma are cured with cisplatin-containing chemotherapy.[1] Salvage regimens for relapsed or unresponsive seminoma are similar to those used for nonseminomatous disease.[1,2]

Malignant neoplasms of the thymus. Thymomas are tumours of the mediastinum, arising from thymic tissue. They are rare, and most commonly present in patients between 40 and 60 years of age. Thymoma originates from the epithelium of the thymus but may also contain a lymphocyte component, which is probably not neoplastic. Up to 50% of patients are asymptomatic, and others have local symptoms such as cough, chest pain, dyspnoea, and obstruction of the vena cava; associated systemic disorders include myasthenia gravis, red cell aplasia, and hypogammaglobulinaemia.

Thymomas may be classified based on cell type; they are also staged as non-invasive (encapsulated, stage I), invasive (localised, stage II; extensive, stage III; and disseminated, IVa), and metastatic (IVb).

The treatment of thymoma may involve surgery, radiation, and chemotherapy; these may be combined, with the combination determined by the stage of the tumour.[1] Non-invasive stage I disease can be treated solely by surgical resection[1-4] with low recurrence rates and long-term survival approaching 100%.[3] Use of adjuvant radiation therapy for stage II thymoma has been controversial,[2] with studies showing conflicting results.[3] Generally, however, routine adjuvant radiotherapy is not recommended for stage II disease;[1,4] it may be considered in those patients at high risk for local recurrence,[1] or in patients with incomplete resection;[4] late complications of radiation therapy may occur.[1,2] Patients with stage I or II disease who are medically unfit for surgery may be offered chemoradiotherapy or radiotherapy alone.[1]

For patients with potentially resectable invasive disease (stages III and IVa), surgery is considered either initially or after neoadjuvant therapy. Chemoradiotherapy is often used before surgery, although the optimal regimen or sequencing has not yet been established.[1] Cisplatin-based combination regimens are recommended.[1,4] Concurrent chemoradiotherapy is recommended, but if the tumour is bulky, sequential therapy, with chemotherapy given before radiation, is an option.[1] Adjuvant radiotherapy is also often used in stage III,[1] and is recommended to maximise local control.[4] Adjuvant chemotherapy may be considered, but is not routinely recommended.[1] For stage IVa, adjuvant chemoradiotherapy is an option.[1] Patients with unresectable invasive disease may be treated with chemotherapy alone,[1] radiotherapy alone,[4] or concurrent or sequential chemoradiotherapy.[1,4] Cisplatin plus anthracycline-containing regimens similar to those in metastatic disease (below) are used first-line, and single agents second-line.[1]

Therapy for recurrent or metastatic disease is not well established because of the rarity of the condition.[1,5] Radiotherapy may be appropriate in stage IVB, especially for life-threatening situations,[1] but chemotherapy is often used.[1,4] Cisplatin and anthracycline-containing regimens are used first-line.[1,4] These include cisplatin, doxorubicin, and cyclophosphamide (CAP or PAC regimen), and the same drugs with vincristine (ADOC regimen). Cisplatin plus

etoposide (PE regimen) or these 2 drugs with ifosfamide (VIP regimen) are also options.[2,4,5] For these and other commonly used chemotherapy regimens, see Table 1, p. 719. Carboplatin and paclitaxel can also be used first-line.[4] Second-line single agents with activity include etoposide, ifosfamide, pemetrexed, fluorouracil, gemcitabine, and paclitaxel.[4] There is some evidence that thymomas possess somatostatin receptors, and octreotide, alone or with a corticosteroid, is also a second-line option.[1,4]

Surgery is considered for localised recurrence after apparently successful initial therapy. For some patients with stage IV disease, resection of isolated pleural metastases is appropriate. Radiotherapy, alone or with cisplatin-based chemotherapy, may be used. Octreotide with or without a corticosteroid is also a reasonable option for recurrent disease.[1]

Malignant neoplasms of the thyroid. Thyroid cancer accounts for only about 1% of all malignancies. The incidence is reportedly higher in women than men, in patients who received irradiation of the thyroid during childhood, and in populations where goitre is endemic. The natural history varies with the cell type and degree of differentiation. Well-differentiated papillary or follicular tumours (which constitute over 80% and about 10% of cases, respectively) are very slow to grow and metastasise, sometimes persisting for years with little change in size and extent, although they may prove more aggressive in children. In contrast medullary carcinomas (5 to 10% of cases), which develop from the cells responsible for calcitonin secretion, and undifferentiated (anaplastic) tumours (1%) metastasise early and follow a much more rapid and aggressive course. About 25% of medullary cancers are hereditary, including those due to multiple endocrine neoplasia type 2.

The well-differentiated types usually present as a thyroid nodule, although most nodules are not malignant, while with anaplastic tumours there is usually invasion into the trachea, larynx, or recurrent laryngeal nerve which leads to obstructive symptoms, haemoptysis, dysphagia, and hoarseness.

In patients with **well-differentiated tumours** total or partial thyroidectomy is the treatment of choice.[1-7] This may be followed by a course of iodine-131 to destroy any residual tumour (thyroid ablation), although in patients who have small tumours with no other high-risk features (such as extension beyond the thyroid capsule or lymph node metastases) there are no benefits to such ablation and iodine-131 is not usually recommended.[1-7] External radiation therapy may be considered in patients with evidence of extrathyroid extension at the time of surgery.[3,4] There is no role for routine adjunctive chemotherapy in the management of differentiated thyroid cancer.[4] Levothyroxine treatment is given to all patients to prevent hypothyroidism and to minimise stimulation of tumour growth by thyroid stimulating hormone (TSH).[2,5,6] Measurement of serum thyroglobulin concentrations aids the detection of residual, recurrent, or metastatic disease. After surgery and thyroid ablation, this should be undetectable after about 3 months, although occasionally it may take up to 2 years; raised concentrations imply the presence of functional thyroid tissue or tumour. Sensitivity of thyroglobulin measurements is enhanced by an increase in TSH. TSH stimulation can be achieved either by levothyroxine withdrawal or by injections of human recombinant thyrotropin alfa.[1-4,6]

Disease recurrence or metastases are commonly treated with further surgery, ablative iodine-131 therapy or external radiation therapy.[1-4] Chemotherapy for metastatic disease has been inadequately studied.[2,5] It may have a role in refractory disease.[1,3,6] Doxorubicin is often used,[5] with a response rate of up to 40%;[2] cisplatin is also used.[1] Durable responses are rare.[1,2] Combination chemotherapy is not clearly superior to doxorubicin monotherapy.[3] Some[7] recommend against chemotherapy due to a lack of efficacy and recommend enrolment into clinical studies. Novel agents are under investigation;[1,3,5,7,8] preliminary results with tyrosine kinase inhibitors have been promising.[7]

In patients with **medullary cancers** total thyroidectomy and central neck compartment dissection are indicated,[1-3,7] with levothyroxine treatment if needed.[2,3] Serum calcitonin should be measured to detect residual disease.[2,3] Adjuvant external beam radiotherapy may be used in patients at high risk of regional recurrence[2,3] but routine use has not shown any survival benefit.[1] There is no role for radioactive iodine in medullary disease,[2,3] and chemotherapy is generally ineffective.[1,3] Further surgery with or without adjuvant radiotherapy is recommended for recurrent disease. Palliative resection or radiofrequency ablation can be tried for distant metastases; chemotherapy is usually dacarbazine-based.[3] Novel agents such as tyrosine kinase inhibitors have been investigated, with promising initial results;[7] cabozantinib is used for metastatic disease, and vandetanib for unresectable locally advanced or metastatic disease. Prophylactic thyroidectomy may be considered in patients with a hereditary predisposition to medullary cancer.[1,2] In patients with **anaplastic tumours**, cure is impossible and treatment is purely palliative, with survival measured in months.[2,3,7] Treatment options include surgery, radiotherapy, and chemotherapy. *Multimodality* therapy should be considered.[2,3,9] Use of hyperfractionated radiotherapy with doxorubicin can increase response, with median survival of 1 year. Paclitaxel has also been tried.[2,3,7] Novel agents are under investigation,[7,8,10] including the vascular targeting agent fosbretabulin.[3]

Neuroblastoma. Neuroblastoma accounts for about 7% of all childhood malignancies overall but is the most common extra-cranial solid tumour in children. The majority of cases present before the age of 5 years. The tumour is derived from cells of the neural crest, and may occur anywhere within the sympathetic nervous system, notably the sympathetic ganglia and the adrenal medulla. Clinical behaviour ranges from spontaneous remission to rapid metastatic progression and death. Sites of metastasis include lymph nodes, bone marrow, liver, and skin. Symptoms depend on the site of the primary tumour and extent of disease. About 50% of children present with metastatic disease. Adverse prognostic factors include age over 1 year at diagnosis, advanced or metastatic disease, and amplification of the oncogene MYCN. The International Neuroblastoma Staging System (INSS) divides localised tumours into stages 1 and 2, based on regional lymph node status; unresectable tumours are classified as stage 3, and stage 4 refers to all patients aged 1 year or older with distant disease. Stage 4S (4 special) refers to infants less than 1 year of age with small localised primary tumour and limited dissemination (confined to liver, skin, or bone marrow).[1,2] However, the INSS is based on the extent of surgical excision, and a new staging system has also been developed by the International Neuroblastoma Risk Group, which is based on tumour imaging and risk factors. Locoregional tumours are staged as L1 or L2 based on the absence or presence of one or more image-defined risk factors, respectively. Metastatic tumours are classified as stage M, except for stage MS, in which metastases are confined to the liver, skin, and/or bone marrow in children younger than 18 months of age.[3,4]

Treatment protocols are designed according to the risk stratification:[1,5,6]

- the *low-risk* group consists of stage 1, stage 2, and stage 4S non-amplified hyperploid tumours with favourable histology
- the *intermediate-risk* group includes stage 3, 4, and 4S MYCN non-amplified tumours
- the *high-risk* group consists of stage 2 to 4 MYCN amplified tumours, including stage 3 tumours with unfavourable histology in children older than 18 months

Surgical resection alone is appropriate for those with **low-risk** tumours; these patients have a good prognosis.[1,2,6] Patients with local recurrence after surgery can be salvaged with chemotherapy and local radiotherapy. Neoadjuvant chemotherapy is also an option for those with paraspinal tumours and spinal cord compression, in order to avoid the morbidity of laminectomy and radiation. Patients with symptomatic stage 4S disease may also require chemotherapy.[2]

In those classified as **intermediate-risk**, surgery is usually followed by a short course of standard-dose combination chemotherapy.[1,2,6] Regimens used include cisplatin (or carboplatin), etoposide, cyclophosphamide, and doxorubicin.[2]

High-risk tumours can be treated with surgery, combination chemotherapy, myeloablative chemotherapy with haematopoietic stem cell transplantation, and local radiation.[1,2,6] Most remission induction regimens incorporate some or all of the most active drugs available for neuroblastoma, including the platinum derivatives, cyclophosphamide, ifosfamide, doxorubicin, etoposide, and topotecan.[1,2] One such dose-intensive regimen that was reported to have good response rates in a small study consisted of cyclophosphamide, vincristine, plus doxorubicin, alternating with cisplatin and etoposide.

Consolidation with myeloablative chemotherapy is used to eradicate any residual cancer cells. The addition of isotretinoin improved event-free survival and some consider high-dose myeloablation followed by isotretinoin to be the standard of care for children with high-risk disease who are older than 1 year at diagnosis.[2] Stem cell transplantation may be autologous or allogeneic,[2] although autologous peripheral blood stem cells appear to be the preferred source; tandem transplants are under investigation.[2,7]

Neuroblastoma is radiosensitive and if complete surgical resection is not possible, adjuvant radiation is indicated. It may also be used after chemotherapy, and occasionally as palliation for metastases.[1] However, the role of total body irradiation (TBI) in the treatment of high-risk neuroblastoma has not been established, and most protocols do not include TBI.[2]

Metaiodobenzylguanidine (*m*-iodobenzylguanidine; iobenguane; MIBG) is a guanethidine derivative and norepinephrine analogue that concentrates in neural crest tissues. When radiolabelled with isotopes of iodine, MIBG has been shown to be useful for both imaging and treatment of neuroblastoma. MIBG uptake can be seen at the site of primary disease as well as metastatic tumour sites.[6] Iodine-123-labelled MIBG is the radioisotope of choice for imaging, whereas Iodine-131-labelled MIBG is used for therapeutic purposes.[5,6] It has been used as monotherapy or with combination chemotherapy in advanced, relapsed, or refractory disease, and has been investigated for use in newly diagnosed patients.[6,8] MIBG with radiosensitisers is also under investigation.[6] Multiple infusions of MIBG have also been used.[6,8]

Neuroendocrine tumours. Neuroendocrine tumours are rare and constitute a heterogeneous group of neoplasms that share certain biological features. They originate from cells that produce and secrete regulatory hormones, and frequently present as hypersecretory syndromes. Common sites of origin include the endocrine pancreas, gastroenteric tissue in the gut, and neuroendocrine cells in the respiratory epithelium, as well as the thyroid, parathyroid, adrenal, or pituitary glands. Examples of syndromes associated with such secretory neoplasms include acromegaly (p. 1921.1), Cushing's syndrome (p. 2559.1), hyperprolactinaemia (p. 2252.2), and phaeochromocytoma (p. 1278.1). Multiple endocrine neoplasia type 1 (MEN1) and type 2 (MEN2) are inherited conditions in which many tumours occur in often more than one endocrine organ; tumours in this disorder are often secretory.

Gastroenteropancreatic neuroendocrine tumours include carcinoid tumours and pancreatic endocrine tumours.

Carcinoid syndrome. Carcinoid tumours have traditionally been classified according to their embryological origin, namely fore-gut (bronchi, stomach, duodenum), mid-gut (jejunum, ileum, appendix, proximal colon), and hind-gut (distal colon and rectum).[1-4] Carcinoid tumours can secrete various hormones. The carcinoid syndrome describes symptoms related to the secretion of serotonin, histamine, or tachykinins. However, symptomatic carcinoid syndrome

is rare, both because the tumours vary in their behaviour depending on their embryological origin and because the liver is capable of metabolising those tumour products which are secreted into the portal circulation; only if the carcinoid tumour secretes into the systemic circulation, notably after metastasis to the liver, do symptoms occur. Carcinoid syndrome is therefore most often associated with tumours of the mid-gut, since they are commonest, and frequently metastasise.[2,5]

The characteristic **symptoms** of carcinoid syndrome include episodic flushing of the face and upper trunk (which may be provoked by alcohol, food, or stress), secretory diarrhoea, wheezing and dyspnoea, weight loss, pellagra, painful hepatomegaly, and right-sided valvular heart disease, which sometimes progresses to right heart failure and death.[2,4,5]

The **management** of carcinoid tumours usually involves surgical resection.[2-5] For localised disease, surgery may be curative.[1,6] Although many patients present with metastatic disease,[1] cytoreductive surgery is a mainstay of management.[4,6] Other cytoreductive procedures can also be used, such as radiofrequency ablation, laser therapy, and hepatic regional therapy (arterial embolisation, or trans-arterial chemoembolisation).[1,2,4-6] Drugs used for chemoembolisation include doxorubicin, streptozocin,[5] or a combination regimen of cisplatin, doxorubicin, and mitomycin.[4] Systemic antineoplastic chemotherapy has been used, but is considered to be of limited benefit for carcinoid tumours.[5-7] However, combination regimens may be used first-line for malignant, highly proliferative carcinoid tumours.[4] A common combination includes streptozocin, fluorouracil, plus doxorubicin;[4] cisplatin plus etoposide has also been used.[7] Despite some initial reports of response to interferon alfa, its value has not been borne out in practice.[5] It has, however, been considered to be of value for symptomatic control.[7]

For **symptomatic relief** of carcinoid syndrome somatostatin analogues such as octreotide or lanreotide are highly effective[4,5,8] and are the treatment of choice.[1,2] The availability of depot intramuscular preparations has simplified treatment, removing the need for multiple daily subcutaneous injections.[1,7,9] However, with prolonged use a few patients develop resistance even to the highest doses; the mechanism behind this tachyphylaxis is not yet known, although down-regulation of receptors has been suggested.[3,4,7] Octreotide is also used in the perioperative management of these patients to treat or prevent carcinoid crisis, when it may be given intravenously.[1] Use of somatostatin analogues with interferon alfa does not appear to be superior to monotherapy with either drug, and most do not recommend combination therapy as a standard treatment option.[7,9,10] While some consider the sequential use of these drugs, or the use of the combination after progression on monotherapy, to be justified,[10] others rarely add interferon when somatostatin analogues are no longer effective.[3] There is growing interest in the use of radiolabelled somatostatin analogues for the management of tumours that express high levels of somatostatin receptors;[2,4,5,9] promising results have been reported with palliative use in inoperable or metastatic disease.[1,11] Newer therapies such as gefitinib, everolimus, sunitinib, and bevacizumab are also being tried.[2,5,6] Other drugs that reduce the effects of serotonin have been tried, including cyproheptadine.[5] Patients with histamine-producing tumours should avoid histaminic drugs; treatment is with somatostatin analogues, blockade of histamine receptors, and possibly corticosteroids.[3]

Apart from such specific pharmacological therapies, antidiarrhoeals such as loperamide are sometimes helpful in controlling diarrhoea. Supplementation with vitamin B substances is advisable to prevent pellagra. It is also important to avoid provocative factors such as stress, alcohol, and particular foods.[3]

Pancreatic endocrine tumours. Neoplasms of the pancreatic islet cells (pancreatic endocrine tumours) are uncommon compared with those of the exocrine pancreas (see Malignant Neoplasms of the Pancreas, p. 712.1). Pancreatic endocrine tumours, whether benign or malignant, often secrete clinically significant amounts of hormone; the hormone secreted, and hence the resultant clinical syndrome, depends on which of the several types of hormone-secreting islet cells is the origin of the tumour.[2] Primary **therapy** for solitary pancreatic endocrine tumours is surgical resection;[2] metastatic tumours may require a combination of symptomatic drug therapy, chemotherapy, radiotherapy, and surgical debulking. As for carcinoid tumours, somatostatin analogues such as octreotide or lanreotide are used to control symptomatic disease.[1,2] For those who present with significant tumour burden, or with disease progression, options include everolimus or sunitinib, which have been found to improve progression-free survival, or cytotoxic chemotherapy.[2] The most frequently used regimens involve combinations of streptozocin, doxorubicin, fluorouracil, and dacarbazine.[1,2,7] Capecitabine and temozolomide have also been used.[2] Hepatic regional therapy, including arterial embolisation or chemoembolisation, is used for patients who are not surgical candidates.[2]

Symptoms of hormonal excess should be treated, before surgery and/or after resection if needed; therapies depend on the tumour type,[2] and are used in cases refractory to somatostatin analogues, or in combination with them.[3]

- Up to 90% of **insulinomas** are benign[2,6] and do not metastasise. Only about half of these tumours have somatostatin type II receptors and are thus less sensitive to treatment with somatostatin analogues.[1,3] Excessive insulin secretion results in hypoglycaemia; glucose concentrations can be stabilised by diet and/or diazoxide.[1-3] Glucose infusions may be needed.[1]
- Most **glucagonomas**, which secrete glucagon, are malignant, and over 80% have metastases at presentation.[2,3] Common symptoms include a characteristic rash (necrolytic migratory erythema), diabetes mellitus, weight loss, and diarrhoea. Patients should be stabilised with intravenous fluids, octreotide, and zinc.[2,3]
- Another well-characterised syndrome results from tumours which release vasoactive intestinal polypeptide (VIP). Such **VIPomas** result in profound secretory diarrhoea, with consequent hypokalaemia and acidosis;[2,3] the syndrome is sometimes known as pancreatic cholera. Metabolic imbalances should be corrected by fluid and electrolyte supplementation.[1,2] Somatostatin analogues such as octreotide are used for chronic control of the diarrhoea;[1-3] other antidiarrhoeals are seldom effective, although glucocorticosteroids can be used for acute exacerbations.[3]
- Of the other pancreatic endocrine tumours **gastrinoma** is the commonest: it results in Zollinger-Ellison syndrome, for which proton pump inhibitors are the treatment of choice. For further information on the treatment of Zollinger-Ellison syndrome see p. 1817.3. Rarer malignant tumours include **somatostatinoma** (which secretes somatostatin) and **PPoma** (which secretes pancreatic polypeptide).[2,3]

Retinoblastoma. Retinoblastoma is the most common eye tumour in children and accounts for about 3% of all childhood malignancies in the UK (for other malignant neoplasms of the eye, see p. 705.1). In about 60% of cases the tumour is sporadic and non-hereditary, producing a unilateral, unifocal lesion. In other cases there is an inherited abnormal tumour suppressor gene (RB1 gene mutation): these tumours are typically bilateral and are sometimes associated with an intracranial neuroblastic tumour or pinealoblastoma (trilateral retinoblastoma). In addition, patients with the hereditary form are at very high risk of secondary primary malignancies, particularly osteosarcoma and soft tissue sarcomas. Onset after age 5 is rare, but retinoblastomas are occasionally reported in adults. The most common manifestations of retinoblastoma are leukocoria (white pupil) and strabismus (squint). In intra-ocular disease, the tumour is confined to the eye; the majority of patients with unilateral disease present with advanced intra-ocular disease. Nevertheless, 5-year disease-free survival after treatment in these patients is over 90% in developed countries. Extra-ocular retinoblastoma is an advanced stage of the disease where the tumour has spread into the tissues around the eye (orbital invasion) or beyond the optic nerve with metastatic spread to the CNS and beyond. Extra-ocular disease is more prevalent in developing countries due to delayed diagnosis. The 5-year survival rate is less than 10% despite treatment. Management of retinoblastoma is individualised with consideration of the size and location of the tumour, laterality of the disease, age, risk of metastases, and stage.

The aim of treatment for **intra-ocular** retinoblastoma is to cure the disease, and to preserve as much vision as possible.[1,2] In patients with unilateral tumours, enucleation (removal of the eye) is the standard primary treatment when there is no expectation of useful vision (e.g. extensive disease within the eye).[3] The role of *adjuvant* treatment is controversial; adjuvant chemotherapy regimens include carboplatin plus etoposide, or vincristine, cyclophosphamide, and doxorubicin. Radiotherapy has also been used in cases of incomplete resection.[4] In bilateral retinoblastoma, standard treatment was enucleation of the advanced eye and external beam radiation therapy in the less advanced eye. However, there is increasing use of therapies to preserve the eye and to reduce the use of external beam radiotherapy which further increases the risk of secondary malignancies.[1,4,5] These include local treatments such as laser therapy, cryotherapy, thermotherapy, and plaque radiotherapy (brachytherapy).[1,3,4] Intravenous *neoadjuvant* chemotherapy may be given before local treatment to reduce tumour size (chemoreduction); regimens usually include carboplatin, etoposide (or teniposide), and vincristine.[1,3-5] Ciclosporin has also been included to overcome multidrug resistance due to P-glycoprotein.[3,5]

Chemothermotherapy (chemotherapy and thermotherapy used within hours of each other) may be useful for larger tumours, or for small tumours adjacent to the fovea or optic nerve.[3] *Local delivery* of chemotherapy directly into the periorbital tissues (focal chemotherapy) has also been investigated;[1,4,5] subconjunctival carboplatin may be useful in cases of vitreous seeding,[4] but local toxicity may be a problem and some reserve periocular injection for advanced intra-ocular disease that has not responded to multiple cycles of systemic chemotherapy.[5]

There is no standard treatment for **extra-ocular** retinoblastoma.[1,6] Patients with regional disease without overt metastases (micrometastatic retinoblastoma) may benefit from conventional systemic chemotherapy and external beam radiotherapy.[3,6] Patients with orbital extension may be treated with enucleation, radiotherapy, and intensive chemotherapy.[1] Regimens typically include cyclophosphamide, doxorubicin, and vincristine, and may include carboplatin and etoposide.[3,6] Intrathecal methotrexate and cranial irradiation may be added for CNS involvement or trilateral retinoblastoma.[6] Metastatic disease may be treated similarly,[6] but although conventional combination chemotherapy may produce a response it is rarely curative in such advanced disease.[1,3] High-dose chemotherapy with autologous stem cell rescue may be beneficial in metastatic disease, but it has not been effective for disease involving the CNS.[1,3]

Sarcomas. The sarcomas are tumours arising from mesodermal cells, which form the bone and connective tissue (as opposed to carcinomas, which arise from ectodermal and endodermal cells, and leukaemias and lymphomas, which arise from the bone marrow and immune system).

Sarcomas are uncommon, and vary considerably in their sites, presentation, and prognosis. The primary malignancies of bone include osteosarcoma and Ewing's sarcoma, which most often occur in older children and adolescents, and chondrosarcoma which is most common in later life. Soft tissue sarcomas include those of fibrous tissue (fibrosarcoma), skeletal muscle (rhabdomyosarcoma), smooth muscle (leiomyosarcoma), adipose tissue (liposarcoma), and blood vessels (a group which includes Kaposi's sarcoma).

BONE SARCOMA. The commonest primary malignant tumour of bone is **osteosarcoma** (osteogenic sarcoma). It is composed of malignant osteoblasts, which form an osteoid matrix within which new bone formation may occur. Most osteosarcomas are aggressive high-grade malignancies that destroy overlying cortical bone and invade adjacent soft tissue, as well as spreading along the medulla. Metastasis, almost exclusively via the vascular system to the lungs and other distant sites, is usual and occurs early. Most patients present between 15 and 25 years of age.

Therapy is multimodal. Complete surgical resection is primarily used, with an increasing trend to more conservative, limb-sparing operations rather than amputation. Adjuvant chemotherapy is an important component of therapy, as metastasis of the tumour is common.[1-3] Neoadjuvant chemotherapy is also often given before surgery to attack micrometastases, shrink the primary tumour and enable evaluation of the tumour response.[2,4,5] Combinations of cisplatin, doxorubicin (or epirubicin),

ifosfamide, and high-dose methotrexate are recommended.[1-6] Aggressive treatment regimens can result in long-term relapse-free survival rates of 70%, although patients with overt metastatic disease at presentation have a poorer prognosis.[1,7] Osteosarcomas are relatively resistant to radiation therapy;[1,3] however, for unresectable high-grade osteosarcoma, radiotherapy followed by adjuvant chemotherapy is recommended.[4] Recurrent disease is treated surgically where possible. The role of second-line chemotherapy remains to be defined.[3,6,8] Regimens may include combinations of cyclophosphamide or ifosfamide, carboplatin, and etoposide. Gemcitabine, alone or with docetaxel, may also be tried. Progressive disease after second-line therapy can be treated with resection, palliative radiotherapy, or best supportive care.[4] Osteoclast-targeted therapy (such as bisphosphonates)[9] and the addition of mifamurtide to conventional chemotherapy[2,4] are under investigation.

Like osteosarcoma, **Ewing's sarcoma** is seen mainly in adolescents and older children. It is a round cell tumour that most often arises in the pelvis or the long bones of the limbs. There may be diffuse erosion of the bone and marked periosteal reaction. It spreads through the medullary cavity, and metastases to lung and other bones are common. Treatment is also multimodal.[9,10]

Initial treatment is neoadjuvant chemotherapy for several months.[1,4,6] Combinations of cyclophosphamide, ifosfamide, etoposide, doxorubicin, dactinomycin, and vincristine are recommended,[1,2,4,6,9] although the use of dactinomycin for localised disease is controversial.[1] Typically, patients are then given local therapy (surgery, radiation, or both), with additional adjuvant chemotherapy.[1,4,9,10] Ewing's sarcoma is relatively radiosensitive,[1] and unresponsive or progressive disease is best managed with radiation therapy with or without surgery, followed by chemotherapy or best supportive care.[4] The prognosis of recurrent Ewing's sarcoma is poor.[4,6,9] Salvage chemotherapy regimens are not standardised.[6,9] Combinations include ifosfamide plus etoposide with or without carboplatin, cyclophosphamide plus topotecan, temozolomide plus irinotecan, and gemcitabine plus docetaxel.[4] High-dose chemotherapy with stem cell rescue has been investigated[2,5,6] but its role has yet to be determined.[4] Targeted therapy with anti-angiogenic agents may represent a future therapeutic approach.[9]

Chemotherapy appears to have little place in the treatment of other bone sarcomas such as **chondrosarcoma**[1,4] (despite some reports of efficacy[4]) or **osteoclastoma** (giant cell tumours of bone);[1] it has been used in high-grade **fibrosarcomas** and in **histiocytoma** but its value is uncertain.

KAPOSI'S SARCOMA. Kaposi's sarcoma is a tumour of endothelial or spindle cell origin. In its classical form it manifests as red or violet cutaneous lesions of the limbs in elderly men, usually of Jewish or Mediterranean ancestry. An endemic form is also seen in certain areas of Africa.[1,2] Lesions may eventually affect the whole of the skin, upper airways, gastrointestinal tract, lungs, and lymph nodes, but in general disease is only very slowly progressive, and may require no treatment. Patients given immunosuppressive therapy may be at greater risk of developing Kaposi's sarcoma, particularly if they are from ethnic groups that are susceptible to the classic or endemic forms of the disease.[1] In recent years an epidemic form of the disease has appeared in patients with disease due to HIV infection (p. 957.2).[2] HIV-associated Kaposi's sarcoma is more aggressive, with a greater tendency to disseminated and metastatic disease.

A novel herpesvirus (human herpesvirus 8, HHV8) has been implicated in the pathogenesis of Kaposi's sarcoma. HHV8 induces changes in endothelial cells that make them more susceptible to inflammatory cytokines and angiogenesis.[3] Some antivirals, such as cidofovir and to a lesser extent foscarnet and ganciclovir, have shown activity against HHV8 *in vitro*, but they have not been equally successful in treating Kaposi's sarcoma *in vivo*. Treatment with HAART has greatly reduced the occurrence of Kaposi's sarcoma in AIDS patients, and may cause regression of milder forms of the disease, but this is thought to be due to improvements in immune function rather than a direct effect on Kaposi's sarcoma.[4] The development of Kaposi's sarcoma is likely to be multifactorial, and as infection with HHV8 alone does not produce disease, and the replication of HHV8 in sarcoma cells is low, antiviral therapy alone is unlikely to be sufficient to control symptoms.[4]

Patients with classic or **endemic** Kaposi's sarcoma are often treated with surgery or radiotherapy of individual lesions.[1] Extensive or recurrent disease may be treated with vinca alkaloids, bleomycin, doxorubicin, and dacarbazine, alone or in combination.[1] Etoposide and interferon alfa have also been tried.[1] Patients with immunosuppression-associated Kaposi's sarcoma may be treated similarly to those with the classic form, or preferably by alteration of the immunosuppressive regimen if this can be done without graft loss.[1] Clinical and histological regression of cutaneous Kaposi's sarcoma has been described in a small number of renal transplant recipients when ciclosporin and mycophenolate mofetil were replaced with sirolimus.[5]

The **epidemic** form of Kaposi's sarcoma is associated with HIV infection, and seen particularly in homosexual patients. HAART may control Kaposi's sarcoma, and is considered first-line therapy,[6-8] but the response is unpredictable, so specific therapy is often needed.[1] ***Localised*** disease may be managed with cryotherapy or radiotherapy, but intralesional vinblastine, interferon alfa, and topical alitretinoin are also used.[2,3,6-9] Photodynamic therapy is also used.[2,7,8]

Systemic chemotherapy is generally reserved for patients with more *extensive* disease or mucosal or visceral involvement.[6,8] In patients with a CD4 cell count of 200 cells/mm^3 or above, treatment with interferon alfa plus zidovudine, has been advocated by some, but systemic chemotherapy is the treatment of choice.[1,3,4,6,7] The main combination regimens use a vinca alkaloid and bleomycin, with or without doxorubicin.[3,4] Liposomal formulations of doxorubicin and daunorubicin have produced response rates of 40 to 85%, and may be less toxic than conventional chemotherapy;[3,4,9] it has been suggested that a liposomal anthracycline is the drug of choice in extensive disease.[1,3,6-8] Paclitaxel is also used as a single agent in advanced disease.[3,4,8,9] However, although highly effective, doses may need to be reduced if given to patients taking HAART because of the risk of drug interactions.[6,8] Although data are limited, docetaxel may be a reasonable alternative.[8] Some response has also been reported for oral etoposide.[1]

Control of Kaposi's sarcoma has been reported in a few patients given high-dose intramuscular chorionic gonadotrophin, but tumour regression ceased and regrowth occurred when dosage was reduced or withdrawn.[10] Further reports of intralesional or systemic use have included partial remissions and disease stabilisation, as well as no effect or disease progression. The reasons for these contradictory results are unclear, but they may be due to variability in chorionic gonadotrophin preparations, which contain a mixture of biological contaminants. A cytotoxic ribonuclease and the degradation product of the β-hCG subunit have been proposed as active contaminants against Kaposi's sarcoma, but other contaminants may stimulate the tumour.[11] Other lines of investigation include the use of sulfated polysaccharide peptidoglycans, imatinib, the tyrosine kinase inhibitors sorafenib and sunitinib, other inhibitors of angiogenesis including thalidomide, and the retinoids.[1,2,6-9]

SOFT-TISSUE SARCOMA. Soft-tissue sarcomas are a varied group of malignant tumours that originate from mesenchymal stem cells residing in muscle, fat, or connective tissue,[1,2] and whose subtypes vary in terms of prognosis and response to different treatments.[3] The majority of soft-tissue sarcomas occur in the limb or limb girdle; some occur within the abdomen (retroperitoneal), in the head or neck, or in the gastrointestinal tract.[4,5] Patients have a 5-year survival rate of about 50 to 60%;[4] survival in those with extremity sarcomas is better than that in patients with retroperitoneal sarcomas.[2] Tumours often metastasise to the lung; those arising in the abdomen metastasise to the liver and peritoneum.[4]

Rhabdomyosarcoma is the commonest soft-tissue sarcoma in childhood, and is thought to arise from progenitor cells for skeletal muscle. The most frequent sites are the head and neck, genito-urinary tract, and extremities. Some genetic disorders are associated with rhabdomyosarcoma.[6,7] All patients are presumed to have micrometastatic disease at diagnosis; histologically the most common types are embryonal, which occurs at an earlier age, and alveolar, which is more common in adolescents.[7]

Surgery is the primary *therapy* for soft-tissue sarcomas,[1,2,4,8,9] and may be curative for *localised disease*.[5,10,11] Radiotherapy, as external-beam therapy or brachytherapy, may be given with surgery, or alone if surgery is inappropriate or declined by the patient.[5] Radiation may be given pre-operatively, during surgery, or postoperatively;[1,9] optimal timing is unclear.[5,8] Similar rates of local control and progression-free survival have been reported for pre- and postoperative radiotherapy, although preoperative treatment has been associated with a greater incidence of wound complications, especially in lower extremity tumours.[4] Postoperative radiation can cause acute and delayed bowel toxicity in those with retroperitoneal tumours, and significant toxicity has occurred with the use of brachytherapy, especially when used in the upper abdomen.[2]

Surgery and/or radiotherapy may be combined with chemotherapy. Pre-operative chemotherapy may allow for more efficient resection of the tumour.[1,8] The use of postoperative chemotherapy is controversial,[5,8,9] except for some tumours such as extraosseous Ewing's sarcoma or rhabdomyosarcoma. For these tumours, combinations of vincristine, dactinomycin, doxorubicin, cyclophosphamide, ifosfamide, or etoposide form the basis of most regimens.[5-8,11]

For those with *unresectable* or *metastatic* disease, chemotherapy may be used: ifosfamide and doxorubicin are routinely used in this setting.[5,9] These may be used as single agents or in combination; other acceptable single agent choices are dacarbazine, epirubicin, gemcitabine, temozolomide, or liposomal doxorubicin.[4] Data support the use of adjuvant doxorubicin-based chemotherapy to improve disease-free survival;[12] however, overall survival is not improved. For palliative treatment in advanced soft-tissue sarcoma, a systematic review[13] concluded that combination chemotherapy did not significantly increase survival rates compared with single-agent doxorubicin. A retrospective analysis[14] found that, in patients with high-risk disease, clinical benefits of doxorubicin-based chemotherapy were not sustained beyond 1 year. There is no consensus on the best second-line chemotherapy regimen for patients with metastatic disease refractory to doxorubicin-or ifosfamide-based regimens.[2,3] Dose-intensified combination regimens, with colony-stimulating factor support, have been investigated as adjuvant therapy[15] and in advanced disease;[16] although both these studies found a delay in disease progression, a beneficial effect on overall survival was only found in the former. Intensive combination chemotherapy benefited a subgroup of children with metastatic rhabdomyosarcoma and fewer than 2 unfavourable risk factors, in terms of event-free survival and overall survival. However, most patients have more than 2 risk factors; these patients should be considered for novel first-line therapies. No evidence was found for improved outcome after consolidation therapy with high-dose melphalan and autologous bone marrow or peripheral-blood stem cell rescue.[17] Response to topotecan has been reported in a study of metastatic rhabdomyosarcoma,[18] and trabectedin has shown some activity in advanced soft-tissue sarcomas.[3,5] Tasonermin and melphalan can be used together for isolated limb perfusion of unresectable soft-tissue sarcomas, but severe toxicity may limit use of this regimen. Potential salvage therapy options after failure of first-line therapy include paclitaxel, docetaxel, gemcitabine, trofosfamide, temozolomide, and various combinations thereof.[3]

The gastrointestinal stromal tumours (GISTs) are soft-tissue sarcomas arising in the gastrointestinal tract, most commonly in the stomach and small bowel.[4,8,19] Symptoms may include abdominal pain, anorexia, weight loss, haemorrhage, changes in bowel movements, bowel obstruction, or perforation. Patients with liver metastases may have oedema of the lower extremity, ascites, or jaundice.[20] Spread to the lungs and other locations is seen only in advanced cases.[4]

Continued on p. 726.

Table 1. Common chemotherapy regimens for malignant disease.

Regimen	Drugs and Administration	Cycle	Typically used for	References
ABCM	Doxorubicin 30 mg/m^2 iv day 1; carmustine 30 mg/m^2 iv day 1; cyclophosphamide 100 mg/m^2 oral days 22–25; and melphalan 6 mg/m^2 oral days 22–25.	42 days	Multiple myeloma	1
ABVD	Doxorubicin 25 mg/m^2 iv days 1, 15; bleomycin 10 000 IU/m^2 iv[(b)] days 1, 15; vinblastine 6 mg/m^2 iv days 1, 15; and dacarbazine 375 mg/m^2 iv days 1, 15.	28 days	Lymphomas	2, 3
AC	Doxorubicin 60 mg/m^2 iv day 1 and cyclophosphamide 600 mg/m^2 iv day 1.	21 days (for 4 cycles; some studies used up to 8 cycles)	Breast cancer	4–6
AC + paclitaxel	As above, then followed by paclitaxel 175 mg/m^2 iv day 1.	21 days (further 4 cycles)	Breast cancer	7
AC + trastuzumab	Doxorubicin 60 mg/m^2 iv day 1; cyclophosphamide 600 mg/m^2 iv day 1; and trastuzumab 4 mg/kg iv loading dose on day 1 then 2 mg/kg once each week.	21 days (for 6 cycles)	Breast cancer (HER2 overexpressing)	8
ACE	Doxorubicin 45 mg/m^2 iv day 1; cyclophosphamide 1 g/m^2 iv day 1; and etoposide 50 mg/m^2 iv days 1–5.	21 days	Small cell lung cancer	9
AT	Doxorubicin 60 mg/m^2 iv day 1 and paclitaxel 200 mg/m^2 iv day 1.	21 days (for 4 cycles)	Breast cancer	4
AT	Doxorubicin 50 mg/m^2 iv day 1 and docetaxel 75 mg/m^2 iv day 1.	21 days (for up to 8 cycles)	Breast cancer (metastatic)	5
BEAM (Mini-BEAM)	Carmustine 60 mg/m^2 iv day 1; etoposide 75 mg/m^2 iv days 2–5; cytarabine 100 mg/m^2 twice daily iv days 2–5; and melphalan 30 mg/m^2 iv day 6.	usually 28 to 42 days	Lymphomas (salvage)	10
BEP	Bleomycin 30 000 IU iv[(b)] days 2, 9, 16; etoposide 100 mg/m^2 iv days 1–5; and cisplatin 20 mg/m^2 iv days 1–5.	21 days (for 4 cycles)	Testicular cancer	11
CAF	Cyclophosphamide 500 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; and fluorouracil 500 mg/m^2 iv day 1.	21 days	Breast cancer	12
CAP	Cyclophosphamide 750 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; and prednisone 40 mg/m^2 oral days 1–5.	28 days	Chronic lymphocytic leukaemia	13
CAP	Cyclophosphamide 500 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; and cisplatin 50 mg/m^2 iv day 1 (these doses are optimised from the original 600 mg/m^2, 45 mg/m^2, and 50 mg/m^2 respectively).	21 days (for 6 cycles)	Ovarian cancer	14, 15
CAV	Cyclophosphamide 900 mg/m^2 iv day 1; doxorubicin 45 mg/m^2 iv day 1; and vincristine 2 mg iv day 1.	21 days (for 6 cycles)	Small cell lung cancer	16
CHOP	Cyclophosphamide 750 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; vincristine 1.4 mg/m^2 (max. 2 mg) iv day 1; and prednisone 100 mg oral days 1–5.	21 days (for 6 to 8 cycles)	Lymphomas, chronic lymphocytic leukaemia	17, 18
CMF	Cyclophosphamide 100 mg/m^2 oral days 1–14; methotrexate 40 mg/m^2 iv days 1, 8; and fluorouracil 600 mg/m^2 iv days 1, 8.	28 days	Breast cancer	6, 19

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous

Table 1. Common chemotherapy regimens for malignant disease. *(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
CMF	Cyclophosphamide 600 mg/m^2 iv day 1; methotrexate 40 mg/m^2 iv day 1; and fluorouracil 600 mg/m^2 iv day 1.	21 days	Breast cancer	20
CMF	Cyclophosphamide 750 mg/m^2 iv day 1; methotrexate 40 mg/m^2 iv days 1, 8; and fluorouracil 600 mg/m^2 iv days 1, 8.	28 days	Breast cancer	6
CMV	Cisplatin 100 mg/m^2 iv day 2; methotrexate 30 mg/m^2 iv days 1, 8; and vinblastine 4 mg/m^2 iv days 1, 8.	21 days	Bladder cancer	21
COP (CVP)	Cyclophosphamide 800 mg/m^2 iv day 1; vincristine 2 mg iv day 1; and prednisone 60 mg/m^2 oral days 1–5, then tapered over days 6–8.	21 days (for 6 cycles)	Lymphomas (the original report of this regimen used a 14-day cycle)	22
CP	Cisplatin 100 mg/m^2 iv day 1 and cyclophosphamide 600 mg/m^2 iv day 1 *or* carboplatin 300 mg/m^2 iv day1 and cyclophosphamide 600 mg/m^2 iv day 1.	28 days (for 6 cycles)	Ovarian cancer	23
CT	Cisplatin 50 mg/m^2 iv day 1; topotecan 750 micrograms/m^2 iv days 1–3.	21 days	Cervical cancer	72
CYVADIC	Cyclophosphamide 500 mg/m^2 iv day 1; vincristine 1.5 mg/m^2 iv[a] days 1, 5; doxorubicin 50 mg/m^2 iv day 1; and dacarbazine 250 mg/m^2 iv days 1–5.	21 days	Sarcoma (alternative versions of this regimen using vincristine on day 1 only have also been reported)	24
Dartmouth regimen	Dacarbazine 220 mg/m^2 iv days 1–3, 22–24; cisplatin 25 mg/m^2 iv days 1–3, 22–24; carmustine 150 mg/m^2 iv day 1; and tamoxifen 10 mg oral twice daily.	42 days	Melanoma (metastatic)	25, 26
DCF	Docetaxel 75 mg/m^2 iv day 1; cisplatin 75 mg/m^2 iv day 1; fluorouracil 750 mg/m^2 continuous iv days 1–5.	21 days	Gastric cancer	75
DHAP	Dexamethasone 40 mg oral or iv days 1–4; cytarabine 2 g/m^2 iv over 3 hrs, repeated after 12 hrs, day 2; and cisplatin 100 mg/m^2 iv over 24 hrs, day 1.	21–28 days	Lymphomas (salvage)	27
EAP	Etoposide 120 mg/m^2 iv days 4–6; doxorubicin 20 mg/m^2 iv days 1, 7; and cisplatin 40 mg/m^2 iv days 2, 8.	21–28 days	Stomach cancer	28, 29
EC	Etoposide 100 mg/m^2 iv days 1–3 and carboplatin 450 mg/m^2 iv day 1.	28 days	Small cell lung cancer	30
EC	Etoposide 100 mg/m^2 iv days 1–3 and carboplatin 325 mg/m^2 iv day 1.	21 days	Non-small cell lung cancer	31
ECF	Epirubicin 50 mg/m^2 iv day 1; cisplatin 60 mg/m^2 iv day 1; and fluorouracil 200 mg/m^2 daily continuous iv.	21 days (for up to 8 cycles)	Stomach cancer	32
EDAP	Etoposide 100–200 mg/m^2 continuous iv, days 1–4; dexamethasone 40 mg oral or iv days 1–5; cytarabine 1 g/m^2 iv day 5; and cisplatin 20 mg/m^2 continuous iv, days 1–4.	21–28 days	Multiple myeloma (salvage), lymphomas	33

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous

Table 1. Common chemotherapy regimens for malignant disease. *(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
EMA-CO (or EMA-EP)	Etoposide 100 mg/m^2 iv days 1, 2; methotrexate 300 mg/m^2 iv over 12 hrs, day 1; folinic acid 15 mg oral or im, twice daily for 4 doses, starting day 2; and dactinomycin 500 micrograms iv days 1, 2. *with* cyclophosphamide 600 mg/m^2 iv day 8 and vincristine 1 mg/m^2 iv[a] day 8. *or* etoposide 150 mg/m^2 iv day 8 and cisplatin 75 mg/m^2 iv day 8.	14 days	Gestational trophoblastic tumours	34
EOX	Epirubicin 50 mg/m^2 iv day 1; oxaliplatin 130 mg/m^2 iv day 1; capecitabine 1.25 g/m^2 oral days 1–21.	21 days	Oesophagogastric cancer	74
EP (PE)	Etoposide 80 mg/m^2 iv days 1–3 and cisplatin 80 mg/m^2 iv day 1.	21 days	Small cell lung cancer (standard dose – other versions exist)	35
EP (PE)	Etoposide 80 mg/m^2 iv days 1–5 and cisplatin 27 mg/m^2 iv days 1–5.	21 days	Small cell lung cancer (high dose)	35
EP (PE)	Etoposide 100 mg/m^2 iv day 1, *then* 200 mg/m^2 oral days 2–4 and cisplatin 75 mg/m^2 iv day 1.	21 days	Small cell lung cancer	36
EPOCH	Etoposide 50 mg/m^2 continuous iv days 1–4; vincristine 400 micrograms/m^2 continuous iv[a] days 1–4; doxorubicin 10 mg/m^2 continuous iv days 1–4; cyclophosphamide 750 mg/m^2 iv day 5; and prednisone 60 mg/m^2 oral days 1–5.	21 days	Lymphomas (salvage)	37
ESHAP	Etoposide 40 mg/m^2 iv days 1–4; methylprednisolone 250–500 mg iv days 1–5; cisplatin 25 mg/m^2 continuous iv days 1–4; and cytarabine 2 g/m^2 iv day 5.	21–28 days (for up to 8 cycles)	Lymphomas (salvage)	38
FAM	Fluorouracil 600 mg/m^2 iv days 1, 8, 29, 36; doxorubicin 30 mg/m^2 iv days 1, 29; and mitomycin 10 mg/m^2 iv day 1.	56 days	Stomach cancer, pancreatic cancer	39–41
FAMTX	Fluorouracil 1.5 g/m^2 iv day 1; doxorubicin 30 mg/m^2 iv day 15; methotrexate 1.5 g/m^2 iv day 1, 1 hour before fluorouracil; and folinic acid 15 mg/m^2 oral every 6 hrs for 3 days, starting 24 hrs after methotrexate.	28 days	Stomach cancer	29, 32
FOLFIRI	Irinotecan 180 mg/m^2 iv day 1; folinic acid 200 mg/m^2 iv day 1; fluorouracil 400 mg/m^2 iv bolus day 1, then 2.4 g/m^2 continuous iv infusion (increased to 3 g/m^2 from cycle 3 if tolerated) over 46 hours.	14 days	Colorectal cancer	69
FOLFOX4	Oxaliplatin 85 mg/m^2 iv day 1; folinic acid 200 mg/m^2 iv days 1, 2; fluorouracil 400 mg/m^2 iv bolus then 600 mg/m^2 continuous iv infusion, days 1, 2.	14 days	Colorectal cancer (in addition to FOLFOX6, below, other variants of the FOLFOX regimen exist; combination with bevacizumab or cetuximab is also being tried)	70
FOLFOX6	Oxaliplatin 100 mg/m^2 iv day 1; folinic acid 200 mg/m^2 iv day 1; fluorouracil 400 mg/m^2 iv bolus day 1, then 2.4 g/m^2 continuous iv infusion (increased to 3 g/m^2 from cycle 3 if tolerated) over 46 hours.	14 days	Colorectal cancer	69
5FU/Folinic acid	Fluorouracil 370 mg/m^2 iv days 1–5 and folinic acid 200 mg/m^2 iv days 1–5.	28–35 days	Colorectal cancer	42

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous

Table 1. Common chemotherapy regimens for malignant disease. *(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
5FU/Folinic acid (Mayo regimen, Poon regimen)	Fluorouracil 425 mg/m^2 iv days 1–5 and folinic acid 20 mg/m^2 iv day 1–5.	28–35 days	Stomach cancer, colorectal cancer	42, 43
5FU/Folinic acid (de Gramont regimen)	Fluorouracil 400 mg/m^2 iv bolus then 600 mg/m^2 continuous iv infusion, days 1, 2 and folinic acid 200 mg/m^2 iv days 1, 2.	14 days	Colorectal cancer	44
Gemcitabine + cisplatin	Gemcitabine 1 g/m^2 iv days 1, 8, 15 and cisplatin 70 mg/m^2 iv day 2.	28 days	Bladder cancer (metastatic)	45
Hyper-CVAD	*Course A:* Cyclophosphamide 300 mg/m^2 iv every 12 hrs, days 1–3; doxorubicin 50 mg/m^2 iv day 4; vincristine 2 mg iv days 4, 11; and dexamethasone 40 mg iv or oral, days 1–4, 11–14. *CNS prophylaxis* Methotrexate 12 mg intrathecal, day 2 and cytarabine 100 mg intrathecal, day 8. *Course B:* Methotrexate 200 mg/m^2 iv over 2 hrs, then 800 mg/m^2 iv over 24 hrs, day 1; folinic acid 15 mg iv every 6 hrs for 8 doses, from 24 hrs after methotrexate (increased to 50 mg iv every 6 hrs if methotrexate levels are high); methylprednisolone 50 mg iv every 12 hrs, days 1–3; and cytarabine 3 g/m^2 every 12 hrs, days 2, 3.	4 cycles of A alternated with 4 cycles of B, given over as short a period as possible; the number of A cycles in which CNS prophylaxis is given varies with expected risk of CNS disease	Lymphomas, adult acute lymphoblastic leukaemia (some variants of this regimen exist, including the substitution of daunorubicin 60 mg/m^2 for doxorubicin in course A, the omission of methylprednisolone and addition of oral bicarbonate in course B, and simplification of methotrexate and folinic acid dosing; mesna, which was given in course A of the original regimen, is usually omitted)	48
ICE (ICbE)	Ifosfamide 5 g/m^2 iv over 24 hrs, day 1 (with mesna); carboplatin 400 mg/m^2 iv day 1; and etoposide 100 mg/m^2 iv days 1–3.	28 days (for 6 cycles)	Small cell lung cancer	46
IFL (Douillard 1-week regimen)	Irinotecan 80 mg/m^2 iv, day 1; fluorouracil 2.3 g/m^2 continuous iv infusion, day 1; folinic acid 500 mg/m^2 iv, day 1.	7 days	Colorectal cancer	71
IFL (Douillard 2-week regimen)	Irinotecan 180 mg/m^2 iv, day 1; fluorouracil 400 mg/m^2 iv bolus then 600 mg/m^2 continuous iv infusion, days 1, 2; folinic acid 200 mg/m^2 iv, days 1, 2.	14 days	Colorectal cancer	71
IFL (Saltz regimen)	Irinotečan 125 mg/m^2 iv; fluorouracil 500 mg/m^2 iv; and folinic acid 20 mg/m^2 iv all once a week for 4 weeks.	42 days	Colorectal cancer	47
M2	Vincristine 30 micrograms/kg iv[a] day 1; carmustine 500 micrograms/kg iv day 1; cyclophosphamide 10 mg/kg iv day 1; melphalan 250 micrograms/kg oral days 1–4 *or* 100 micrograms/kg oral days 1–7 *or* 1–10; and prednisone 1 mg/kg oral, days 1–7, then taper and discontinue by day 21 unless hypercalcaemia or bone disease persist.	35 days	Multiple myeloma	49
MACOP-B	Methotrexate 400 mg/m^2 iv days 8, 36, 64 (as 100 mg/m^2 iv bolus, then 300 mg/m^2 iv over 4 hrs); folinic acid 15 mg oral every 6 hrs for 6 doses, from 24 hrs after methotrexate; doxorubicin 50 mg/m^2 iv days 1, 15, 29, 43, 57, 71; cyclophosphamide 350 mg/m^2 iv days 1, 15, 29, 43, 57, 71; vincristine 1.4 mg/m^2 iv[a] days 8, 22, 36, 50, 64, 78; bleomycin 10 000 IU/m^2 iv[b] days 22, 50, 78; and prednisone 75 mg oral, daily for 10 weeks then tapered over 15 days.	12 weeks	Lymphomas	50
MCF	Mitomycin 7 mg/m^2 (max 14 mg) iv day 1; cisplatin 60 mg/m^2 iv days 1, 22; fluorouracil 300 mg/m^2 daily continuous iv.	42 days	Oesophagogastric cancer	76

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous

Table 1. Common chemotherapy regimens for malignant disease. *(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
MIC	Mitomycin 6 mg/m^2 iv day 2; ifosfamide 3 g/m^2 iv day 2; and cisplatin 120 mg/m^2 iv day 1.	21 days	Non-small cell lung cancer	51
MIC	Mitomycin 6 mg/m^2 iv day 1; ifosfamide 3 g/m^2 iv day 1; and cisplatin 50 mg/m^2 iv day 1.	21 days	Non-small cell lung cancer	52
MOPP	Chlormethine 6 mg/m^2 iv days 1, 8; vincristine 1.4 mg/m^2 (max. 2 mg), days 1, 8; procarbazine 100 mg/m^2 oral days 1–14; and prednisone 40 mg/m^2 oral days 1–14, cycles 1, 4.	28 days (for 6 cycles)	Lymphomas, Hodgkin's disease	3, 53
M-VAC	Methotrexate 30 mg/m^2 iv days 1, 15, 22; vinblastine 3 mg/m^2 iv days 2, 15, 22; doxorubicin 30 mg/m^2 iv day 2; and cisplatin 70 mg/m^2 iv day 2.	usually 28 days	Bladder cancer	45, 54, 55
MVP	Mitomycin 8 mg/m^2 iv day 1, cycles 1 and 2, day 15 cycle 3; vinblastine 4 mg/m^2 iv day 1, cycle 1 2 mg/m^2 iv day 8, cycle 1 4.5 mg/m^2 iv days 15, 22, cycle 1 4.5 mg/m^2 iv days 1, 15, cycle 2 and later; and cisplatin 120 mg/m^2 iv day 1	28 days	Non-small cell lung cancer (neoadjuvant)	56
MVP	Mitomycin 8 mg/m^2 iv day 1, cycles 1 and 2, day 15 cycle 3; vindesine 3 mg/m^2 iv days 1, 8, 15, 22, day 1 of cycle 2, then every 2 weeks until the 15th week; and cisplatin 120 mg/m^2 iv day 1, for 3 cycles.	28 days	Non-small cell lung cancer (neoadjuvant)	56, 57
MVP	Mitomycin 8 mg/m^2 iv day 1, cycles 1 and 2, day 15 cycle 3; vinorelbine 25 mg/m^2 iv once a week for 16 weeks; and cisplatin 120 mg/m^2 iv day 1, for 3 cycles.	28 days	Non-small cell lung cancer (neoadjuvant)	57
PAC	Cisplatin 50 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; and cyclophosphamide 500 mg/m^2 iv day 1.	21 days (for up to 8 cycles)	Thymoma	58
Paclitaxel and carboplatin	Paclitaxel 175 mg/m^2 iv day 1 and carboplatin – adjust dose to AUC of 7.5 mg/mL/minute by Calvert formula, iv day 1.	21 days (for 6 cycles)	Ovarian cancer	59
Paclitaxel and cisplatin	Paclitaxel 135 mg/m^2 continuous iv over 24 hrs, day 1 and cisplatin 75 mg/m^2 iv day 1.	21 days (for 6 cycles)	Ovarian cancer	60
Paclitaxel (standard) and trastuzumab	Paclitaxel 175 mg/m^2 iv on day 1 and trastuzumab 4 mg/kg iv loading dose on day 1 then 2 mg/kg once each week.	21 days	Breast cancer (HER2 overexpressing)	8
Paclitaxel (weekly) and trastuzumab	Paclitaxel 90 mg/m^2 iv on day 1 and trastuzumab 4 mg/kg iv loading dose on day 1 then 2 mg/kg once each week.	7 days	Breast cancer (HER2 overexpressing)	61
PCV	Procarbazine 60 mg/m^2 oral days 8–21; lomustine 110 mg/m^2 oral day 1; and vincristine 1.4 mg/m^2 iv[a] days 8, 29.	42–56 days	Gliomas (adjuvant)	62

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous				

Table 1. Common chemotherapy regimens for malignant disease. *(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
ProMACE-CytaBOM	Prednisone 60 mg/m^2 oral days 1–14; doxorubicin 25 mg/m^2 iv day 1; cyclophosphamide 650 mg/m^2 iv day 1; etoposide 120 mg/m^2 iv day 1; cytarabine 300 mg/m^2 iv day 8; bleomycin 5000 IU/m^2 iv[b] day 8; vincristine 1.4 mg/m^2 iv[a] day 8; methotrexate 120 mg/m^2 iv day 8; and folinic acid 25 mg/m^2 oral every 6 hrs for 4 doses, from 24 hrs after methotrexate.	21 days	Lymphomas	63
PVB	See VBP			
SMF	Streptozocin 1 g/m^2 iv days 1, 8, 29, 36; mitomycin 10 mg/m^2 iv day 1; and fluorouracil 600 mg/m^2 iv days 1, 8, 29, 36.	56 days	Pancreatic cancer	41
Stanford V regimen	Doxorubicin 25 mg/m^2 iv days 1, 15; vinblastine 6 mg/m^2 iv days 1, 15; chlormethine 6 mg/m^2 iv day 1; vincristine 1.4 mg/m^2 iv (max 2mg) days 8, 22; bleomycin 5000 IU/m^2 iv[b] days 8, 22; etoposide 60 mg/m^2 iv days 15, 16; prednisone 40 mg/m^2 oral on alternate days for 10 weeks then tapered by 10 mg on alternate days.	28 days (for 3 cycles)	Hodgkin's disease	64
TAP	Doxorubicin 45 mg/m^2 iv day 1; cisplatin 50 mg/m^2 iv day 1; paclitaxel 160 mg/m^2 iv day 2.	21 days[c] (up to 7 cycles)	Endometrial cancer	73
VAD	Vincristine 400 micrograms iv days 1–4; doxorubicin 9 mg/m^2 iv days 1–4; and dexamethasone 40 mg oral days 1–4, 9–12, 17–20.	28 days (usually for 4 cycles)	Multiple myeloma	65
VBAP	Vincristine 1 mg iv day 1; carmustine 30 mg/m^2 iv day 1; doxorubicin 30 mg/m^2 iv day 1; and prednisone 60 mg/m^2 oral or parenteral (may be rounded to 100 mg oral) days 1–4.	21 or 28 days	Multiple myeloma	66, 67
VBP	Vinblastine 150 micrograms/kg iv days 1, 2; bleomycin 30 000 IU iv[b] days 2, 9, 16; and cisplatin 20 mg/m^2 iv days 1–5.	21 days	Germ-cell (ovarian, testicular) cancer	11
VCMP	Vincristine 1 mg iv day 1; melphalan 9 mg/m^2 oral days 1–4; cyclophosphamide 500 mg/m^2 iv day 1; and prednisone 60 mg/m^2 oral or parenteral, days 1–4.	28 days	Multiple myeloma	67
VeIP	Vinblastine 110 micrograms/kg iv days 1, 2; ifosfamide 1.2 g/m^2 iv days 1–5 (with mesna); and cisplatin 20 mg/m^2 iv days 1–5.	21 days (for 4 cycles)	Germ-cell (especially testicular) cancer	68
VIP	Etoposide 75mg/m^2 iv days 1–5; ifosfamide 1.2 g/m^2 iv days 1–5 (with mesna); and cisplatin 20 mg/m^2 iv days 1–5.	21 days (for 4 cycles)	Germ-cell (especially testicular) cancer	68

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous

(a) Although not always reflected in the original papers it is now generally accepted that the total dose of vincristine should not exceed 2 mg, in order to minimise neurotoxicity

(b) Doses of bleomycin have been given in international units (IU) in this table, but doses in the original papers may be quoted in mg-potency or USP units. One mg-potency or one USP unit is equivalent to 1000 international units

(c) This regimen is invariably given with haematological support using subcutaneous filgrastim on days 3–12

Surgery is used for localised, resectable disease arising in the gastrointestinal tract, although this does not routinely cure GISTs; median time to recurrence after resection is about 2 years. Imatinib produces durable clinical benefit and objective responses in most patients with GISTS, including those with metastatic or unresectable disease. If the tumour responds to imatinib, surgical resection may be indicated. In patients with imatinib-resistant GIST, or who experience life-threatening adverse effects such as hepatotoxicity and fluid retention with imatinib, sunitinib may be considered.[4,8,11,19,21,22] Regorafenib is an option when both imatinib and sunitinib have failed.

Adverse Effects

The acute effects of antineoplastic drugs often include nausea and vomiting, sometimes extremely severe. In addition, many of these compounds are irritant or vesicant, and produce local pain, irritation, and inflammation at the administration site; extravasation may lead to ulceration and necrosis. Hypersensitivity reactions may also occur.

Many of the adverse effects of antineoplastics are an extension of their therapeutic action, which is generally not selective for malignant cells but affects all rapidly-dividing cells: antineoplastic therapy is then made possible only by increased sensitivity or less effective recovery of malignant cells compared with normal cells, and dosage is carefully controlled and timed, and, where possible, localised, to maximise the differences.

In consequence, adverse effects may be expected from most antineoplastics in tissues where normal cell division is fairly rapid, e.g. the bone marrow, lymphoreticular tissue, gastrointestinal mucosa, skin, and gonads, as well as in the fetus. The effects may not manifest for days or weeks, depending both on the drugs used and the rate of division in the tissue concerned, and may sometimes be cumulative. Perhaps the most common serious effect, and one which has often limited the doses that can be given, is bone-marrow depression. Because of their effects on the various types of white blood cell many antineoplastics also cause profound suppression of normal immunity, and patients may be at greatly increased risk of severe and disseminated infection.

The rapid destruction of large numbers of cells during antineoplastic therapy of certain highly sensitive tumours, and the consequent release of breakdown products, may also lead to problems with hyperuricaemia and acute renal failure due to uric acid nephropathy (the 'tumour lysis syndrome').

Additionally, some drugs may have specific toxicities that are not necessarily related to their therapeutic action, such as cardiotoxicity due to anthracycline antibiotics, nephrotoxicity with cisplatin, or the effects of bleomycin on the lung. Again these can be cumulative, and may limit the total lifetime dose that can be given.

In the very long term, patients who have undergone successful antineoplastic chemotherapy may develop secondary malignancies, suggesting that antineoplastics may themselves be carcinogenic. In addition, most are potentially mutagenic and teratogenic, and use in pregnancy, particularly in the first trimester, may lead to fetal abortion, stunting, or malformation.

Carcinogenicity. There is clear evidence that some antineoplastic drugs may themselves be carcinogenic, although it is difficult to control for the possible effects of primary disease, combination chemotherapy, and combined treatment with radiotherapy.[1]

Most convincingly associated with secondary malignancies are the various **alkylating agents**[2-5] including the nitrosoureas, the topoisomerase II inhibitor **podophyllotoxin derivatives** such as etoposide and teniposide,[2,3,5,6] and the **anthracyclines**.[7] Leukaemias, particularly acute myeloid leukaemia, are the most common forms of secondary disease.[1-3] Leukaemia associated with alkylating agents usually occurs about 5 to 7 years after treatment, and is often preceded by a preleukaemic myelodysplasia.[2,3] The nitrosoureas are associated with a relatively high frequency of secondary leukaemia, and busulfan and melphalan are considered to be more leukaemogenic than cyclophosphamide.[3] Another drug that has been associated with the development of secondary leukaemia is procarbazine.[3,4,8,9] Leukaemia associated with the podophyllotoxin derivatives has a shorter latency period of 2 to 3 years, with sudden onset and no myelodysplastic phase.[2,3] There is little evidence of carcinogenicity associated with **antimetabolites** such as methotrexate, although it has been suggested that they may act as co-carcinogens.[10] Fludarabine therapy has been reported to be associated with the development of myelodysplasia and acute myeloid leukaemias,[11] although a review of the purine nucleoside analogues, cladribine and fludarabine, concluded that no significant increase in the risk of secondary malignancy had been shown, but also that long-term follow-up of patients was needed.[12] Immunosuppression caused by antimetabolites including methotrexate, cladribine, and fludarabine, may also allow the development of Epstein-Barr virus-related lymphoma.[12,13]

Solid tumours can also occur as secondary malignancies and include bladder cancer associated with cyclophosphamide used to treat non-Hodgkin's lymphoma,[4,14] and bone sarcomas, and breast and lung cancers after the use of various alkylating agents.[4,7,15] Higher doses of anthracyclines also increase the risk of sarcoma. Podophyllotoxin derivatives are associated with a greater risk of lung carcinoma, while the risk of subsequent colorectal and kidney cancer increases with **platinum** therapy.[7] Platinum derivatives such as carboplatin and cisplatin have also been found in large cohort studies[16,17] to have a dose-response relationship with the development of secondary leukaemia. **Combinations** that may also be associated with leukaemias include cisplatin with doxorubicin,[18] and other anthracycline-based regimens.[19]

Estimates of **risk** have varied very widely between studies, and have been calculated in various ways, making direct comparison impossible. Factors influencing the incidence of secondary malignancy include the use of combination chemotherapy regimens, combined treatment modalities, exposure to environmental carcinogens, predisposing genetic risk factors, ethnicity, age at time of diagnosis and treatment, gender, and spontaneous occurrence.[2,3,20]

The risk of secondary acute myeloid leukaemia appears to be associated mainly with the **cumulative dose** of antineoplastics.[2] Of patients at risk for secondary leukaemias, those with Hodgkin's disease have been most extensively studied. The cumulative 10-year incidence of secondary myeloid leukaemia has been reported to range from less than 1% up to 10%.[2,3] The highest risk is associated with the use of MOPP (chlormethine, vincristine, procarbazine, prednisone) and relative risk increases with cumulative dose of chlormethine.[2,3] Splenectomy or radiation of the spleen doubles the risk of leukaemia, as does an age of more than 45 years at the time of treatment.[2] Secondary solid tumours, such as lung cancer, in patients with Hodgkin's disease have also been attributed to the use of regimens such as MOPP.[4] The risk of secondary acute myeloid leukaemia, in patients treated with adjuvant chemotherapy for breast cancer, increases with cumulative doses of melphalan and cyclophosphamide, and high-dose regimens of doxorubicin with cyclophosphamide.[2,3] In patients treated for multiple myeloma, the increased risk of secondary leukaemia has been attributed to the prolonged use of melphalan.[2,3] Patients treated for testicular cancer appear to be at increased risk of secondary leukaemia associated with cumulative doses of podophyllotoxin derivatives (more than 2 g/m^2 etoposide), and the addition of high cisplatin doses may increase this risk.[2,3] Another review[21] of studies using etoposide or teniposide for various cancers found no relationship between the cumulative dose of these and secondary leukaemia, and suggested that other drugs used in treatment regimens had a greater effect on the development of secondary malignancy. There is growing evidence that the use of high-dose therapy with alkylating agents and/or anthracyclines, followed by autologous stem cell transplantation, is associated with an increased risk of secondary myelodysplasias and leukaemias, and a cumulative incidence of about 9% at 5 years.[2] However, it is unclear whether this is due to the high-dose therapy or to previous chemotherapy that has caused bone-marrow damage.[2,3]

Radiotherapy is an established cause of secondary malignancy. It remains unclear, however, to what extent the use of chemotherapy combined **with radiotherapy** could have an additive effect on the risk of secondary leukaemias, and how dose and treatment regimen influence this effect.[3] Similarly, the role of combined modality treatment in the development of secondary solid tumours has not been defined, even though the radiation-enhancing effect of some antineoplastics is known and used in chemoradiation regimens for this reason.[4]

In many cases the risk of secondary malignancy is far less than that of undertreating, or of failing to treat, the primary disease.[2,4] However, secondary malignancies may be more resistant to treatment and more aggressive than primary disease,[3,22] and the risk of inducing malignant neoplasia is certainly a consideration in the use of alkylating agents and podophyllotoxin derivatives to treat non-malignant disease,[3] and is an increasing challenge in the design of suitable treatment regimens for primary neoplastic disease.

EFFECTS ON CHROMOSOMES. Visible chromosome gaps, breaks, and structural rearrangements are found in blood lymphocytes from patients who have received substantial doses of combination chemotherapy, and the changes persist for years after the end of treatment. A more sensitive, if transient, measure of genetic damage is the increased rate of sister chromatid exchange (SCE) that occurs with even quite small doses of cytotoxic drugs.[1] Evidence from

All cross-references refer to entries in Volume A

a study[2] in patients given chlorambucil suggests that as the dose increases so the capacity of the cells to cope with induced genetic damage is progressively exceeded, and thus SCE frequency reflects cumulative toxicity throughout the course of treatment.

In patients who develop acute myeloid leukaemia after alkylating agent therapy, the most common chromosomal losses involve deletions of chromosome 13, loss of the entire chromosomes 5 and 7, or deletions of part or the whole long arm of chromosomes 5 and 7. Molecular alterations of the suppressor gene p53 have also been found.[3] Balanced translocations, usually involving chromosomes 11 and 21, are associated with treatment using topoisomerase II inhibitors.[3,4]

Effects on the bladder. Cyclophosphamide (p. 772.3) and ifosfamide (p. 806.2) are the antineoplastics most frequently associated with adverse effects on the bladder, but see also Busulfan, p. 755.2, Chlorambucil, p. 764.3, Dacarbazine, p. 776.2, and Mitomycin, p. 831.3.

Effects on the blood. *BONE-MARROW DEPRESSION.* Bone-marrow depression, or myelosuppression, is common to the majority of cytotoxic antineoplastics, and is probably the single most important dose-limiting adverse effect, although its significance has been somewhat reduced in recent years by improvements in supportive care, including the availability of colony-stimulating factors and the development of techniques such as peripheral blood stem cell transfusion.

All the cellular elements of blood (see Haematopoiesis, p. 1121.1) may be affected by antineoplastic therapy, resulting in pancytopenia, but in many cases the toxicity appears to be greater for particular cell types. In addition, white blood cells and platelets tend to have shorter half-lives in circulation than erythrocytes. Hence the most usual manifestation of bone-marrow depression is leucopenia, leading to an increased risk of infection; thrombocytopenia is also fairly common. Anaemia is somewhat less frequent, and may be associated with megaloblastic changes in the bone marrow.

The onset, duration, and severity of bone-marrow depression vary considerably with different antineoplastics. For details, see under the individual monographs. For the management of bone-marrow depression, including discussion of the appropriate thresholds for treatment, see under Treatment of Adverse Effects, p. 730.3.

See also Effects on Immune Response, p. 728.3.

Effects on body-weight. The effects of antineoplastics on the gastrointestinal tract (p. 728.1) may lead to anorexia, malabsorption, and malnutrition, and hence to weight loss. A large cohort study[1] in survivors of childhood cancer found that treatment with total body irradiation, alkylating agents, or anthracyclines was associated with being underweight in females; in males, being underweight was associated with abdominal radiotherapy, younger age at treatment, and treatment with alkylating agents or anthracyclines. Antineoplastic therapy for breast cancer has however also been associated with weight gain, sometimes dramatic.[2] Weight gain appeared to be more likely in premenopausal women, in those receiving multidrug regimens, and in those treated for longer periods of time. A study of premenopausal women found that reduced physical activity may be a contributing factor to the development of this form of weight gain.[3] A subsequent small study has suggested that adjuvant regimens based on doxorubicin and cyclophosphamide, with or without a taxane, may not be associated with significant weight gain, although patients may undergo unfavourable changes in body-mass composition.[4] Weight gain has also been noted after long-term follow-up of paediatric leukaemia patients.[1,5,6] Causes include cranial irradiation[1,7] and corticosteroid therapy,[7] although some have suggested that weight gain depends more on inherent characteristics of the patients than the treatment given.[8]

Effects on bones and joints. Osteoporosis occurs as both an acute[1] and late[2] complication of chemotherapy, but as multicomponent regimens are used and because the pathogenesis of osteoporosis is likely to be multifactorial, it is difficult to assess the impact of individual drugs.[3] A main cause of bone loss is hypogonadism induced by irradiation, surgical gonadal ablation, hormonal therapy, or chemotherapy.[2] These form part of treatment regimens for a variety of neoplasms, including breast, prostate and testicular cancers, lymphomas, and haematological malignancies. In particular, regimens containing cyclophosphamide, chlormethine, chlorambucil, busulfan, mitomycin, or procarbazine may cause ovarian insufficiency and therefore have the potential to lead to osteoporosis in females.[2,3] Males may be somewhat protected from the effects of chemotherapy-induced hypogonadism, as the cells that produce testosterone only replicate slowly.[3] Endocrine therapies for breast cancer such as selective oestrogen-receptor modulators and aromatase inhibitors, and androgen deprivation therapy for prostate cancer can also cause bone loss.[2,4,5]

In addition, several drugs may exert direct effects on the bone. Methotrexate has been found to increase bone resorption and inhibit bone formation to produce a massive uncoupling of bone turnover.[2,3] Repeated doses of methotrexate, given as monotherapy to children with acute lymphoblastic leukaemia in remission, have been associated with pain, osteoporosis, and fractures.[6] Other drugs, including doxorubicin, have been shown to be toxic to bone in *animals*.[3] High-dose conditioning regimens used for bone marrow transplantation may have a direct dose-dependent toxicity on bone marrow osteoprogenitor cells, contributing to osteopenia.[7]

Corticosteroids are believed to cause bone loss by decreasing osteoblast activity, an effect which may be alleviated by chlorambucil. Surprisingly, corticosteroids have not been implicated in bone loss for most chemotherapy regimens, perhaps because the duration of treatment is short.[3] Nevertheless, osteoporosis and fractures have occurred in young patients with acute lymphoblastic leukaemia, treated with regimens containing high total doses of corticosteroids.[6,8,9] However, the disease itself, other chemotherapy, and radiotherapy are also likely to be contributory factors in the development of osteopenia in these patients. Osteonecrosis has also been reported with high doses of corticosteroids used in the treatment of leukaemias and solid tumours in adults and children.[8,10-12] Adolescent patients may be at increased risk because their bones are in the process of maturation.[8,10]

Indirect effects of cancer therapies may also affect bone health. These effects include hyperparathyroidism, hypovitaminosis D, hypophosphataemia, gastrointestinal complications, and hyperprolactinaemia.[2] A study in children with leukaemia has suggested that the effects of chemotherapy on gastrointestinal and renal handling of nutrients may lead to alterations in calcium and magnesium homoeostasis and hence to abnormal turnover of bone mineral.[13] Renal phosphate loss following damage to the renal tubule caused by ifosfamide can lead to osteomalacia.[2,3] Hypophosphataemia, with associated changes in bone and mineral metabolism, has been seen with tyrosine kinase inhibitors such as imatinib, sorafenib, and sunitinib.[2]

Effects on the cardiovascular system. *THROMBOEMBOLISM.* Patients with cancer are at increased risk of thromboembolic disease, and thrombosis can be the earliest clinical sign of malignancy.[1,2] Clinical risk factors for cancer-associated venous thromboembolism include type of cancer, stage of disease, presence of comorbidities, and treatment-related factors such as hospitalisation, and use of systemic chemotherapy.[3] Deep-vein thrombosis and pulmonary embolism have been reported with a variety of chemotherapeutic regimens. Studies in patients with breast cancer have found that adjuvant chemotherapy can significantly increase the risk of venous thromboembolism.[4] An increase in venous thromboembolism, including CNS thromboses, has also been found with the use of asparaginase in the treatment of acute lymphoblastic leukaemia[4] (see also Effects on the Blood, under Asparaginase, p. 744.2). Regimens that include bevacizumab, lenalidomide, or thalidomide have also reported high rates of venous thromboembolism.[3,5] Arterial thrombosis, including acute myocardial infarction, angina, stroke, and peripheral artery thrombosis, has also been reported with various regimens.[4,5] Mechanisms proposed for the possible role of antineoplastics in these effects include activation of coagulation, suppression of anticoagulant proteins and fibrinolysis, and a direct toxic effect on vascular endothelium.[1,4]

Several reports of arterial and venous thromboembolism have implicated combinations of bleomycin with cisplatin and another drug such as a vinca alkaloid or etoposide.[6-8] Such combinations, widely used for testicular cancer, have also been implicated in producing vasospastic reactions including angina[9] and Raynaud's syndrome,[10,11] although there is no evidence of a relationship between thromboembolism and vasospasm.[6]

In men with germ cell cancer there is some evidence that those with liver metastases, or receiving high-dose dexamethasone as antiemetic therapy, are at increased risk of thromboembolic complications.[12]

Various organisations have addressed the problems of prevention and treatment of cancer-associated venous thromboembolism. Generally, unless contra-indicated, most recommend prophylactic anticoagulation for hospitalised or surgical cancer patients; low-molecular-weight or unfractionated heparin or fondaparinux may be used. Prophylaxis is not recommended for the ambulatory cancer patient, with the exception of patients with multiple myeloma given thalidomide- or lenalidomide-based regimens.[13] Treatment of venous thrombosis usually consists of low-molecular-weight or unfractionated heparin therapy and long-term secondary prophylaxis with warfarin,[14] but a multicentre, randomised study found that a low-molecular-weight heparin was more effective than an oral anticoagulant in reducing the risk of recurrent venous thromboembolism without increasing the risk of bleeding,[15] and many now recommend low-molecular-weight heparin therapy for both initial and continuing treatment of cancer patients with venous thromboembolism.[13,14] Patients with arterial thrombosis may require heparin and warfarin, or anti-platelet therapy.[16]

Thromboembolic complications may also be associated with the indwelling catheters used to provide vascular access for antineoplastic therapy.[17,18] Prophylaxis with low-dose warfarin or a low-molecular-weight heparin may reduce the risk.[18]

Effects on electrolytes. Fluid and electrolyte disturbances are common in patients with cancer.[1-4] These can be caused by the disease process, or adverse effects of treatment such as surgery, chemotherapy, antibacterials and diuretics. Mechanisms of chemotherapy-induced electrolyte disturbances include loss of appetite, gastrointestinal electrolyte loss due to vomiting and diarrhoea, impaired intestinal absorption due to mucosal damage, direct nephrotoxicity causing renal electrolyte loss, and a syndrome of inappropriate antidiuretic hormone secretion or a condition resembling it. Hypoparathyroidism, which may be a complication of neck surgery, also affects electrolyte balance and is associated with hyperphosphataemia and hypocalcaemia. As well as the acute signs and symptoms of electrolyte disturbances, changes in electrolyte homoeostasis may result in abnormal bone turnover (see Effects on Bones and Joints, p. 727.2). Release of the contents of cells destroyed by chemotherapy is well-known to be associated with hyperuricaemia, hyperphosphataemia, hyperkalaemia, and hypocalcaemia (see Tumour Lysis Syndrome, p. 730.2).

Disturbances of electrolyte homoeostasis have been reported particularly with cisplatin (p. 767.2), cyclophosphamide (p. 772.3), and ifosfamide (see Effects on the Kidneys, p. 806.3). Hypomagnesaemia has been seen with cetuximab (p. 763.3).

Effects on the gastrointestinal tract. Apart from anorexia, and nausea and vomiting (see below), many antineoplastics produce gastrointestinal disturbances, sometimes severe. Mucosal inflammation (mucositis), notably as stomatitis and sometimes proctitis, is quite common, as are mucosal cellular changes, xerostomia, impaired absorption, and diarrhoea. In some cases gastrointestinal damage may progress to ulceration, haemorrhage, and perforation. Constipation may be a problem with the vinca alkaloids.

Use with radiotherapy may increase the toxicity of some drugs on the gastrointestinal tract. The neutropenia induced by many antineoplastic regimens can also lead to secondary gastrointestinal effects, such as stomatitis and gastrointestinal inflammation, associated with infection.

CLOSTRIDIUM DIFFICILE INFECTION. Antineoplastic therapy has occasionally been associated with the development of *Clostridium difficile*-induced gastrointestinal disease, even in the absence of concomitant antibacterial therapy.[1] Most patients had received multiple drug regimens. Methotrexate, fluorouracil, cyclophosphamide, and doxorubicin have all been associated with a number of cases but this may simply reflect the frequency of their use. A retrospective analysis[2] of a group of patients treated for acute leukaemia or receiving bone marrow transplantation found that predictive variables for *C. difficile* diarrhoea included the use of low intensity chemotherapy, but speculated that patients receiving high intensity chemotherapy may be subjected to more strict isolation and infection control procedures, thereby reducing the risk of nosocomial transmission. Another review[3] of 875 courses of myelosuppressive chemotherapy found 61 episodes of *C. difficile* diarrhoea, and that in 36% of those episodes the patients had received high-dose cytarabine. In 35 of the 61 episodes, patients had also received prior intravenous antibacterials.

For discussion of the treatment of such disease, see Antibiotic-associated Colitis, p. 183.1

MUCOSITIS. The suffering associated with oral mucositis is by far the worst part of treatment for many patients undergoing curative chemotherapy or bone marrow transplantation, and for those undergoing oral radiotherapy.[1-3] Apart from pain and dysphagia the ulcerated mucosa provides a portal of entry for infection; loss of weight and malnutrition can further impair immune function, and if symptoms are severe enough the treatment cycle may have to be interrupted. Before the patient starts any intensive chemotherapy or local or systemic radiotherapy the oral cavity must be assessed with a view to eliminating sources of infection and chronic irritation. Established risk factors for mucotoxicity include smoking, poor oral hygiene, age, female gender, and previous antineoplastic therapy. However, the most significant risk factor is the treatment itself. Drugs such as fluorouracil, methotrexate, and etoposide are associated with an increased risk for mucositis, as are the more aggressive, dose-intense regimens such as TAC (docetaxel, doxorubicin, and cyclophosphamide). Infusional fluorouracil-based regimens appear to have less risk than standard-dose CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) or bolus fluorouracil regimens. Drug dosing and scheduling are important in modulating the risk for mucositis.[4] For further comment on the prophylaxis and treatment of mucositis, see under Treatment of Adverse Effects, p. 732.1.

NAUSEA AND VOMITING. Nausea and vomiting are common adverse effects of antineoplastic therapy, and for many patients, represent a major drawback to treatment. Once experienced, anticipatory vomiting may occur at the sight of medical staff, or a needle. The problem may be severe enough in some cases to hinder or completely prevent further treatment.

Antineoplastic or cytotoxic drugs may induce vomiting by both a central action on the chemoreceptor trigger zone and a peripheral action on the gastrointestinal tract. Several neurotransmitters have been implicated over the years including acetylcholine, histamine, enkephalins, dopamine, and serotonin or 5-hydroxytryptamine (5-HT). The cerebral cortex is probably responsible for anticipatory vomiting. Antineoplastics may not all induce emesis by a common pathway, but 5-HT_3-receptor mechanisms are clearly important in the pathogenesis of *acute* cisplatin-associated vomiting. This was suspected when the antiemetic metoclopramide, a dopamine antagonist, was found to have serotonin (5-HT) antagonist activity at the high doses used against cisplatin emesis and confirmed when specific 5-HT_3 antagonists such as ondansetron proved to be effective. Different mechanisms are probably involved in *delayed* emesis since 5-HT_3 antagonists are less effective.

Some patients are more susceptible to emesis than others. The emetic potential of antineoplastics also varies in terms of severity and incidence, and may depend to some extent on the dose, route, and schedule of administration. Some combination therapy has resulted in a higher incidence of vomiting than would be expected from the constituents.

- Vomiting may be *very severe* with cisplatin, dacarbazine, dactinomycin, chlormethine, high-dose cyclophosphamide, and streptozocin, and occurs in most patients.
- *Moderate* vomiting is likely with the taxanes, doxorubicin, more modest doses of cyclophosphamide, and high-dose methotrexate.
- Vinca alkaloids, fluorouracil, lower doses of methotrexate, chlorambucil, bleomycin, and etoposide have *low* emetogenic potential.

The *onset and duration* of vomiting also varies from drug to drug. With cisplatin the onset may be between 4 and 8 hours after a dose, while the duration may be up to 48 hours or occasionally even longer; a persistent feeling of nausea, and sometimes vomiting, lasting for several days may also occur. After chlormethine, vomiting may begin within a half to 2 hours, whereas after cyclophosphamide there may be a latent interval of 9 to 18 hours, but in both cases vomiting is generally less prolonged than with cisplatin. Acute emesis (that occurring within 24 hours) has generally been easier to control than delayed emesis (that occurring more than 24 hours after chemotherapy) or anticipatory emesis.

The management of chemotherapy-induced nausea and vomiting is discussed on p. 1814.3.

Effects on the heart. The cardiotoxicity of antineoplastics has been reviewed.[1-6] Common cardiovascular complications include left ventricular dysfunction, heart failure, myocardial ischaemia or infarction, QT interval prolongation, arrhythmias, or bradycardia; thromboembolism (see Effects on the Cardiovascular System, p. 727.2) and hypertension are also common. Cardiotoxicity is the major dose-limiting toxicity with anthracyclines such as doxorubicin and daunorubicin (see Effects on the Heart, under Doxorubicin, p. 784.1). Cardiotoxicity has also been associated with other antineoplastics, such as the alkylating agents cyclophosphamide and ifosfamide, antimetabolites such as capecitabine and fluorouracil, taxanes, tyrosine kinase inhibitors, and the monoclonal antibodies bevacizumab and trastuzumab. Amsacrine has been associated with arrhythmias, sometimes fatal. As well as cardiac effects associated with a capillary leak syndrome, arrhythmias can occur with interleukin-2. Occasional reports of cardiotoxicity associated with busulfan, carmustine, cisplatin, cytarabine, etoposide, mitomycin, pentostatin, and vincristine also exist.

Effects on immune response. Lymphocytes are produced by stem cells in the bone marrow and at other sites including the thymus, and are involved in humoral and cell-mediated immunity. Most antineoplastics have a depressant effect on bone marrow (see Effects on the Blood, p. 727.1) and many have immunosuppressant properties although the degree of suppression varies considerably and may depend on the dose and schedule used. Immunosuppression decreases the patient's resistance to infection and has been implicated in the development of malignancies. Response to vaccines may also be reduced, and there is a possibility of generalised infections with live viral vaccines (see Interactions, p. 2375.3).

For a discussion on the effects of immunosuppressant therapy on the immune response and the infections associated with it, see Corticosteroids, p. 1617.2.

Effects on the kidneys. Nephrotoxicity is well-recognised as an adverse effect of cisplatin (p. 767.2), ifosfamide (p. 806.3), and methotrexate (p. 825.2), but renal toxicity may occur with other antineoplastics including the nitrosoureas (such as carmustine and streptozocin), mitomycin (due to haemolytic-uraemic syndrome, see p. 831.3), azacitidine, gemcitabine, and pentostatin.[1] See also under individual monographs—other antineoplastics with which nephrotoxicity has been reported include aldesleukin (p. 811.3), bevacizumab (p. 748.2), and imatinib (p. 808.3).

1. Kintzel PE. Anticancer drug-induced kidney disorders: incidence, prevention and management. *Drug Safety* 2001; 24: 19–38.

Effects on the liver. The range of hepatotoxic reactions that can occur with antineoplastics is wide. Toxic hepatitis (hepatocellular injury) can range from asymptomatic elevations of aminotransferases to signs of overt liver failure with hepatocellular necrosis. Other manifestations of hepatotoxicity include cholestatic injury, steatosis, hepatic veno-occlusive disease (VOD), and hepatic tumours. The important indicator of toxicity is liver biopsy rather than liver function tests as the latter may be normal in this setting.[1] The hepatotoxicity of various chemotherapy drugs has been reviewed.[1-4] Occasional reports of hepatotoxicity exist for many antineoplastics including anastrozole (p. 743.1), aminoglutethimide (p. 739.3), bicalutamide (p. 749.2), busulfan (p. 755.2), dacarbazine (p. 776.2), dactinomycin (p. 777.2), doxorubicin (p. 784.3), erlotinib (p. 789.2), floxuridine (p. 793.3), flutamide (p. 798.3), gemtuzumab, (p. 802.3), hydroxycarbamide (p. 804.2), imatinib (p. 808.2), methotrexate (p. 825.3), mitomycin (p. 832.1), mitoxantrone (p. 833.3), oxaliplatin (p. 838.3), tamoxifen (p. 862.3), tioguanine (p. 872.1), and trastuzumab (p. 877.1). However, the relationship of the drug to the adverse effect is not always easy to establish. The temporal relationship between drug use and the appearance of symptoms is important; rechallenge in most cases is not recommended as liver toxicity may be more severe on re-exposure.[1] Use with radiotherapy may increase the risk of hepatotoxicity.[4,5] Liver toxicity may not be confined to patients: one report described 3 cases of liver damage in nurses working on an oncology ward.[6]

VOD has occurred after the use of high doses of chemotherapy for conditioning regimens before haematopoietic stem cell transplantation.[3-5] Other antineoplastic drugs involved in the development of VOD include the alkylating agents, antimetabolites, and combination chemotherapy, typically with drugs that undergo hepatic metabolism.[4]

Effects on the lungs. Lung injury leading to pulmonary fibrosis occurs in about 10% of all patients who receive bleomycin, being fatal in 1 to 2%. Clinically, the reaction usually presents several months after completion of therapy as non-productive cough and dyspnoea. The reaction is dose-related, being more likely at total doses over 400 000 international units (*400 USP units*), although it has occurred at much lower doses, and is more common in elderly patients. Injury may be exacerbated by the use of combination chemotherapy regimens and radiotherapy, and supplemental oxygen given even years after the use of bleomycin may precipitate pulmonary oedema.[1] Hypersensitivity pneumonitis, which is more amenable to treatment, has also been reported.[2]

Pulmonary damage has also been reported with an increasing number of antineoplastics apart from bleomycin.[1,3,4] Among the alkylating agents cyclophosphamide has been reported to produce lung injury in less than 1% of cases, although this may be increased where it is a component of combination regimens or given with radiotherapy. Busulfan may produce lung toxicity including insidious pulmonary fibrosis in as many as 4% of patients, usually developing several years after initiation of therapy, and with increased risk the longer that therapy lasts. A few reports exist of interstitial pneumonitis and fibrosis associated with chlorambucil and melphalan, but these appear to be extremely rare. The prognosis in patients with alkylating-agent-induced fibrosis is often poor, with mortality rates of 50% or more.

The antimetabolite methotrexate can produce symptoms similar to hypersensitivity pneumonitis in up to 7% of patients, sometimes with pleuritis and acute respiratory failure due to pulmonary oedema, but it is not clear whether a true hypersensitivity mechanism is involved, and symptoms are usually reversible even without stopping therapy. High-dose cytarabine has also been associated with pulmonary oedema. Gemcitabine (p. 801.3) has been associated with interstitial pneumonitis and potentially life-threatening symptoms have occurred when given with thoracic radiotherapy.

Other antineoplastics known to be associated with pulmonary toxicity include mitomycin (usually in less than 10% of patients though the incidence may be much higher in combination regimens); the vinca alkaloids (generally in combination, and usually producing acute respiratory failure); chlorozotocin; procarbazine; and possibly teniposide. The nitrosoureas, and particularly carmustine, have also emerged as pulmonary toxins. Carmustine has been associated with an insidious chronic pulmonary fibrosis, which in some early studies occurred in as many as 30% of patients and had a high mortality. Symptoms are associated particularly with cumulative doses in excess of about 1.4 g/m^2, although toxicity has occurred at cumulative doses as low as 240 mg/m^2. The onset of symptoms may be very delayed: some workers reported fibrosis occurring up to 17 years after treatment in patients who received carmustine as children.[5] Pneumonia and fibrosis have also been reported in patients receiving rituximab (p. 854.2), and fatal lung disease has occurred in patients given erlotinib (p. 789.2).

Effects on mental function. Combination chemotherapy has been associated with psychiatric morbidity (anxiety, depression, behavioural changes) in both adults[1] and children.[2] It has been pointed out that patients receiving cancer chemotherapy inevitably suffer emotional distress, associated in part with the adverse effects of treatment. Patients should be fully informed of aims and likely outcomes of treatment, and adverse effects minimised, in order to keep emotional distress to a minimum.[3] Chemotherapy can also cause cognitive impairment,[4-7] affecting functions such as memory, reasoning, concentration, and language skills. Drugs may have direct central neurological toxic effects, or may indirectly affect brain function through adverse effects such as anaemia. Most studies have examined cognitive impairment in women being treated with chemotherapy for breast cancer, but many other cancer patients develop cognitive impairment, which has been described as 'chemo-brain' or 'chemo-fog'.

Some antineoplastics have been associated with mental symptoms, including methotrexate (p. 826.2), mitotane (p. 832.3), and the vinca alkaloids (see Vinblastine, p. 882.1). In many cases such symptoms can be attributed to direct central neurotoxicity (see also under Effects on the Nervous System, below).

Effects on the nervous system. The neurotoxicity of various antineoplastic drugs has been reviewed.[1-5] Effects can be central or peripheral, and can be dose-limiting.[3,5] For further details see under the individual monographs.

CNS toxicity is usually manifested as encephalopathy of various severities.[5,6] Drugs that can cause CNS toxicity include methotrexate, vincristine, ifosfamide, cytarabine, fludarabine, fluorouracil, cisplatin, and the taxanes.[3] Some drugs cause mental status changes, see Effects on Mental Function, above. Drugs that commonly cause peripheral neuropathy include the platinum compounds, the vinca alkaloids, taxanes, and other agents such as bortezomib.[3,4,7] Peripheral neuropathy can manifest as sensory, motor, or sensorimotor (combination) neuropathies.[8] Two patterns are common: a painful sensory neuropathy (seen with platinum compounds) and a mixed sensorimotor neuropathy with or without autonomic involvement (such as that seen with vincristine and taxanes).[3,8]

In some cases these effects may be associated with particular routes such as the intrathecal.[4] Radiotherapy can also cause damage to the nervous system so its use with chemotherapy may lead to additive effects.[6]

For discussion on management, see Neurotoxicity, p. 732.2.

EFFECTS ON THE EARS. Several antineoplastics have been associated with ototoxicity,[1] including vincristine and vinblastine, but cisplatin in particular is associated with high-frequency hearing loss and tinnitus. In addition, agents such as the nitrogen mustards and bleomycin are potentially ototoxic.

1. Seligmann H, *et al.* Drug-induced tinnitus and other hearing disorders. *Drug Safety* 1996; **14**: 198–212.

Effects on reproductive potential. *CHROMOSOMES.* If patients are fertile after treatment with antineoplastics, no significant increase has been seen in fetal chromosome damage, fetal abnormality, or the miscarriage rate. A review[1] of reports of survivors of *childhood cancers* found that adverse pregnancy outcomes were limited to particular groups of survivors. Female survivors of Wilms' tumours who had been treated with abdominal radiation, with or without chemotherapy, appeared to be at increased risk of complications including miscarriage, low birth-weight neonates, and neonatal death. After treatment of childhood Hodgkin's disease using both radiotherapy and chemotherapy, female survivors and partners of male survivors might be at increased risk of miscarriage; however, treatment with radiotherapy or chemotherapy alone did not increase this risk. For other cancers, data were more limited, but suggested that the risk of adverse pregnancy outcomes was not increased in survivors. The Childhood Cancer Survivor study[2] found that the offspring of women whose treatment included pelvic irradiation were more likely to be premature, to be of low birth-weight, and small for gestational age. Treatment with doxorubicin or daunorubicin increased the risk of low birth-weight independently of radiotherapy. The risk of miscarriage was increased in those women treated with high-dose cranial or craniospinal radiotherapy. In general, the pregnancy outcome of the partners of male survivors was unaffected by the men's previous treatment; however, non-alkylating agent chemotherapy increased the risk of low birth-weight neonates.

Regarding the risk of congenital abnormalities in the offspring of survivors of childhood cancers, most studies have shown no excess of major or minor malformations.[1-3] There was also no evidence that the risk of cancer is increased in the offspring. However, because of the small numbers in many studies and heterogeneity regarding treatments used, it is possible that effects of individual drugs could have been masked. Long-term follow-up is needed as increasing numbers of children survive to adulthood after successful chemotherapy.

For *adult patients*, there is also a lack of evidence of adverse pregnancy outcomes and congenital abnormalities in offspring after chemotherapy. In a large series[4] of women treated with methotrexate, alone or in combination, for gestational trophoblastic tumours, there was no evidence of an increase in adverse outcomes or abnormalities, although women who had received three or more drugs in combination were less likely to have a live birth. A large case-control study carried out in Canada, and involving over 85 000 parents of children with congenital anomalies, also failed to confirm a higher incidence of congenital abnormality in the offspring of patients treated with radiotherapy or alkylating agents.[5] However, despite these generally reassuring results, it has been suggested that women should delay conception for a year after cessation of chemotherapy to allow mature ova that might have been damaged to be eliminated,[6] and that monitoring outcomes in patients who become pregnant shortly after exposure to cytotoxic drugs is desirable.[3]

GONADS. The effects of cytotoxic drugs on the gonads have been reviewed.[1-7] In male patients, antineoplastic drugs may damage the seminiferous tubules, resulting in testicular atrophy with decreased sperm count and motility. Testosterone secretion may also be reduced after damage to Leydig cells. In women, cytotoxic drugs act on the ovary to produce loss of primordial follicles with failure of ovulation, oligomenorrhoea or amenorrhoea, and failure of endocrine function resulting in loss of libido and menopausal symptoms. The degree of damage and its reversibility depend on the drug and its dose and the age and sex of the patient. Age is particularly important for women at the time of treatment, with older women (35 to 40 or over) being more sensitive, probably a reflection of the decrease in oocyte numbers with age.

Although dose also plays a role, estimates of the toxicity of various antineoplastics (as single agents) have been published.[4-6] The risk of gonadal dysfunction is high with alkylating agents (busulfan, chlorambucil, chlormethine, cyclophosphamide, ifosfamide, melphalan), nitrosoureas (carmustine, lomustine), and procarbazine. Medium risk drugs include carboplatin, cisplatin, and doxorubicin. Low risk drugs include bleomycin, dactinomycin, fluorouracil, mercaptopurine, methotrexate, vinblastine, and vincristine.

Severe gonadal dysfunction in both men and women has been associated with combination chemotherapy regimens for Hodgkin's disease. Chlormethine and procarbazine are thought to be mainly responsible for the infertility produced. There is some evidence that currently favoured regimens such as ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) result in less damage to gonadal cells than the earlier MOPP regimen (chlormethine, vincristine, procarbazine, and prednisone). Prolonged gonadal dysfunction has also been seen in patients given combination chemotherapy for acute lymphoblastic leukaemia; girls appear to be at less risk than boys, especially if treated in the prepubertal period.

Techniques for fertility preservation have been reviewed.[3-6,8] Established methods with the highest likelihood of success are sperm cryopreservation (sperm banking) for men and IVF with embryo cryopreservation for women. Other methods for women, for which there is less experience and investigation is underway, include oocyte cryopreservation for future IVF, gonadal tissue cryopreservation for autologous transplantation, and ovarian suppression using oral contraceptives or gonadotrophin-releasing hormone analogues. Such techniques are of little

benefit for the preservation of fertility in patients treated as young children, however, because of gonadal immaturity.

SEXUAL FUNCTION. Loss of libido and decline in sexual performance seem to be relatively common in men receiving combination chemotherapy,[1,2] and may persist after chemotherapy has ended.[1] However, it may sometimes be difficult to distinguish the effects of chemotherapy from those of the disease and the patient's reaction to it: at least one study has shown that gonadal function is disturbed in patients with Hodgkin's disease before treatment.[2] Erectile dysfunction can also result from local damage caused by pelvic surgery or irradiation.[3] Evidence for decreased libido in women is harder to find, but failure of endocrine function after chemotherapy may lead to loss of libido and menopausal symptoms.[4]

Effects on the skin, hair, and nails. Alopecia occurs with many antineoplastics, and may be severe with doxorubicin and other anthracyclines, cyclophosphamide, ifosfamide, etoposide, or teniposide, the taxanes docetaxel and paclitaxel, and topotecan. The alkylating agents and some antibiotic antineoplastics are often associated with hyperpigmentation, most commonly of skin, although pigmentation of nails, hair, and teeth has occurred. Some drugs, such as the taxanes, cause dystrophic changes in the nails. Certain drugs may interact with UV light or x-ray radiation to enhance its effects on the skin and may cause radiation recall, photosensitivity, or, in the case of methotrexate, reactivation of UV light burns. Hypersensitivity to antineoplastics may produce cutaneous reactions including allergic rashes, angioedema, and pruritus. In addition to the above there may be local reactions to irritant and vesicant drugs after extravasation. Finally, certain drugs are associated with specific dermatological reactions: acneform follicular rashes have been reported with cetuximab, bleomycin may produce hyperkeratotic and sclerotic lesions, dactinomycin is associated with an erythematous papular or pustular rash mimicking septic emboli, fluorouracil may produce inflammation of solar keratoses, and plicamycin is associated with a distinctive flushing phenomenon. A palmar-plantar erythrodysesthesia syndrome has been seen with some antineoplastics (see below).

See also Local Toxicity, below. References may also be found under individual monographs.

PALMAR-PLANTAR ERYTHRODYSESTHESIA SYNDROME. Palmar-plantar erythrodysesthesia (PPE; hand-foot syndrome) associated with chemotherapy[1,2] usually presents as a tingling sensation in the palms and soles, which progresses in a few days to burning pain and well-defined swelling and erythema. In severe cases there is desquamation, ulceration, blistering, and severe pain. The reaction appears to be caused by a direct toxic effect and seems to be dose-dependent, affected by both peak drug concentration and total cumulative dose. The drugs most often associated with PPE or similar syndromes are capecitabine (p. 758.3), cytarabine (p. 775.2), docetaxel (p. 782.1), doxorubicin—particularly liposomal doxorubicin (p. 785.1), and fluorouracil (p. 797.2). PPE also occurs with the tyrosine kinase inhibitors, such as lapatinib (p. 815.2), sorafenib (p. 858.1), and sunitinib (p. 859.2). It has also been reported for bevacizumab (p. 747.3), cisplatin (see under Hypersensitivity, p. 768.1), cyclophosphamide (p. 773.1), ixabepilone (p. 815.1), and methotrexate (p. 826.2). PPE is usually managed by reducing the drug dose, increasing the dosage interval, or withdrawing the drug, along with symptomatic treatment and wound care. Systemic corticosteroids and pyridoxine have been used in prophylaxis and treatment. Topical dimethyl sulfoxide has been used for PPE caused by liposomal doxorubicin.

Hyperuricaemia. Overproduction of purines is a known complication of antineoplastic therapy and may result in hyperuricaemia (p. 600.1). Hyperuricaemia is also an important part of the tumour lysis syndrome—see below.

Local toxicity. Local toxicity due to intravenous cancer chemotherapy may include local irritation, extravasation necrosis, and hypersensitivity. **Venous irritation**, presenting as vasospasm and pain or endothelial chemical burn of the vessel, resulting in a painful, streaky, long-lasting sterile phlebitis, may be due to the drug, or, as with carmustine, due to the diluent (alcohol). Irritation and phlebitis have been reported particularly with fluorouracil, carmustine, vinorelbine, and chlormethine.

Some patients treated with peripheral intravenous chemotherapy experience **extravasation** (see p. 731.3), usually with pain, erythema, and swelling at the site of injection. Severe necrosis requiring surgical intervention can develop, particularly with antibiotic antineoplastics such as doxorubicin.

Local **hypersensitivity** reactions, usually self-limiting, must be distinguished from extravasation. In hypersensitivity reactions there is no swelling at the injection site, and pain is felt as a dull ache along the course of the vein, as opposed to the stinging commonly noted after extravasation.

Tumour lysis syndrome. The tumour lysis syndrome represents a biochemical disturbance due to massive release of cellular breakdown products from tumour cells sensitive to therapy. The amount of breakdown products is sufficient to overwhelm normal excretory and metabolic mechanisms for their clearance, and the cardinal features of the syndrome are hyperkalaemia, hyperuricaemia, and hyperphosphataemia accompanied by hypocalcaemia. Clinical symptoms may include urate nephropathy or nephrocalcinosis leading to renal impairment, and cardiac arrhythmias associated with the potassium abnormalities. The syndrome is seen particularly when bulky chemosensitive disease is present, and may be more likely in patients with pre-existing renal impairment or hyperuricaemia. It is most frequent in patients with Burkitt's or lymphoblastic lymphoma, or an acute leukaemia. Of patients with solid tumours, reports have implicated those with germ-cell tumours, small-cell lung cancer, or neuroblastoma although, surprisingly, the syndrome has also been reported in patients with breast cancer, which is normally less rapidly responsive to chemotherapy. For comment on prevention and treatment, see under Treatment of Adverse Effects, p. 732.2.

Treatment of Adverse Effects

Intensive supportive care may be necessary to prevent or control the adverse effects of antineoplastic therapy. Antiemetic therapy should be given to reduce, and if possible prevent, nausea and vomiting, since once experienced it may become a conditioned response, and may not respond to antiemetics. Intensive oral care is desirable to minimise the effects of stomatitis (see also Mucositis, p. 732.1), while corticosteroids, and if necessary nutritional supplements, may be of some help in patients with anorexia. Chemotherapy-induced diarrhoea may also require treatment (see p. 731.3).

Techniques attempting to prevent the occurrence of alopecia have met with varying success (see below). Scalp tourniquets and local hypothermia have been used to minimise concentrations of antineoplastics in the scalp after intravenous injection. However, such methods may allow the development of a cancer-cell sanctuary and should not be used in patients with leukaemia or other conditions with circulating malignant cells.

Of particular importance is the management of bone-marrow depression. Colony-stimulating factors and epoetins can be used to promote the formation of replacement blood elements (see Anaemia, p. 731.1). Active measures may be necessary to combat infection and bleeding. Transfusions of blood products may be required; granulocyte transfusions have been given for infections unresponsive to antibiotics, although their value is a matter of debate, while transfusion of blood platelets or use of growth factors such as oprelvekin (interleukin-11) may be of value in preventing thrombocytopenia-induced bleeding.

Extravasation of antineoplastics can pose serious problems. Infusion should be stopped immediately once extravasation is noticed and any drug remaining at the site aspirated if possible but the details of treatment are controversial (see p. 731.3). If ulceration occurs plastic surgery may be required.

Hyperuricaemia secondary to tumour lysis in patients with leukaemias or lymphomas can be prevented by the addition of allopurinol or rasburicase to treatment schedules, and by adequate hydration and, if necessary, alkalinisation of the urine (see Tumour Lysis Syndrome, p. 732.2). Good hydration is also important to minimise the nephrotoxic effects of drugs such as cisplatin and methotrexate.

Specific treatments exist for the toxicity of certain antineoplastics (for example the use of calcium folinate to reduce methotrexate toxicity, or mesna to control the bladder toxicity of cyclophosphamide or ifosfamide). For further details of the treatment of specific adverse effects see under the individual monographs.

Alopecia. Attempts to prevent or reduce chemotherapy-induced alopecia have relied on either restriction of scalp blood flow with a tourniquet or the use of local hypothermia.[1] Both of these techniques have been based on the rationale that a temporary decrease in blood flow to the scalp will decrease the exposure of hair follicles to the antineoplastic. Therefore, most benefit would be expected for alopecia caused by drugs with a short half-life and for which both active drug and metabolites are rapidly cleared from the circulation.

Studies of scalp tourniquets carried out in the 1970s found head discomfort to be the main adverse effect. They used different chemotherapy regimens, definitions for success, and tourniquet techniques, making conclusions difficult, and tourniquets were largely replaced by local hypothermia techniques.

Regimens vary in their propensity to cause alopecia: drugs that normally produce hair loss include the anthracyclines, cyclophosphamide and ifosfamide, etoposide and topotecan, irinotecan, the taxanes, and vindesine or vinorelbine.[2] Most studies of local hypothermia have attempted to prevent doxorubicin-induced alopecia.[1] Again, chemotherapy regimens, devices used, and exposure times have varied between studies. Varying degrees of efficacy have been reported, but hypothermia has generally been of benefit, particularly with single-agent chemotherapy. The dose of chemotherapy may be relevant, with hypothermia being less effective at doxorubicin doses above 50 mg.[1] Better results have also been reported when cooling is continued for 90 minutes or more; theoretically, cooling time should be related to the half-life of the drugs used and any active metabolites.[2] Headache and cold intolerance may occur, but scalp hypothermia is generally well tolerated.

Despite the successes there is concern that this technique may provide a sanctuary for circulating malignant cells, with the potential risk of metastasis, and there are reports of scalp metastases after the use of hypothermia.[1-3] The technique is considered contra-indicated in patients with haematological malignancies and use is controversial where curative chemotherapy can be given.[2] It has been suggested that the use of scalp hypothermia might therefore be restricted to patients receiving single-agent chemotherapy with a palliative intent, or those with solid tumours that rarely metastasise to the scalp.[1]

In the USA commercial distribution of cooling caps designed to produce localised scalp hypothermia was halted by the FDA in 1990 because of concerns about their efficacy and their potential to create sanctuary sites and interfere with drug distribution elsewhere in the head. However, they continue to be available in many countries.

There has been limited investigation of pharmacological management.[2] For reference to the use of minoxidil to decrease the duration of alopecia after doxorubicin-containing chemotherapy, see p. 1439.1.

Bone-marrow depression. Bone-marrow depression in patients receiving chemotherapy may require a modification of the dose regimen in subsequent cycles, either by delaying or reducing doses, although it is recognised that this may sometimes reduce efficacy.

Licensed product information for several myelosuppressive antineoplastics recommends that if neutropenia or thrombocytopenia occurs subsequent doses should be withheld until white cell counts have returned to 3000 to 3500 cells/mm^3 or more, and blood platelets to about 100 000 cells/mm^3. In practice, however, improved supportive care means that many expert centres routinely give treatment at lower blood counts than these. The values at which it is acceptable to treat will be influenced by whether the regimen is likely to result in further significant falls, and

whether the intent is curative (in which case maintaining treatment intensity is particularly important) or palliative (when avoiding toxicity becomes a prime consideration); local protocols may contain further guidance and should be consulted where available. However, it has been suggested[1] that with appropriate management treatment is usually possible at neutrophil counts of 1500 cells/mm³ and platelet counts above 100 000 cells/mm³.

For guidelines on the use of haematopoietic growth factors in the management of anaemia, neutropenia, and thrombocytopenia, see below.

1. Summerhayes M, Daniels S. *Practical chemotherapy: a multidisciplinary guide*. Oxford: Radcliffe Medical Press, 2003.

ANAEMIA. Chemotherapy-induced anaemia can be managed with transfusion of red cells (p. 1162.1), or treatment with epoetin (p. 1141.1) or darbepoetin (p. 1137.1).[1-4] Iron supplementation may be of benefit in anaemic cancer patients receiving erythropoietic therapy, even in those who are iron-replete.[3]

Guidelines for the use of epoetins and darbepoetin have been issued jointly by the American Society of Clinical Oncology and the American Society of Hematology,[5] and guidelines have also been issued by the US National Comprehensive Cancer Network.[4] In the treatment of chemotherapy-induced anaemia, the use of epoetins or darbepoetin can improve haemoglobin concentration and reduce the need for transfusion of red cells, but whether this improves symptoms and quality of life requires further study. The use of epoetins or darbepoetin is recommended as an option when haemoglobin has fallen to less than 10 g per 100 mL. For patients with a concentration between 10 and 12 g per 100 mL, the decision to use epoetins depends on clinical circumstances and patient preference.[5] In the UK, the use of epoetins or their analogues is not generally recommended[3] for chemotherapy-related anaemia except, in combination with intravenous iron, in patients in whom anaemia is profound and likely to affect survival, and who cannot be given blood transfusions, or in women given platinum-based chemotherapy for ovarian cancer in whom haemoglobin has fallen to 8 g per 100 mL or less.

NEUTROPENIA. Use of granulocyte or granulocyte-macrophage colony-stimulating factors (G-CSF or GM-CSF), alone or with autologous bone marrow transplants or peripheral blood stem-cells, can markedly reduce the period of neutropenia after high-dose chemotherapy regimens (see Filgrastim, p. 1152.1, and Molgramostim, p. 1156.2). The use of filgrastim and pegfilgrastim has been reviewed;[1,2] it was considered that prophylactic use of these agents has enabled the use of more aggressive chemotherapy regimens, including dose-dense regimens (but see below), and treatment of a broader range of patients.

The American Society of Clinical Oncology has issued detailed guidelines for the use of colony-stimulating factors (CSFs) in patients receiving chemotherapy.[3] These point out that in current practice infectious mortality resulting from febrile neutropenia is rare, and that the incidence with common chemotherapy regimens seldom exceeds 20% in previously untreated patients; however, episodes of febrile neutropenia prolong hospital stay, expose the patient to further interventions, and may result in delay or dose-reduction of further chemotherapy cycles. Unfortunately, although CSFs can markedly reduce the incidence of febrile neutropenia, there was little evidence of improved clinical outcomes from the use of CSFs in most situations.

- Use of CSFs for **primary prophylaxis** in previously untreated patients should not normally be considered except where the risk of febrile neutropenia was 20% or more, or where the risk was less than 20% but bone-marrow compromise or comorbidity indicated a patient at high risk (and even here the evidence for improved clinical outcome was modest).
- There was no evidence of clinical benefit from the use of CSFs in **secondary prophylaxis**. In patients with a previous episode of febrile neutropenia the usual option (except where it would compromise the chances of cure) was dose reduction of the chemotherapy regimen.
- For adjunctive **treatment** of episodes of neutropenia, it was recommended that CSFs should not be routinely used for patients who were *afebrile*; there was also strong and consistent evidence against routine use for uncomplicated fever and neutropenia in *febrile* patients. Use might be considered in high-risk patients with febrile neutropenia.
- Although CSFs could permit **increased dose-density or dose-intensity** of chemotherapy, this was considered only justified within the context of a clinical study, since the limited data suggest survival benefit from dose-dense regimens with CSF support in only a few specific settings. Use in patients receiving combined **chemoradiotherapy** was not recommended.
- In patients with **haematological malignancies**, CSFs should be considered after induction chemotherapy in patients with acute myeloid leukaemias (patients aged over 55 may be most likely to benefit), after consolidation chemotherapy, and after initial induction or postremission chemotherapy in patients with acute lymphoblastic leukaemia; a subset of patients with myelodysplastic syndrome, severe neutropenia, and recurrent infection, might also benefit, but use in patients with refractory or relapsed myeloid leukaemia was not thought to be of benefit.
- CSFs were recommended as adjuncts to **progenitor cell transplantation** to help mobilise peripheral blood stem cells and to speed autologous engraftment.
- As **older patients** treated with curative chemotherapy for diffuse aggressive lymphoma are at increased risk of febrile neutropenia and infections, and dose reduction strategies have been associated with a reduced response rate and survival, prophylactic CSF was recommended for such patients aged 65 and older.
- Although the guidelines in adults were held to be generally applicable to **children**, it was noted that the potential for secondary myeloid leukaemia or myelodysplastic syndrome associated with CSFs was of concern in children with acute lymphoblastic leukaemia.

Guidelines issued by the US National Comprehensive Cancer Network[4] adopt a similar attitude to the use of CSFs, and suggest that they should be used for prophylaxis in all patients with a more than 20% risk of febrile neutropenia or neutropenia sufficient to compromise treatment, and may be considered in patients in whom this risk is judged to be between 10 and 20%. Factors that contribute to risk categorisation include the type of chemotherapy regimen and patient risk factors such as age, type of disease, disease stage, previous chemotherapy or irradiation, general health, and performance status.

For details on the management of infections in neutropenic patients, see Infections in Immunocompromised Patients, p. 186.3.

THROMBOCYTOPENIA. Chemotherapy-induced thrombocytopenia can be managed by chemotherapy dose reductions or delaying the next cycle of chemotherapy; treatment modifications depend on the drug used and the severity of the thrombocytopenia.[1] Severe thrombocytopenia can be rapidly treated with transfusion of platelets (p. 1159.3). Recombinant thrombopoietin[2] (p. 1164.1), interleukin-3 (p. 1155.2), and interleukin-6 have been evaluated for their ability to increase platelet numbers *in vivo*. Interleukin-11 has also been studied and is now available as oprelvekin (p. 1157.2), which can reduce chemotherapy-induced thrombocytopenia.[1,3,4] Interleukin-1 (p. 2533.3) has also been investigated in the prevention or treatment of thrombocytopenia. Eltrombopag (p. 1140.1) and romiplostim (p. 1162.2) are also under investigation.[1]

The American Society of Clinical Oncology has issued guidelines for the use of platelet transfusion.[5] They recommend that prophylactic platelet transfusion be given for thrombocytopenia resulting from impaired bone-marrow function to reduce the risk of haemorrhage when the platelet count falls below a predefined threshold. This threshold will vary depending on the patient's diagnosis, clinical condition, and treatment modality. A threshold of 10 000 cells/mm³ has been recommended for patients being treated for acute leukaemia, with haematopoietic stem cell transplantation, or for solid tumours. A higher threshold of 20 000 cells/mm³ may need to be considered for patients with signs of haemorrhage, high fever, rapid fall of platelet count, coagulation abnormalities, patients receiving aggressive therapy for bladder tumours, or those with necrotic solid tumours who are at increased risk of bleeding from these sites.

Diarrhoea. Patients receiving chemotherapy should be monitored for onset, duration, and severity of diarrhoea. Uncomplicated mild to moderate diarrhoea may be managed conservatively with dietary modification and loperamide. Severe diarrhoea, and mild to moderate cases that are complicated by moderate to severe cramping, nausea and vomiting, decreased performance status, fever, sepsis, neutropenia, frank bleeding, or dehydration, may require more aggressive management including intravenous fluids, octreotide, and antibacterials.[1-3]

Extravasation. Extravasation is the leakage of a drug into subcutaneous tissue during parenteral dosage. Extravasation injuries can range from mild erythema to ulceration, and severe necrosis in some cases if not dealt with promptly. Antineoplastics vary in their propensity to cause extravasation injury:[1]

- *vesicant antineoplastics* cause pain, inflammation and blistering of the local skin, tissue death and necrosis; they include amsacrine, the anthracyclines (doxorubicin and its derivatives), carmustine, dacarbazine, dactinomycin, mitomycin, chlormethine, paclitaxel, plicamycin, streptozocin, and the vinca alkaloids
- *exfoliants* can cause inflammation and exfoliation, but are less likely to cause tissue death, and include cisplatin, docetaxel, mitoxantrone, oxaliplatin, and topotecan
- carboplatin, irinotecan, and the podophyllotoxin derivatives (etoposide and teniposide) are examples of *irritant drugs* which may cause inflammation and irritation, but rarely cause breakdown of tissue. Fluorouracil, methotrexate, and raltitrexed can cause mild to moderate inflammation of local tissue.

Measures to prevent the occurrence of extravasation include giving vesicant or irritant drugs via a central line, or peripherally via a recently sited cannula; vesicants are generally given by intravenous injection into a fast-running infusion. Glyceryl trinitrate patches applied distally to the cannula may be used to dilate veins where venous access is a problem. The site of administration should be regularly checked, and the patient asked to report any untoward sensations.

If extravasation should occur the infusion should be stopped immediately and as much as possible of the infiltrating drug removed by aspiration. Beyond this, however, the management of extravasation is not well standardised and there has been disagreement as to the most appropriate course; there is little data from controlled studies and much practice is based on anecdotal reports and individual experience. Intravenous and subcutaneous injection of a corticosteroid (usually hydrocortisone) has been suggested, although some consider it ineffective or possibly even disadvantageous. Topical application of a 1% hydrocortisone cream to inflamed skin has also been suggested, and antihistamines and, if necessary, analgesics, may be given orally. In most cases application of a cold dressing or ice pack is appropriate. However, after extravasation of the taxanes, vinca alkaloids, or cisplatin, the use of warm packs with hyaluronidase to enhance uptake from the skin has been recommended; a similar procedure has been suggested for large volume extravasations of the podophyllotoxin derivatives.

The use of specific antidotes is a particularly contentious area, since few are clinically validated and some (such as the use of sodium bicarbonate 8.4% for anthracycline extravasations) may do more harm than good. Brief infiltration of a less concentrated (2.1%) sodium bicarbonate solution, followed after a few minutes by aspiration, is still, however, advocated by some in the management of extravasations of the anthracyclines, carmustine, and plicamycin. Better accepted in the management of anthracycline and mitomycin extravasation is the topical application of dimethyl sulfoxide about every 6 hours,

sometimes alternated with hydrocortisone 1% cream. Dexrazoxane is also used for the management of anthracycline extravasation. Sodium thiosulfate 3 or 4% has been used to infiltrate the site of extravasations of cisplatin, dactinomycin, or chlormethine.

The role of surgery is also important. It is unequivocally necessary in cases where other methods have failed to prevent evolving tissue damage, but there is some dispute as to the role of early surgery to remove drug-laden tissue and prevent the development of more serious ulceration and necrosis. Techniques of saline flushout and liposuction have been developed for removing drug and non-viable tissue while preserving overlying skin.

Some references to the management of extravasation are given below.[1-6]

Hypersensitivity. Desensitisation protocols have been described for cancer patients with hypersensitivity reactions to chemotherapy, including taxanes, platinum agents, and monoclonal antibodies.[1]

1. Castells M. Rapid desensitization for hypersensitivity reactions to chemotherapy agents. *Curr Opin Allergy Clin Immunol* 2006; 6: 271–7.

Mucositis. Many drugs have been tried for the *prophylaxis* of mucositis caused by antineoplastic therapy, by modifying exposure of the oral mucosa to chemotherapy, modifying epithelial proliferation, or reducing the potential for infection and inflammatory complications of mucositis.[1] Some drugs showed limited evidence of benefit in small studies, including benzydamine, betacarotene, granulocyte-macrophage colony-stimulating factor, povidone-iodine, propantheline bromide, vitamin E, and tretinoin. There are conflicting reports of benefit from studies of sucralfate and chlorhexidine. Other options that have been tried with less success include aciclovir, allopurinol, dinoprostone, glutamine, misoprostol, pentoxifylline, and bacterial and fungal decontamination.

A large systematic review[2] considered many of these and found that some drugs showed evidence of benefit, albeit weak, including amifostine, benzydamine, calcium phosphate, honey, hydrolytic enzymes, iseganan, and zinc sulfate; local cooling with ice chips and Chinese medicinal herb mixtures also showed some benefit. Practice guidelines[3] also suggested that local cooling may prevent oral mucositis associated with bolus fluorouracil or edatrexate and that ranitidine or omeprazole may prevent epigastric pain after treatment with cyclophosphamide, methotrexate, and fluorouracil, or after fluorouracil with or without folinic acid. Palifermin may prevent oral mucositis in patients with haematological neoplasms given high-dose chemotherapy and total body irradiation before autologous stem cell transplantation. Local cooling may be used in patients given high-dose melphalan. Amifostine may prevent radiation proctitis in those receiving standard-dose radiotherapy for rectal cancer, and although it has been suggested that it may reduce oesophagitis associated with chemoradiotherapy for non-small cell lung cancer,[3] others feel that data are insufficient to recommend routine use in such patients.[4]

There will be some overlap between measures for prophylaxis and treatment of mucositis, and another systematic review[5] of *treatment* strategies found that there was some evidence that topical allopurinol or granulocyte-macrophage colony-stimulating factor might improve chemotherapy-induced oral mucositis, but the evidence was weak and unreliable. Given the number of variables involved in the development of mucositis it is unlikely that any one prophylactic or treatment regimen will prove suitable for all patients.

Nausea and vomiting. For a detailed discussion of the management of chemotherapy-induced nausea and vomiting, see p. 1814.3.

Neurotoxicity. Overall management of neurotoxicity comprises prevention, restoration of function, and symptomatic treatment.[1] Many agents have been tried for neuroprotection, including amifostine, carnitine, erythropoietin, glutamine, glutathione, and vitamin E.[1-4] Drug regimes have also been modified in an attempt to prevent neurotoxicity.[1] Treatment is supportive and symptomatic; pain management is similar to the management of other types of neuropathic pain.[1] Non-pharmacological interventions have also been investigated.[2]

Osteoporosis. Bone loss that occurs with cancer therapy is generally more rapid and severe than postmenopausal bone loss in women or normal age-related osteoporosis in men. However, treatment principles are generally the same. For a detailed discussion on the management of osteoporosis, see p. 1168.1.

Thromboembolism. For discussion on the management of venous or arterial thrombosis, see Effects on the Cardiovascular System, p. 727.2.

Tumour lysis syndrome. Management of tumour lysis syndrome is based on hydration, correction of metabolic abnormalities, and supportive treatment of renal failure.[1-3] Aggressive hydration with isotonic sodium chloride reduces concentrations of uric acid, phosphate, and potassium, and should be considered in all patients at risk of the syndrome, except those at risk of volume overload. Management of acute hyperkalaemia may include cardiac membrane stabilisation with calcium gluconate, intracellular shift of potassium using insulin (with glucose) or inhaled beta$_2$ agonists, and increased excretion of potassium by diuretics or dialysis. In the management of hyperuricaemia[1,3,4] allopurinol may be given prophylactically to reduce the formation of uric acid, and rasburicase may be used for both prophylaxis and treatment by increasing uric acid oxidation. Adequate hydration, sometimes with urinary alkalinisation using sodium bicarbonate, also improves the solubility and hence renal excretion of uric acid.

Precautions

In view of their severe toxicity and possible carcinogenicity these drugs should generally be reserved for severe or life-threatening disease, and it is widely suggested that their use should be confined to experienced staff in specialised centres.

Immunosuppression and bone-marrow depression are features of many of these drugs and their use is associated with an increased risk of infections caused by pathogenic or opportunistic micro-organisms, and a reduced capacity to cope with them. Where possible, immunosuppressant drugs should not be given to patients with acute infections, and dosage reduction or withdrawal should be considered if infection develops, until the infection has been controlled. For cautions regarding the use of vaccines in patients receiving these drugs see Interactions, p. 733.3. For discussion of the treatment of infections in immunosuppressed patients, see p. 186.3. Special care is necessary in debilitated patients.

Blood counts and measurement of haemoglobin concentrations should be carried out routinely to help predict the onset of bone-marrow depression. Great caution is needed when the marrow is already depressed from radiotherapy or therapy with other antineoplastics, and modification of dosage regimens may be required. The blood counts below which treatment is contra-indicated will vary depending on the regimen to be used and the therapeutic intent of that treatment (see Bone-Marrow Depression, p. 730.3); local protocols, including those for the use of colony-stimulating factors, should always be consulted.

Although positive evidence of teratogenicity in humans is not available for all antineoplastics, pregnancy should be avoided in women receiving them: in particular they should not be given, if possible, during the first trimester. Mothers receiving antineoplastic therapy should not breast feed. Because some regimens may result in permanent infertility, the storage of semen samples for male patients, and embryos for females before such therapy may be desirable.

Many antineoplastics are vesicant or irritant. Care must be taken to avoid extravasation since severe pain and tissue damage may ensue. They must be handled with great care and contact with skin and eyes avoided; they should not be inhaled. In many countries official or professional guidelines on precautions for the safe handling of cytotoxic drugs have been issued.

For precautions specific to particular drugs, see under the individual monographs.

Administration. Oral antineoplastic drugs have the same potential for treatment-related toxicity and serious medication errors as intravenous antineoplastic drugs.[1] The National Patient Safety Agency (NPSA) in the UK received 3 reports of fatalities and 400 safety incidents with oral antineoplastic drugs between November 2003 and July 2007. Errors included the incorrect dose, frequency, quantity, or duration of medication.[2] The NPSA has recommended that the prescribing, dispensing, and use of oral antineoplastics (excluding hormonal therapy) should be carried out and monitored to the same standard as that of parenteral therapy, requiring the inclusion of some of the following procedures:

- treatment should be started by a cancer specialist
- prescription in the context of a written protocol and treatment plan, including guidance on monitoring and treatment of toxicity
- access to the written protocol and treatment plan, and access to advice from an experienced cancer pharmacist, for non-specialist prescribers and dispensers
- patients should be provided with written information, including details of the original regimen and treatment plan and arrangements for monitoring

Recommendations for the dispensing and supply of oral chemotherapy in the primary care setting have been made by specialist organisations.[1]

Doses of antineoplastics are determined using different methods, including body-surface area or body-weight; alternatively, doses may be fixed. Doses are further adjusted after consideration of a patient's individual health status. Dose regimens may be complex and may differ depending on its indication, or on whether a drug is used as monotherapy or as part of a combination regimen. The *BNF* omits some dose statements of antineoplastic drugs for this reason, while stating that, even where dose statements are given, specialist literature, chemotherapy protocols, or local cancer networks should be consulted before prescribing, dispensing, and giving these drugs; furthermore, they advocate that prescriptions for these drugs should not be repeated without specialist instruction.

Administration in the elderly. The use of antineoplastics in the elderly should take into consideration age-related physiological changes including decline in renal and hepatic function, reduced haematopoietic reserve, and reduced gastrointestinal and cardiac function. Other factors to consider are comorbid conditions and potential drug interactions with associated medications.[1-9] Neoplastic disorders in the elderly have been undertreated because of an impression that these diseases are less aggressive,[10] and the effects of chemotherapy more likely to be severe.[1,2,10,11] Elderly patients have often been excluded from clinical studies for reasons that included physician bias, protocol eligibility criteria with restrictions on comorbidities, and poor patient functional status.[2] There is evidence, however, that healthy older patients can tolerate chemotherapy as well as younger patients.[1,2] However, there have been few studies of chemotherapy specifically in elderly patients,[4,10] and selection of a suitable dosage regimen is more difficult as a consequence, although there is increasing effort to address this lack of data.[2,10,11] Old people vary as much as any other group in their response to drugs, and the consensus is that they should not be excluded from any form of treatment on the grounds of age alone.

Administration at home. Outpatients taking oral antineoplastic therapy (such as capecitabine or tegafur with uracil) at home do not receive the same level of monitoring as inpatients, and should be cautioned to report any adverse effects, since such treatments may still produce severe toxicity. Problems with home administration include non-compliance, interactions with other drugs and food, and medication errors. However, many patients prefer oral therapy to intravenous administration, and such problems can be managed with better communication and patient education. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

Contraception. The *BNF* recommends that intra-uterine devices for contraception be used with caution in patients with drug- or disease-induced immunosuppression, because of the risk of infection; such devices are contra-indicated in marked immunosuppression.

Handling and disposal. Antineoplastics are usually potent and potentially highly toxic drugs that must be handled with due care. In many countries official or professional guidelines are available for the handling, reconstitution, and disposal of antineoplastics, and most centres or institutions in which these drugs are used will have individual handling policies based on these.[1]

Recommendations generally include:

- that these drugs be reconstituted by trained personnel;
- that reconstitution take place in designated areas, designed to protect personnel and the environment—for example, the use of safety cabinets;
- that protective clothing be worn, including gloves, eye protection, and masks if necessary (it should be noted that gloves may vary in their resistance to penetration, depending upon their thickness, the material of which they are made, and the drug in question[1,2]);
- that waste should be disposed of carefully in suitable separate containers, clearly labelled as to their contents (it should be noted that the patient's body fluids and excreta may contain appreciable amounts of antineoplastic agents and it has been suggested that they and materials such as bed linen contaminated with them should also be treated as hazardous waste[3,4]);
- that adequate procedures should be in place for accidental contamination due to spillages;
- that staff exposure to antineoplastic agents be recorded and monitored;
- that pregnant staff should avoid handling these drugs if possible.

Pregnancy. Antineoplastics may be used during pregnancy for their immunosuppressant properties in auto-immune disease, and for the treatment of cancer, which can complicate 1 in 1000 pregnancies.[1-3] Although the use of potentially teratogenic drugs would normally be avoided during pregnancy, the risk to the mother of inadequate treatment may outweigh whatever risks exist of abnormality in the fetus.[1]

The highest incidence of adverse effects appears to occur after exposure during the first trimester:[1-4] about 10 to 20% of fetuses exposed to cytotoxics during this period have major malformations, compared with 3% in the general population.[1] Malformations reflect the gestational age at exposure. The fetus is particularly vulnerable when exposed during organogenesis (weeks 2 to 8 after conception), and the heart, neural tube, and limbs are affected earlier than the palate and ear; after organogenesis, the eyes, genitalia, haematopoietic system, and CNS remain vulnerable to continued exposure.[3]

The risk of fetal malformations after exposure during the second and third trimesters is probably no higher than the background rate, but there may still be an increased risk of still-birth, fetal growth restriction, premature birth, and maternal or fetal myelosuppression.[1-3]

The delayed effects of antineoplastics on development have not been well-documented. Despite concerns that premature birth and low birth-weight could contribute to retardation of growth, development, and intellect,[5] long-term follow-up of a limited number of children has not shown any evidence of abnormalities.[3-5] Similarly, although maternal antineoplastic therapy has been implicated in a case of childhood neuroblastoma and papillary thyroid cancer, the child's fraternal twin, exposed to the same drugs *in utero*, was healthy.[3] There have been no reports of secondary leukaemias in exposed offspring, but the longer term risk is unknown.[3]

The teratogenicity of any drug depends on the timing of exposure, the dose, and the characteristics affecting placental transfer,[3] as well as the actions of the drug. Of the antineoplastics, the greatest risk seems to be associated with alkylating agents and antimetabolites, in particular aminopterin, fluorouracil, and methotrexate.[1,2,6] The vinca alkaloids and doxorubicin (but not epirubicin or idarubicin) may entail less risk,[2,3] although the former have produced malformations in *animals*.[1] Other drugs reported to be teratogenic or potentially teratogenic include busulfan,[1] chlorambucil,[1,6] chlormethine,[1] cyclophosphamide,[1,6] cytarabine,[1] and the podophyllotoxin derivatives.[1] The problems with thalidomide and its congeners are well known.

There are no specific dosage recommendations for the use of antineoplastics during pregnancy, but physiological changes occurring in the mother can alter the pharmacokinetics of drugs.[1-3] This could potentially increase the toxicity of the antineoplastic, or decrease its efficacy.[2] Anecdotal evidence suggests that adverse effects may be less marked during pregnancy, perhaps reflecting reduced peak or free-drug concentrations in the blood.[3] Myelosuppressive chemotherapy should be avoided 3 weeks before the anticipated delivery so that the mother is neither neutropenic nor thrombocytopenic.[1-3] For the same reason, chemotherapy should be avoided after 35 weeks of gestation, when spontaneous delivery is more likely to occur.[3] The timing of delivery is also critical for the neonate, as chemotherapy given shortly before delivery may not be eliminated through the placenta, prolonging exposure in the newborn.[1,3]

There has also been concern that long-term *occupational exposure* to antineoplastics might have an adverse effect on the fetus of pregnant healthcare workers: a study in 650 Finnish nurses found that women who experienced fetal loss were more than twice as likely to have had first trimester exposure to antineoplastic drugs as women who successfully gave birth.[7] These results have been criticised on the grounds that such results are not generally seen in cancer patients,[8,9] who presumably are exposed to much higher doses of antineoplastics. However, similar results were seen in a cross-sectional analysis of 7094 pregnancies involving 2815 nursing and pharmacy staff.[10] Another study[11] has suggested that the rate of ectopic pregnancy may be increased in nurses occupationally exposed to antineoplastics, but the small number of ectopic pregnancies involved (15 in 734 pregnancies) means that the association with antineoplastics may be due to chance. A further, larger, case-control study[12] by the same investigators found no evidence of an increased rate of ectopic pregnancy, and suggested that occupational exposure to higher levels of antineoplastics in the past possibly explained the earlier findings. Again, such an effect does not appear to have been reported in women treated with antineoplastics.

Interactions

Because of their effects on the gastrointestinal mucosa antineoplastics have the potential to interfere with the absorption of drugs given orally. Antineoplastics that have an immunosuppressant effect may reduce the response to vaccines, and there is a possibility of generalised infection with live vaccines. Use with live vaccines should generally be avoided.

Many antineoplastics are inhibitors of certain isoenzymes of cytochrome P450 and some antineoplastics are also metabolised by these enzymes, and in consequence the possibility of interactions between antineoplastics, or between antineoplastics and other medication, cannot be discounted.

Interactions affecting specific drugs are covered under the individual monographs.

Antiepileptics. Retrospective review of outcomes in children treated for acute lymphoblastic leukaemia indicated that long-term antiepileptic therapy increased the clearance of several antileukaemic drugs and reduced the efficacy of therapy.[1] Management of patients with brain tumours or metastases, which may predispose patients to convulsions, thus poses particular problems in the choice of antiepileptic treatment if interactions are to be avoided; the topic has been reviewed.[2,3]

3. Ruggiero A, *et al.* Interactions between antiepileptic and chemotherapeutic drugs in children with brain tumors: is it time to change treatment? *Pediatr Blood Cancer* 2010; **54**: 193–8.

Antivirals. The potential for interaction between antiretrovirals and antineoplastics has been reviewed.[1] Although clinical evidence of interactions is scanty, various HIV-protease inhibitors and NNRTIs can inhibit or induce cytochrome P450 isoenzymes, and thus have the potential to interact with some antineoplastics including taxanes, vinca alkaloids, and cyclophosphamide.

1. Antoniou T, Tseng AL. Interactions between antiretrovirals and antineoplastic drug therapy. *Clin Pharmacokinet* 2005; **44**: 111–45.

Antoxidants. The potential for interactions between antoxidants and antineoplastics has been reviewed.[1] Theoretically, antoxidants might reduce the efficacy of antineoplastic chemotherapy. The authors raised three concerns regarding this effect:

- *acetylcysteine* should not be used with *cisplatin* or *doxorubicin*;
- *tangeretin*, a flavonoid, should not be used with *tamoxifen*; and
- *betacarotene* should not be used with *fluorouracil*.

Aside from these possible interactions, no *in-vivo* evidence was found to suggest that natural antoxidants interfere with conventional cancer chemotherapy.

Effects on other drugs. Antineoplastics have been reported to affect several drugs including:

- digoxin (reduced absorption, see p. 1357.1)

- oral anticoagulants (increased or decreased effect, see Warfarin, p. 1532.2)
- phenytoin (increased or decreased effect, see p. 544.1)
- suxamethonium (prolonged effect, see p. 2039.3)
- vaccines (decreased response, see p. 2375.3).

Herbal medicines. The potential for interactions between antineoplastics and herbal medicines has been reviewed.[1,2] There is a general lack of information and reports, and warnings are largely based on theory and extrapolation from herbal interactions with other drugs.

Pharmacokinetics

Many antineoplastics have intra- and interindividual pharmacokinetic variability that can be influenced by various factors. Patient age, disease state, and drug interactions can affect drug absorption, distribution, metabolism, and excretion. Genetic polymorphisms also affect drug disposition and are under investigation, but the clinical use of such information is currently limited. Various methods have been tried or are being investigated as ways of tailoring initial drug dosage and therapeutic drug monitoring for individual patients in order to improve treatment efficacy and minimise toxicity. Such methods include population pharmacokinetic modelling and individual pharmacogenetic typing; examples include carboplatin dosing based on glomerular filtration rate (see Administration, p. 759.2) and genotyping of patients thought to be at increased risk of irinotecan toxicity (see Genetic Factors, p. 813.3).

Action

Much of the development of cancer chemotherapy has been based on an understanding of the way in which tumour cells grow, and the way in which the drugs affect this growth.

After cell division the daughter cells enter a period of growth, G_1, which lasts for different lengths of time in different tissues. This is followed by a period of DNA synthesis, **S**, in which the amount of chromosomal material is doubled, then a postsynthetic, or premitotic, phase, G_2, then finally by mitotic cell division, **M**. As an alternative to re-entering the cycle, the products of cell division may enter a kinetically-dormant, nonproliferative stage, G_0, although it is not exactly clear what recruits such 'resting' cells back into the cell cycle.

The rate of cell division varies for different tumours; the doubling time for Burkitt's lymphoma and acute lymphoblastic leukaemia is less than 5 days, whereas the mean doubling time for seminoma is about 20 days, that for small-cell lung cancer about 50 days, and those for colon cancer and advanced breast cancer about 100 and 150 days respectively. The range of reported doubling times may also vary widely for a particular tumour type. Most common cancers increase very slowly in size in comparison with sensitive normal tissues, including those from which they derive, and the rate may decrease further in large tumours. This difference allows normal cells to recover more quickly than malignant ones from chemotherapy, and is the rationale behind cyclic dosage schedules. The lethal body tumour burden is reached when the tumour cell mass approaches or exceeds 1×10^{12} cells, equivalent to about 1 kg of tissue, and representing about 40 doublings.

Cell killing by cytotoxic agents is generally a first order process, so a given dose or course of antineoplastic kills a fixed percentage of tumour cells rather than a fixed number. Thus a drug that killed 99% of tumour cells would leave behind 10^{10} cells from a tumour containing 10^{12} cells, but only 10^2 cells from one containing 10^4, reinforcing the importance of treating malignant neoplasms as early as possible.

Cytotoxic drugs act to damage the reproductive integrity of cells. Some are active at a particular stage of the cell cycle. The antimetabolites interfere with DNA synthesis, as does hydroxycarbamide, and are thus active against cells in S phase, while the vinca alkaloids inhibit microtubular function and act on cells in phase M. Other drugs such as the alkylating agents, the anthracyclines, and cisplatin are not phase-specific, but since their actions are dependent at least in part on damaging DNA they are more effective against proliferating cells, particularly in S phase. It is now thought that many antineoplastics exert their ultimate effect by inducing cellular apoptosis (programmed cell death). Some drugs, such as bleomycin or vinblastine also have the property of arresting the cycle in a particular phase, and attempts have been made to synchronise tumour cell division in this way, to maximise the number of cells in a sensitive phase when a particular drug is used. However, in practice this approach has been less successful than early experimental results suggested.

Some drugs used in the treatment of neoplasms do not attack the tumour cells directly but are given in order to increase cell vulnerability to other modalities: these include radiosensitisers (which have proved of only limited benefit to date), and photosensitisers such as porfimer sodium, used in photodynamic therapy (PDT).

Apart from attacking cell division, increased understanding of the molecular biology of tumour cells has begun to open the possibility of other approaches to the treatment of malignant neoplasms. Some monoclonal antibodies are designed to bind to specific cell-surface proteins or receptors, enabling the immune system to recognise and attack tumour cells (targeted therapy); anti-tumour vaccines have also been developed. Control of tumour growth through inhibition of angiogenesis is also being used. Other areas of investigation include inducing tumour cells to differentiate into non-malignant forms, manipulation of cellular apoptosis and signal transduction, inhibiting the expression of abnormal growth factors, telomerases and other oncogene products (including the use of ribozymes or of 'antisense' compounds which inhibit oncogenic messenger RNA), and prevention or inhibition of metastasis. Gene therapy (p. 2511.2) is another form of treatment under consideration.

Resistance

Resistance to antineoplastics is one of the greatest limitations to the use of chemotherapy in malignant disease. Resistance may be intrinsic to the tumour or may be acquired during chemotherapy, which effectively acts to select resistant cells from a heterogeneous population; the latter is one reason that relapses, or malignancies in heavily-pretreated patients, may be particularly difficult to treat.

The mechanisms of resistance in cancer cells are complex and imperfectly understood, but appear to include:

- hypoxia and imperfect drug penetration in the centre of large, solid tumours
- the small proportion of cells actively dividing and thus vulnerable to antineoplastics (particularly in slow-growing tumours)
- decreased cellular uptake or increased efflux of antineoplastic
- increased metabolic breakdown or decreased activation of antineoplastic
- increased expression of target enzymes
- metabolism via alternative biochemical pathways to those blocked by the antineoplastic
- more efficient repair of damaged DNA
- possibly the expression of genes which inhibit drug-induced apoptosis.

Several of these mechanisms may be in operation at one time. Much interest has been expressed in the potential use of drugs which can modulate or inhibit mechanisms of resistance, and in particular in compounds such as valspodar, verapamil, quinidine, and ciclosporin, which have the ability to block the action of P-glycoprotein, a membrane glycoprotein which acts as an efflux pump for a range of cytotoxic substances and which is one of a group of so-called ATP-binding cassette (ABC) drug transporters responsible for the multidrug resistant (MDR) phenotype. However, for sustained benefit it seems likely that several drugs would be required, each to overcome a different mechanism of resistance, and it would be necessary to ensure that toxicity of antineoplastics to normal cells was not also enhanced.

If the emergence of heritable resistant phenotypes is a natural part of tumour-cell biology (the Goldie-Coldman hypothesis) it implies that the larger and older the tumour, the more likely is resistance to occur. This would confirm the benefits of surgery and radiotherapy to shrink the primary tumour, and of starting chemotherapy as soon as possible after (a preferably early) diagnosis.

Antiresistance agents. Some drugs have been reported to partially abolish multidrug resistance to antineoplastics *in vitro*.[1,2] These include:

- verapamil, its enantiomers and analogues such as Ro-11-2933
- other calcium-channel blockers including prenylamine, diltiazem, nifedipine analogues such as nicardipine and bepridil
- various phenothiazines and thioxanthenes including trifluoperazine and the *trans*-isomer of flupentixol
- structural analogues of the anthracyclines and vinca alkaloids
- progesterone and other steroid hormones, as well as, to some extent, anti-oestrogens such as tamoxifen
- ciclosporin and various of its nonimmunosuppressive analogues (such as valspodar)
- miscellaneous drugs including amiodarone, quinidine, propranolol, reserpine, yohimbine, dipyridamole, erythromycin, cefoperazone, and ceftriaxone

However, despite reported effects on resistance *in vitro* clinical results may be less impressive: studies in which verapamil was added to therapy for small cell lung cancer[3] or multiple myeloma[4] failed to show any benefit, and second-generation P-glycoprotein inhibitors such as valspodar have unpredictable pharmacokinetic interactions with cytotoxics.[5] Nevertheless, there is ongoing development of inhibitors of P-glycoprotein and other ATP-binding cassette drug transporters,[6] and drugs such as tariquidar are undergoing clinical studies.[5] It has been suggested that tumour growth may rely on a malignant equivalent of stem cells, with innate multidrug resistance, and that this may make overcoming resistance without damaging normal stem cells particularly difficult.[7]

Abiraterone Acetate (BANM, USAN, rINNM)

Abirateron-azetat; Abiratérone, Acétate d'; Abirateroni Acetas; Acetato de abiraterona; CB-7630; Абиратерона Ацетат.

17-(Pyridin-3-yl)androsta-5,16-dien-3β-yl acetate.

$C_{26}H_{33}NO_2$=391.6

CAS — 154229-19-3 (abiraterone); 154229-18-2 (abiraterone acetate).

UNII — EMSOCB9YJ6.

Uses and Administration

Abiraterone acetate suppresses testosterone production by inhibiting the enzyme CYP17, which plays a key role in sex hormone synthesis, and is given orally with prednisone or prednisolone for the treatment of metastatic castration-resistant prostate cancer (p. 712.3). It is used in patients given previous docetaxel-based chemotherapy, and in those where androgen deprivation therapy has failed but chemotherapy is not yet indicated. Medical castration therapy with a gonadorelin (LHRH) analogue should be continued. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

The recommended dose is 1 g daily as a single dose, plus prednisone or prednisolone 5 mg twice daily (or 10 mg daily). Abiraterone should be taken on an empty stomach, at least 2 hours after and one hour before any food. For doses in patients who develop hepatotoxicity or with pre-existing hepatic impairment, see below.

Administration in hepatic impairment. No dose adjustment of abiraterone is necessary for patients with pre-existing mild hepatic impairment (Child-Pugh class A). In patients with baseline moderate hepatic impairment (Child-Pugh class B), US licensed product information recommends that the oral dose of abiraterone acetate be reduced to 250 mg daily. Use in patients with severe hepatic impairment (Child-Pugh class C) should be avoided since data are lacking.

For patients who develop increases in liver enzymes above 5 times the upper limit of normal (ULN) or total bilirubin >3 times ULN during treatment, US licensed product information states that therapy should be interrupted, and only restarted (at a reduced dose of 750 mg daily) once these values have fallen to acceptable levels (baseline or no more than half the increased values above). If hepatotoxicity recurs at the lower dose, a dose of 500 mg daily is recommended once values have fallen to acceptable levels, but if it recurs again, treatment should be stopped.

UK licensed product information states that, for patients who develop increases in liver enzymes above 5 times the ULN, therapy should be stopped, and advocates restarting at 500 mg daily once values return to baseline levels; if hepatotoxicity recurs at this reduced dose, treatment should be stopped. If patients develop increases in enzymes 20 times the ULN at any time while on therapy, abiraterone should be stopped permanently and patients should not be re-treated.

Adverse Effects, Treatment, and Precautions

Abiraterone acetate inhibits the enzyme CYP17, which can result in mineralocorticoid excess, very often leading to hypertension, hypokalaemia, and fluid retention or oedema; patients should be monitored at least monthly for these effects, and treated appropriately. Use with a glucocorticoid can reduce the incidence and severity of these adverse effects. However, adrenocortical insufficiency has been reported in those treated with abiraterone acetate plus prednisone or prednisolone, and patients should be monitored for manifestations of this, particularly after withdrawal from the corticosteroid.

Caution is needed when treating patients with heart failure, recent myocardial infarction, ventricular arrhythmia, or any underlying medical condition likely to be adversely affected by mineralocorticoid effects. Cardiac disorders are common with abiraterone acetate, and include cardiac failure, chest pain, angina pectoris, arrhythmias, atrial fibrillation, and tachycardia.

Hepatotoxicity can occur, and treatment may need to be stopped, or the dose adjusted (see Administration in Hepatic Impairment, above). Serum transaminases and bilirubin levels should be measured before starting treatment, then every two weeks for the first three months, and monthly thereafter.

Joint swelling or discomfort, muscle discomfort, hot flushes, dyspepsia, diarrhoea, cough, urinary-tract infection, urinary frequency, nocturia, and upper respiratory-tract infection are common, as is hypertriglyceridaemia.

Interactions

Abiraterone inhibits the cytochrome P450 isoenzyme CYP2D6; caution is advised when abiraterone acetate is used with drugs activated or metabolised by CYP2D6, especially those with a narrow therapeutic index. *In-vitro studies have shown that abiraterone is also an inhibitor of CYP2C8.*

Abiraterone is metabolised by the cytochrome P450 isoenzyme CYP3A4. Strong inhibitors or inducers of CYP3A4 should be avoided, or used with caution, during treatment with abiraterone acetate.

Pharmacokinetics

Abiraterone acetate is hydrolysed to abiraterone, which is active. Peak plasma concentrations of abiraterone occur about 2 hours after an oral dose of abiraterone acetate. Systemic exposure to abiraterone is increased when abiraterone acetate is given with food. Abiraterone is over 99% bound to plasma proteins. Abiraterone is metabolised via sulfation, hydroxylation, and oxidation, mainly in the liver. The two main metabolites are abiraterone sulfate and *N*-oxide abiraterone sulfate, which are inactive; these are formed by the enzymes SULT2A1, and cytochrome P450 isoenzyme CYP3A4 and SULT2A1, respectively. The mean terminal plasma half-life of abiraterone is reported to be about 15 hours in healthy subjects, and about 12 hours in patients with metastatic castration-resistant prostate cancer. About 88% of a dose is excreted in the faeces, of which about 55% is unchanged abiraterone acetate and about 22% is abiraterone; about 5% of a dose is excreted in the urine.

ATC — L01DB04.

ATC Vet — QL01DB04.

UNII — 501948RI66.

Pharmacopoeias. In *Jpn*.

Profile

Aclarubicin is an anthracycline antibiotic with actions similar to those of other anthracyclines such as doxorubicin (p. 782.3), although it inhibits RNA synthesis more strongly than DNA synthesis. It has been given by intravenous infusion as the hydrochloride in the treatment of malignant blood disorders, such as acute myeloid leukaemia. Alopecia and cardiotoxicity may be less pronounced than with doxorubicin, and extravasation of aclarubicin causes less local tissue inflammation.

Stability. In a study of the stability of anthracycline antineoplastic agents in 4 infusion fluids—glucose 5%, sodium chloride 0.9%, lactated Ringer's injection, and a commercial infusion fluid—stability appeared to be partly related to pH; aclarubicin was most stable in sodium chloride injection, with a pH of 6.2, and any increase or decrease in pH appeared to affect stability adversely.[1]

1. Poochikian GK, *et al.* Stability of anthracycline antitumor agents in four infusion fluids. *Am J Hosp Pharm* 1981; 38: 483–6.

Adverse effects. An early review[1] noted that a strikingly high incidence of ECG changes had been seen with aclarubicin, but that although acute cardiotoxicity occurred, the chronic cardiomyopathy classically associated with the anthracyclines (see p. 784.1) appeared to be rare. Alopecia was also rare, although gastrointestinal disturbances and mucositis were as common or more common than with doxorubicin.

1. Warrell RP. Adacinomycin A: clinical development of a novel anthracycline antibiotic in the haematological cancers. *Drugs Exp Clin Res* 1986; 12: 275–82.

Uses. An early review of studies in patients with relapsed acute myeloid leukaemia confirmed the activity of aclarubicin, with reported complete remission rates of the order of 12 to 24%.[1] Doses varied from 10 to 30 mg/m² daily to higher doses of 75 to 120 mg/m² for 2 to 4 days; in general a total dose of about 300 mg/m² appeared to be necessary to induce remission. Less information was available concerning activity in acute lymphoblastic leukaemia, but response rates were lower than those in acute myeloid leukaemia. Results in the malignant lymphomas were generally disappointing.

Longer-term follow-up has confirmed that remission rates and survival are similar for induction regimens in acute myeloid leukaemia using either aclarubicin or daunorubicin.[2,3] A regimen of aclarubicin with low-dose cytarabine and granulocyte colony-stimulating factor (CAG) has been used, including in elderly patients and those with refractory disease.[4-6]

Afatinib *(USAN, rINN)*

Afatinibum; BIBW-2992; Афатиниб.
(2*E*)-*N*-[4-(3-Chloro-4-fluoroanilino)-7-[[(3*S*)-oxolan-3-yl]oxy]quinazolin-6-yl]-4-(dimethylamino)but-2-enamide.
$C_{24}H_{25}ClFN_5O_3$=485.9
CAS — 850140-72-6.
ATC — L01XE13.
ATC Vet — QL01XE13.
UNII — 41UD74L59M.

NOTE. The name Tomtovok has been used as a trade mark for afatinib.

Afatinib Maleate *(rINNM)*

Afatinib Dimaleate (USAN); Afatinib, Maléate de; Afatinibi Maleas; BIBW-2992 MA2; Maleato de afatinib; Афатиниба Малеат.
$C_{24}H_{25}ClFN_5O_3.2C_4H_4O_4$=718.1
CAS — 850140-73-7.
UNII — V1T5K7RZ0B.

Uses and Administration

Afatinib is a tyrosine kinase inhibitor directed against the epidermal growth factor receptor (EGFR) family; it is used in the treatment of metastatic non-small cell lung cancer (p. 711.1) that has EGFR exon 19 deletions or exon 21 (L858R) substitutions. It is given as the maleate but doses are expressed in terms of the base; 59.12 mg of afatinib maleate is equivalent to about 40 mg of afatinib. A usual oral dose of 40 mg once daily is taken on an empty stomach. A missed dose should not be taken within 12 hours of the next dose. Treatment may need to be modified if toxicity occurs, see Administration in Subsequent Cycles, below. Afatinib therapy is continued until disease progression or unacceptable toxicity occurs. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

If afatinib is poorly tolerated when given with a P-glycoprotein inhibitor, the daily dose of afatinib should be reduced by 10 mg; afatinib may be increased back to the previous dose on stopping treatment with the inhibitor. If chronic treatment with a P-glycoprotein inducer is required, the daily dose of afatinib should be increased by 10 mg as tolerated; afatinib should be decreased back to the previous dose 2 to 3 days after stopping the inducer.

Afatinib is also under investigation in various other malignancies.

References.
1. Chen X, *et al.* Clinical perspective of afatinib in non-small cell lung cancer. *Lung Cancer* 2013; 81: 155–61.
2. Nelson V, *et al.* Afatinib: emerging next-generation tyrosine kinase inhibitor for NSCLC. *Onco Targets Ther* 2013; 6: 135–43.

Administration in subsequent cycles. Treatment with afatinib may need to be modified for toxicity. Doses should be withheld if any of the following adverse effects occur:
- grade 3 or worse adverse effects
- grade 2 or worse diarrhoea that persists for more than 2 consecutive days despite anti-diarrhoeal medication
- grade 2 cutaneous reactions that are intolerable or prolonged (lasting more than 7 days)
- grade 2 or worse renal dysfunction

When the adverse effect has resolved, returned to baseline, or improved to grade 1, afatinib can be restarted at a reduced oral dose of 10 mg less than that at which the effect occurred. Afatinib should be permanently stopped if severe adverse effects occur at a dose of 20 mg daily, or if any of the following reactions occur:
- life-threatening bullous, blistering, or exfoliative skin lesions
- interstitial lung disease
- severe drug-induced hepatic impairment
- persistent ulcerative keratitis
- symptomatic left ventricular dysfunction

Adverse Effects and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Commonly reported adverse effects with afatinib are diarrhoea, stomatitis, cheilitis, rash, pruritus, dry skin, conjunctivitis, epistaxis, rhinorrhoea, paronychia, cystitis, decreased appetite and body weight, and pyrexia. Skin reactions can be severe and include bullous, blistering, or exfoliating lesions. Pulmonary toxicity has been reported including interstitial lung disease. Hepatotoxicity with increased liver enzyme values, hypokalaemia, and ventricular dysfunction have also occurred. Treatment may need to be stopped or modified for severe toxicity, see Administration in Subsequent Cycles, above.

Based on its mechanism of action and data from *animal* studies, afatinib is not recommended during pregnancy. Women of reproductive potential should use effective contraception during and for at least 2 weeks after treatment.

References.
1. Lacouture ME, *et al.* Dermatologic adverse events associated with afatinib: an oral ErbB family blocker. *Expert Rev Anticancer Ther* 2013; 13: 721–8.

Interactions

Afatinib is a substrate of P-glycoprotein and use with P-glycoprotein inhibitors or inducers could affect exposure to afatinib; dose adjustments may be required, see Uses and Administration, above. *In vitro* data suggest that afatinib is also an inhibitor of P-glycoprotein, and a substrate and an inhibitor of the breast cancer resistance protein (BCRP) transporter.

Pharmacokinetics

Peak concentrations of afatinib occur 2 to 5 hours after oral dosing. Exposure is reduced when afatinib is taken with a high-fat meal. It is 95% bound to plasma proteins. Afatinib is excreted, mainly as unchanged drug, in the faeces (85%) with a small amount in the urine (4%). The elimination half-life is 37 hours after repeated dosing, and steady state concentrations occur within 8 days.

Exposure to afatinib is increased in patients with renal impairment.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *USA*: Gilotrif.

Aflibercept *(USAN, rINN)*

Afliberceptum; AVE-0005; VEGF Trap; VEGF Trap-Eye; VEGF $Trap_{R1R2}$; Афлиберцепт.
Des-432-lysine-[human vascular endothelial growth factor receptor 1-(103-204)-peptide (containing Ig-like C2-type 2 domain) fusion protein with human vascular endothelial growth factor receptor 2-(206-308)-peptide (containing Ig-like C2-type 3 domain fragment) fusion protein with human immunoglobulin G1-(227 C-terminal residues)-peptide (Fc fragment)], (211-211′:214-214′)-bisdisulfide dimer.
CAS — 862111-32-8.
ATC — S01LA05.
ATC Vet — QS01LA05.
UNII — 15C2VL427D.

NOTE. There are significant differences in the processing and formulation of preparations containing the active ingredient aflibercept and consequently they are not therapeutically interchangeable.

To emphasise this in the USA, preparations are available as:
- *Eylea* (*Regeneron, USA*): described as containing aflibercept
- *Zaltrap* (*Regeneron, USA*): described as containing ziv-aflibercept

However, in Europe and other countries the preparations *Eylea* and *Zaltrap* are both described as containing aflibercept, and the name ziv-aflibercept is not used.

Uses and Administration

Aflibercept is a recombinant human fusion protein that acts as a soluble decoy receptor and binds to vascular endothelial growth factor-A (VEGF-A), factor-B (VEGF-B), and placental growth factor (PlGF); this inhibits the activation of receptor tyrosine kinases, VEGFR-1 and VEGFR-2. The inhibition of these growth factors reduces neovascularisation and angiogenesis.

Aflibercept (*Eylea*) is used to treat neovascular (wet) age-related macular degeneration (p. 880.2). The initial recommended dose is 2 mg by intravitreal injection once each month for 3 doses, followed by 2 mg every 2 months. After 12 months of treatment, doses may be given less frequently, according to response. Aflibercept is also used for the treatment of macular oedema following central retinal vein occlusion, in a dose of 2 mg by intravitreal injection once every month. When visual and anatomical measures are stable for 3 monthly assessments, the interval between doses may be gradually increased and treatment stopped. Monitoring should continue and therapy may be restarted if necessary. However, if there is no improvement from the first 3 doses, treatment should be stopped.

Aflibercept, or as ziv-aflibercept in the USA, (*Zaltrap*) is used with fluorouracil, folinic acid, and irinotecan in the treatment of metastatic colorectal cancer (p. 706.3) that is resistant to or has progressed after an oxaliplatin-containing regimen. A dose of aflibercept 4 mg/kg is given by intravenous infusion over 1 hour every 2 weeks, and it should be given before any other component of the regimen on that day of treatment. The dose should be diluted to a final concentration of 0.6 to 8 mg/mL in sodium chloride 0.9% or glucose 5% and infused through a 0.2 micrometre polyethersulfone filter; other filters made of polyvinylidene fluoride or nylon should not be used. Doses may need to be reduced or withheld if severe hypertension, proteinuria, or neutropenia develop (see Administration in Subsequent Cycles, below). Therapy should continue until there is disease progression or unacceptable toxicity.

8. Evoy KE, Abel SR. Aflibercept: newly approved for the treatment of macular edema following central retinal vein occlusion. *Ann Pharmacother* 2013; 47: 819–27.

Administration in subsequent cycles. In the treatment of metastatic colorectal cancer, aflibercept, or as ziv-aflibercept in the USA, (*Zaltrap*) should be withheld in patients who develop recurrent or severe hypertension. Treatment may be restarted when the blood pressure is under control, at a permanently reduced dose of 2 mg/kg by intravenous infusion every 2 weeks. Aflibercept should be withheld in patients who develop proteinuria, until it is less than 2 g per 24 hours. If the proteinuria is recurrent, treatment should be restarted at a permanently lower dose of 2 mg/kg by intravenous infusion every 2 weeks. Dose of aflibercept should also be delayed in patients who have a neutrophil count below 1500 cells/mm^3.

Adverse Effects, Treatment, and Precautions

The most common adverse effects of aflibercept **intravitreal injection** are conjunctival haemorrhage, eye pain, cataract, vitreous detachment, vitreous floaters, and increased intra-ocular pressure. Other adverse effects include endophthalmitis, retinal detachment, and retinal tear. Hypersensitivity reactions have been reported. There is a potential risk of thromboembolic events such as stroke, myocardial infarction, or vascular death following intravitreal use of vascular endothelial growth factor (VEGF) inhibitors.

Common adverse effects that occur in patients given **intravenous** aflibercept, or as ziv-aflibercept in the USA, include bleeding, hypertension, proteinuria, leucopenia, neutropenia, thrombocytopenia, decreases in body-weight and appetite, diarrhoea, abdominal pain, stomatitis, dysphonia, increases in liver function tests and serum-creatinine, fatigue, and headache. Arterial and venous thromboembolic events and severe hypersensitivity reactions have occurred. Reversible posterior leukoencephalopathy syndrome has been reported in patients given aflibercept.

Severe and sometimes fatal haemorrhage and gastrointestinal perforation have been associated with the use of intravenous aflibercept. Fistula formation can occur and wound healing may be compromised. Aflibercept should be stopped at least 4 weeks before elective surgery. After major surgery it should not be restarted for at least 4 weeks and not

until the surgical wound is fully healed; after minor surgery it may be restarted when the wound is fully healed.

Severe hypertension, including cases of hypertensive crisis, has been reported. Blood pressure should be monitored every 2 weeks and antihypertensive therapy started when necessary. Aflibercept may need to be withheld and the dose reduced after severe or recurrent hypertension is under control; it should be stopped in patients with hypertensive crisis or hypertensive encephalopathy. Patients should also be monitored for proteinuria during aflibercept therapy, which may need to be withheld or the dose reduced; it should be stopped in those who develop nephrotic syndrome or thrombotic microangiopathy.

A complete blood count with differential count should be made before each dose of intravenous aflibercept; treatment should be delayed if the neutrophil count is below 1500 cells/mm³.

Pharmacokinetics

Systemic absorption occurs after intravitreal administration of aflibercept; peak plasma concentrations are low and occur within 3 days, and free plasma-aflibercept concentrations are undetectable 2 weeks following administration. The terminal half-life of free aflibercept in plasma is about 6 days following intravenous administration of doses of 2 to 4 mg/kg.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Fr.*: Eylea; *Jpn*: Eylea; *Neth.*: Zaltrap; *Switz.*: Eylea; Zaltrap; *UK*: Eylea; Zaltrap; *USA*: Eylea; Zaltrap.

Alemtuzumab *(BAN, rINN)*

Alemtutsumabi; Alemtuzumabum; Campath-1; Campath-1H; Алемтузумаб.

Immunoglobulin G 1 (human-rat monoclonal CAMPATH-1H γ1-chain antihuman antigen CD52), disulfide with human-rat monoclonal CAMPATH-1H light chain, dimer.

CAS — 216503-57-0.
ATC — L01XC04.
ATC Vet — QL01XC04.
UNII — 3A189DH42V.

NOTE. The name FluCam has been used for a regimen of alemtuzumab with fludarabine. Distinguish from Flucam, which is a proprietary name for ampiroxicam (p. 21.1).

Uses and Administration

Alemtuzumab is a humanised derivative of campath-1G, a rat monoclonal antibody to the CD52 antigen found on lymphocytes. It is used in the treatment of B-cell chronic lymphocytic leukaemia (p. 693.3) and is also licensed in the EU (under the trade name of *Lemtrada*) for use in relapsing-remitting multiple sclerosis (below).

For the treatment of **chronic lymphocytic leukaemia** the dose of alemtuzumab must be increased gradually to avoid infusion-related reactions (see Adverse Effects, below). Alemtuzumab should be diluted in 100 mL sodium chloride 0.9% or glucose 5%. The initial dose is 3 mg daily, given as an intravenous infusion over 2 hours (it may be increased up to 8 hours in some patients, see Adverse Effects, below). This dose should be repeated daily until it is tolerated; the dose should then be increased to 10 mg daily. When this dose is tolerated, the maintenance dose of 30 mg can be started; this dose escalation usually takes 3 to 7 days. The maintenance dose of 30 mg is given three times weekly on alternate days. The total duration of therapy, including dose escalation, is 12 weeks. Doses should be modified according to haematological toxicity (see Administration in Subsequent Cycles, below).

For the treatment of **multiple sclerosis** alemtuzumab has been given by intravenous infusion over 4 hours for 2 treatment courses, as follows:

- initial treatment course: 12 mg daily for 5 consecutive days, to a total dose of 60 mg
- second treatment course given 12 months after the initial course: 12 mg daily for 3 consecutive days, to a total dose of 36 mg

Missed doses within a treatment course should not be given on the same day as a scheduled dose. Patients should be pretreated with a corticosteroid on each of the first 3 days of any course. Oral prophylaxis with 200 mg twice daily of aciclovir (or similar) for herpes infection should also be started on the first day of each course and continued for a minimum of 1 month following treatment.

Alemtuzumab is under investigation for induction therapy in transplantation (see Organ and Tissue Transplantation, p. 1936.2, *et seq*).

Administration. Subcutaneous use of alemtuzumab has been investigated as a means of reducing adverse infusion reactions associated with intravenous dosage. Studies have found it to be safe and effective.[1,2] Similar blood concentrations are achieved to those after intravenous use, although accumulation in the blood took longer to achieve with subcutaneous use, and higher cumulative doses were required.[3] A dose of 30 mg subcutaneously three times weekly has been widely used; given for 4 to 12 weeks it has been shown to be as effective and safe as intravenous alemtuzumab in patients with fludarabine-refractory disease, and it has been suggested that the convenience of subcutaneous injection, which can be given on an outpatient basis, makes it the preferred route for this indication.[4] Although treatment has normally been started with lower doses and gradually increased (e.g. 3 mg on day 1, 10 mg on day 2, 30 mg on day 3, and then 30 mg three times weekly), use with the higher dose from the outset has been investigated.[5] Prolonged treatment with subcutaneous low-dose alemtuzumab (10 mg three times weekly for 18 weeks) has also been tried and was reported to be as effective as intravenous infusion in patients with chronic lymphocytic leukaemia and a poor prognosis.[6]

Administration in subsequent cycles. The dose of alemtuzumab may be modified from the usual intravenous maintenance dose (see Uses and Administration, above) for neutropenia and thrombocytopenia in those being treated for chronic lymphocytic leukaemia as follows:

In patients with higher baseline values whose absolute neutrophil count (ANC) falls to < 250 cells/mm³ and/or whose platelet count falls to $\leq 25\,000$ cells/mm³:

- for first occurrence: withhold alemtuzumab. Resume at 30 mg when ANC ≥ 500 cells/mm³ and platelet count $\geq 50\,000$ cells/mm³
- for second occurrence: withhold alemtuzumab. Resume at 10 mg when ANC ≥ 500 cells/mm³ and platelet count $\geq 50\,000$ cells/mm³
- for third occurrence: stop alemtuzumab

In patients who are started on alemtuzumab with a baseline ANC already ≤ 250 cells/mm³ and/or a baseline platelet count $\leq 25\,000$ cells/mm³, and who have a $\geq 50\%$ decrease from baseline:

- for first occurrence: withhold alemtuzumab. Resume at 30 mg upon return to baseline value
- for second occurrence: withhold alemtuzumab. Resume at 10 mg upon return to baseline value
- for third occurrence: stop alemtuzumab

If alemtuzumab is withheld, and the time to recovery is ≥ 7 days, then alemtuzumab should be restarted at the usual initial dose and increased gradually (see Uses and Administration, above).

Multiple sclerosis. Alemtuzumab has been licensed in the EU for the treatment of multiple sclerosis (p. 996.3). However, an FDA committee has raised concerns about its adverse effects such as auto-immune cytopenias and autoimmune thyroid disease which can be fatal and may outweigh its benefits. For further information on the adverse effects of alemtuzumab, see under Adverse Effects, Treatment, and Precautions, below.

It has been proposed that the secondary progressive phase of the disease might be due to post-inflammatory neurodegeneration and that immunotherapy would influence long-term disability only if given early in the disease course. A phase 2 randomised study assigned treatment-naive patients with early, relapsing-remitting multiple sclerosis to either alemtuzumab or interferon beta. Alemtuzumab (at a dose of either 12 mg daily or 24 mg daily) was given by intravenous infusion on 5 consecutive days during the first month, and on 3 consecutive days at months 12 and 24; interferon beta-1a at a dose of 44 micrograms was given subcutaneously 3 times weekly after dose escalation. All patients received intravenous methylprednisolone at the time of infusion. There were no significant differences between the groups receiving either dose of alemtuzumab on any outcome measure or adverse event. However, 6 cases of immune thrombocytopenic purpura occurred with alemtuzumab treatment, including one fatality, prompting suspension of therapy with alemtuzumab. Nonetheless, compared with interferon beta, alemtuzumab significantly improved mean disability scores and reduced the rate of relapse; efficacy was maintained over 36 months, even though some 70% of alemtuzumab-treated patients were not given the planned third cycle due to safety concerns. Alemtuzumab also increased brain volume on magnetic resonance imaging, whereas brain atrophy advanced among patients receiving interferon beta. The authors of the study noted that, while alemtuzumab appears to be more effective than interferon beta when given in the earliest stages of multiple sclerosis, there is a dilemma as to whether to expose young adults with little disability to the potentially serious adverse effects of alemtuzumab.[1]

Extended follow-up of patients in this study group, for up to 5 years from the start of therapy, found that alemtuzumab remained significantly more effective than interferon beta-1a.[2] The superiority of alemtuzumab compared with interferon beta-1a was further confirmed in a phase 3 study of previously untreated patients with early, relapsing-remitting multiple sclerosis[3] and also in those with at least one relapse after disease-modifying therapy with either interferon beta or glatiramer.[4]

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Alemtuzumab commonly causes bone marrow depression, which may be severe and prolonged; fatalities have occurred. Auto-immune anaemia and auto-immune thrombocytopenia and haemolytic anaemia have been reported less commonly; however, fatalities have been reported. Single doses greater than 30 mg, or cumulative weekly doses greater than 90 mg should not be used, because of the increased incidence of pancytopenia. Complete blood and platelet counts should be measured weekly during alemtuzumab therapy, and more frequently if anaemia, neutropenia, or thrombocytopenia occur. Treatment should be interrupted if severe myelosuppression or evidence of haematological toxicity are seen and stopped permanently if auto-immune anaemia or auto-immune thrombocytopenia develops. Lymphopenia may be profound with alemtuzumab therapy, and opportunistic infections are common, and occasionally life-threatening. Antimicrobial prophylaxis is recommended from the start of therapy until after completion; if serious infection occurs, treatment should be interrupted. Recovery of lymphocyte counts may take 6 months or longer after stopping treatment.

Alemtuzumab commonly causes an acute cytokine release syndrome. The reaction usually includes rigors, fever, nausea and vomiting, hypotension, rash, urticaria, pruritus, shortness of breath, headache, and diarrhoea. Rarer, more serious reactions may include bronchospasm, syncope, pulmonary infiltrates, acute respiratory distress syndrome, respiratory arrest, myocardial infarction, and cardiac arrest. Cardiac adverse effects have been fatal in

some instances. These infusion-related reactions are most common at the start of therapy: the dose must be increased gradually when beginning treatment, or if it is interrupted for 7 days or more. Pre-medication with an oral or intravenous corticosteroid, oral antihistamine, and analgesic should also be used, particularly before the first dose, and with dose increases. If acute infusion reactions persist, the infusion time may be extended to 8 hours from the time of reconstitution.

Other adverse effects include fatigue, anorexia, asthenia, malaise, arthralgia, myalgia, bone pain, back pain, chest pain, hypertension, cyanosis, and bradycardia or tachycardia. Localised oedema, stomatitis, mucositis, and abdominal pain have been reported, as have dizziness, paraesthesia, tremor, and taste loss. Confusion, insomnia or somnolence, depression, or anxiety may occur. Electrolyte disturbances include hyponatraemia and hypocalcaemia. Coughing, haemoptysis, sinusitis, bronchitis, and pharyngitis have been reported.

Alemtuzumab is contra-indicated for patients with active systemic infection, or underlying immunodeficiency.

Auto-immune disorders. Aside from auto-immune cytopenias, alemtuzumab has been associated with the development of auto-immune thyroid disease in 20 to 30% of patients, occurring months to years after treatment.[1] Anti-glomerular basement membrane disease has also been reported after alemtuzumab,[2] as has Guillain-Barré syndrome.[3] It has been commented[2] that B-cell recovery tends to precede T-cell recovery after alemtuzumab treatment, and that the auto-immune diseases seen after therapy are mainly antibody-mediated, and respond to B-cell depletion.

1. Jones JL, *et al.* IL-21 drives secondary autoimmunity in patients with multiple sclerosis, following therapeutic lymphocyte depletion with alemtuzumab (Campath-1H). *J Clin Invest* 2009; **119**: 2052–61.

Effects on the lungs. Diffuse alveolar haemorrhage has been reported after a single dose of alemtuzumab was used during renal transplantation in a patient with X-linked Alport syndrome (an inherited disorder involving damage to the kidneys, haematuria, and hearing loss).[1]

1. Sachdeva A, Matuschak GM. Diffuse alveolar hemorrhage following alemtuzumab. *Chest* 2008; **133**: 1476–8.

Infection. Reactivation of hepatitis B,[1] hepatitis C,[2] and CMV[3] has been reported with the use of alemtuzumab. Patients who have been pretreated with purine analogues or those with advanced disease and not responding to alemtuzumab therapy appear to be at highest risk for infectious complications. Recommendations for screening and prophylaxis[4] and guidelines[5] and reviews[6] concerning management have been published. Six infection-related deaths have been reported[7] after previously untreated patients with B-cell chronic lymphocytic leukaemia were treated with fludarabine and rituximab, followed by alemtuzumab. These deaths may have resulted from a prolonged period of immunosuppression due to the sequencing of these drugs without sufficient recovery time. In the EU, alemtuzumab is licensed for use in patients for whom fludarabine combination chemotherapy is not appropriate.

Important safety information: six infection-related deaths reported after treatment with MabCampath(alemtuzumab) following Fludarabine+Rituximab induction in patients with B-Cell Chronic Lymphocytic Leukemia (CLL) (issued 11th February 2008). Available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON014104&RevisionSelectionMethod=Latest (accessed 12/05/08)

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies alemtuzumab as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

There are no formal interaction studies with alemtuzumab; however, it is recommended that it should not be given within 3 weeks of other chemotherapy drugs, and that patients should not receive live viral vaccines for at least 12 months after receiving alemtuzumab.

Pharmacokinetics

In patients with B-cell chronic lymphocytic leukaemia, distribution of alemtuzumab is mainly to the extracellular fluid and plasma. Over 12 weeks, clearance has been found to decrease with repeated dosing, with consequent accumulation in plasma, and the rate of elimination to approach zero-order kinetics. The half-life is reported to be 8 hours after a first dose of 30 mg, and 6 days after the last 30 mg dose. Steady-state concentrations are reached after about 6 weeks of therapy.

Ácido 9-*cis*-retinoico; AGN-192013; Alitretinoiini; Alitretinoína; Alitrétinoïne; Alitretinoinum; ALRT-1057; BAL-4079; 9-*cis*-Retinoic Acid; LG-100057; LGD-1057; NSC-659772; Алитретиноин.

(2*E*,4*E*,6*Z*,8*E*)-3,7-Dimethyl-9-(2,6,6-trimethyl-1-cyclohexen-1-yl)-2,4,6,8-nonatetraenoic acid.

$C_{20}H_{28}O_2$=300.4

CAS — 5300-03-8.

ATC — D11AH04; L01XX22.

ATC Vet — QD11AH04; QL01XX22.

UNII — 1UA8E65KDZ.

Uses and Administration

Alitretinoin is a retinoid related to isotretinoin (p. 1706.2). It is given orally for severe chronic hand eczema (p. 1684.1) that is unresponsive to treatment with potent topical corticosteroids. Patients with mainly hyperkeratotic eczema are more likely to respond to treatment with alitretinoin. It is also used topically, in the management of cutaneous lesions in patients with AIDS-related Kaposi's sarcoma (p. 718.1).

The recommended starting dose of oral alitretinoin in adults is 30 mg once daily, with reduction to 10 mg once daily if adverse effects occur. The usual dose range is from 10 to 30 mg once daily, taken with meals. Treatment may be continued for 12 to 24 weeks depending on response. In the event of relapse, further treatment courses may be considered.

Topical treatment with a 0.1% alitretinoin gel is applied directly to the lesions twice daily, increasing to up to 4 times daily if tolerated. Doses should be increased at intervals of at least 2 weeks. If local toxicity occurs, application frequency should be reduced, or treatment temporarily stopped, until the symptoms subside. EU licensed product information states that if no response is seen after 12 weeks, therapy should be stopped; however, US licensed product information states that some patients have required over 14 weeks to respond. Treatment may be continued as long as the patient responds.

Adverse Effects

Oral doses of alitretinoin may produce similar adverse effects to those of isotretinoin (see p. 1707.2). Decreases in concentrations of thyroid stimulating hormone and free T_4 are also often reported with alitretinoin, as are increases in platelets and increases in blood concentrations of creatine phosphokinase. Ankylosing spondylitis is uncommon.

Local skin toxicity may occur on topical application of alitretinoin, in particular erythema and oedema, and in some patients this may be dose-limiting. Pain, paraesthesia, rashes, pruritus, exfoliative dermatitis, and other skin disorders may also occur locally. Lymphadenopathy, phlebitis, cellulitis, and bacterial infections have been reported. Alitretinoin may have a weak photosensitising effect, and patients should minimise exposure of treated areas to sunlight or other ultraviolet light during therapy.

Precautions

When alitretinoin is given orally, the precautions described under isotretinoin (see p. 1709.2) including contra-indication of use in pregnancy and during breast feeding, should be adopted. Although absorption does not seem to occur to any great extent with topical use licensed product information also contra-indicates such use in pregnancy and in breast-feeding mothers. Oral alitretinoin is further contra-indicated in patients with severe renal impairment and uncontrolled hypothyroidism. Topical treatment with alitretinoin should not be used on lesions in close proximity to other skin disorders.

Interactions

The interactions described under isotretinoin (see p. 1710.1) also apply to oral alitretinoin. Alitretinoin is metabolised by the hepatic cytochrome P450 isoenzyme system, particularly CYP3A4. Use with CYP3A4 inhibitors such as ketoconazole increases the plasma concentration of alitretinoin and dose reduction may be required. Use of products containing diethyltoluamide is not recommended during topical alitretinoin therapy, as *animal* studies indicate an increase in diethyltoluamide toxicity with concurrent use.

Pharmacokinetics

After oral doses alitretinoin is variably absorbed from the gastrointestinal tract. When alitretinoin is taken with food, absorption becomes less variable and the systemic exposure is enhanced by a factor of 4. Alitretinoin is highly bound to plasma proteins. It undergoes metabolism by oxidation in the liver by the cytochrome P450 isoenzyme system into the major metabolite 4-oxo-alitretinoin. Alitretinoin and its metabolites are excreted mainly in the urine, with about 30% excreted in the faeces. The elimination half-life of unchanged alitretinoin is about 2 to 10 hours. Alitretinoin and 4-oxo-alitretinoin do not accumulate in the body.

Systemic absorption of topical alitretinoin is not considered to be extensive.

Pharmacopoeias. In *Chin.* and *US.*

USP 36: (Altretamine). A white crystalline powder. Insoluble in water; soluble in chloroform. Store in airtight containers.

Uses and Administration

Altretamine is an antineoplastic agent structurally similar to the alkylating agent tretamine (triethylenemelamine) although its mode of action may be different. It is given orally and is licensed for use as a single agent in the palliative treatment of ovarian carcinoma (p. 711.2). Altretamine has also been tried in lung cancer. ***Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.***

The usual dose as a single agent in ovarian cancer is 260 mg/m² daily in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle. Up to 12 cycles may be given. Therapy should be interrupted for at least 14 days, and subsequently restarted at a lower dose of 200 mg/m² daily, if the white cell count falls below 2000 cells/mm³ or the platelet count below 75 000 cells/mm³ or if neurotoxic or intolerable gastrointestinal symptoms occur. Lower doses are also used in combination regimens.

Reviews.

Adverse Effects, Treatment, and Precautions

For a general outline see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bone-marrow depression is usually moderate, manifesting as leucopenia, thrombocytopenia, and anaemia, and may require dosage reduction; blood counts should be monitored regularly. Nausea and vomiting are common and usually moderate although they may be dose-limiting. Prolonged or high-dose therapy may be associated with neurotoxicity, both peripheral (neuropathies) and central (ataxia, depression, confusion, drowsiness, and hallucinations); neurological examination should be performed regularly and treatment interrupted or the dose reduced as appropriate. Renal toxicity may also be dose-limiting. Other rare adverse effects include rashes, alopecia, and hepatotoxicity.

Handling. Altretamine is irritant; avoid contact with skin and mucous membranes.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies altretamine as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Pyridoxine appears to reduce the activity of altretamine.

Antidepressants. Severe and potentially life-threatening orthostatic hypotension developed in 3 patients who took *amitriptyline* or *imipramine* with altretamine and in a fourth patient who took *phenelzine* and altretamine.[1] One patient was able to tolerate the antineoplastic with *nortriptyline*.

1. Bruckner HW, Schleifer SJ. Orthostatic hypotension as a complication of hexamethylmelamine anddepressant interaction. *Cancer Treat Rep* 1983; 67: 516.

Pharmacokinetics

Altretamine is well absorbed from the gastrointestinal tract after oral doses, but is rapidly demethylated in the liver producing variation in plasma-altretamine concentrations. The principal metabolites are pentamethylmelamine and tetramethylmelamine, which are excreted in urine. The elimination half-life has been reported to be 4 to 10 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Austral.*: Hexalen†; *Canad.*: Hexalen; *Fr.*: Hexastat; *India*: Cantret; *Neth.*: Hexalen†; *Rus.*: Hexalen (Гексален); *Thai.*: Hexalen†; *USA*: Hexalen.

Pharmacopoeial Preparations
USP 36: Altretamine Capsules.

Alvocidib *(BAN, USAN, rINN)*

Alvocidibum; Avodenib; Flavopiridol; HL-275; HMR-1275; L86-8275; MDL-107826A; NSC-649890; Альвоцидиб.
(-)-*cis*-2-(2-Chlorophenyl)-5,7-dihydroxy-8-(3-hydroxy-1-methylpiperidin-4-yl)-4*H*-1-benzopyran-4-one.
$C_{21}H_{20}ClNO_5$=401.8
CAS — 146426-40-6.
UNII — 45AD6X575G.

Alvocidib Hydrochloride *(BANM, USAN, rINNM)*

Alvocidib, Chlorhydrate d'; Alvocidibi Hydrochloridum; Hidrocloruro de alvocidib; HL-275; HMR-1275; L-868275; MDL-107826A; NSC-649890; Альвоцидиба гидрохлорид.
(-)-*cis*-2-(2-Chlorophenyl)-5,7-dihydroxy-8-(3-hydroxy-1-methylpiperidin-4-yl)-4*H*-1-benzopyran-4-one hydrochloride.
$C_{21}H_{20}ClNO_5$,HCl=438.3
CAS — 131740-09-5.
UNII — D48MS3A6N9.

Profile

Alvocidib is an inhibitor of cyclin-dependent kinase that is under investigation as an antineoplastic for the treatment of chronic lymphocytic leukaemia.

Amatuximab *(USAN, rINN)*

Amatuximabum; MORAb-009; Аматуксимаб.
Immunoglobulin G1, anti-(mesothelin) (human-mouse monoclonal MORAb-009 heavy chain), disulfide with human-mouse monoclonal MORAb-009 κ-chain, dimer.
CAS — 931402-35-6.

Profile

Amatuximab is a humanised immunoglobulin G1 monoclonal antibody that targets the cell surface glycoprotein mesothelin which is overexpressed in several malignancies. It is under investigation in the treatment of mesothelioma.

Aminoglutethimide *(BAN, rINN)* ⊗

Aminoglutethimid; Aminoglutéthimide; Aminoglutethimidum; Aminoglutetimid; Aminoglutetimida; Aminoglutetimidas; Aminoglutetimidi; Aminoglutetymid; Aminoglutethimide; Ammlnoglutetimide; Ba-16038; Аминоглутетимид.
2-(4-Aminophenyl)-2-ethylglutarimide; 3-(4-Aminophenyl)-3-ethylpiperidine-2,6-dione.
$C_{13}H_{16}N_2O_2$=232.3
CAS — 125-84-8.
ATC — L02BG01.
ATC Vet — QL02BG01.
UNII — 0O54ZQ14I9.

Pharmacopoeias. In *Chin., Eur.* (see p. vii), and *US.*

Ph. Eur. 8: (Aminoglutethimide). A white or slightly yellow, crystalline powder. Practically insoluble in water; freely soluble in acetone; soluble in methyl alcohol.

USP 36: (Aminoglutethimide). A white or creamy-white, fine, crystalline powder. Very slightly soluble in water; readily soluble in most organic solvents. It forms water-soluble salts with strong acids. The pH of a 0.1% solution in dilute methyl alcohol (1 in 20) is between 6.2 and 7.3.

Uses and Administration

Aminoglutethimide is an analogue of glutethimide and was formerly used for its weak anticonvulsant properties. Aminoglutethimide blocks the production of adrenal steroids and acts as an aromatase inhibitor to block the conversion of androgens to oestrogens (the major source of oestrogens in women without ovarian function). It was used in the treatment of metastatic breast cancer (p. 702.1) in postmenopausal or oophorectomised women and as palliative treatment in men with advanced prostatic cancer (p. 712.3) but has largely been superseded by other drugs.

Aminoglutethimide has also been used in the treatment of Cushing's syndrome (p. 2559.1). Usual oral doses range from 1 to 2 g daily, in divided doses.

The *dextro*-isomer of aminoglutethimide, dexaminoglutethimide has been investigated.

Adverse Effects

The most frequent adverse effects reported with aminoglutethimide include drowsiness, lethargy, and rash (sometimes with fever); these generally diminish after the first 6 weeks of therapy. Dizziness and nausea occasionally occur. Leucopenia, thrombocytopenia, agranulocytosis, or severe pancytopenia have occurred rarely. Adrenal insufficiency may rarely occur, and there have been reports of other endocrine disturbances including hypothyroidism, and virilisation. Other rare effects include ataxia, headache, depression, gastrointestinal disturbances, hypercholesterolaemia, and orthostatic hypotension.

Overdosage may lead to CNS depression and impairment of consciousness, electrolyte disturbances, and respiratory depression.

Effects on the liver. Aminoglutethimide has been associated with reports of cholestatic jaundice, accompanied by rash[1,2] and fever,[2] and probably due to an idiosyncratic hypersensitivity reaction.[1] It has been suggested that liver function tests should be carried out in patients receiving aminoglutethimide who develop fever and eruptions.[2]

1. Gerber SB, Miller KB. Cholestatic jaundice and aminoglutethimide. *Ann Intern Med* 1982; 97: 138.
2. Perrault DJ, Domovitch E. Aminoglutethimide and cholestasis. *Ann Intern Med* 1984; 100: 160.

Effects on the lungs. Pulmonary infiltrates in a patient who developed progressive dyspnoea on starting therapy with aminoglutethimide were found to be due to diffuse alveolar damage and haemorrhage; thrombocytopenia was present but prothrombin and bleeding times were normal. The patient's gas exchange and chest radiographs improved on stopping aminoglutethimide and giving corticosteroids.[1] Blood and pulmonary eosinophilia, which resolved on stopping aminoglutethimide therapy, has also been reported.[2]

1. Rodman DM, *et al.* Aminoglutethimide, alveolar damage, and hemorrhage. *Ann Intern Med* 1986; 105: 633.
2. Bell SC, Anderson EG. Pulmonary eosinophilia associated with aminoglutethimide. *Aust N Z J Med* 1998; 28: 670–1.

Lupus. SLE occurred in a patient who received aminoglutethimide, and resolved when the drug was withdrawn.[1] In another report, however, a patient with a lupus-like syndrome had a reduction in disease activity when tamoxifen therapy was changed to aminoglutethimide.[2]

1. McCraken M, *et al.* Systemic lupus erythematosus induced by aminoglutethimide. *BMJ* 1980; 281: 1254.
2. Etherington J, *et al.* Effect of aminoglutethimide on the activity of a case of a connective tissue disorder with features of systemic lupus erythematosus. *Lupus* 1993; 2: 387.

Precautions

Aminoglutethimide inhibits adrenal steroid production so supplementary glucocorticoid therapy with hydrocortisone must normally be given, although supplementation may not be necessary in patients with Cushing's syndrome. Some patients also require a mineralocorticoid. It has been suggested that aminoglutethimide should be temporarily withdrawn in patients who undergo shock or trauma, or develop intercurrent infection.

Blood pressure, blood counts, and serum electrolytes should be regularly monitored during aminoglutethimide therapy and periodic monitoring of liver and thyroid function is recommended.

Aminoglutethimide should not be given during pregnancy as pseudohermaphroditism may occur in the fetus.

Aminoglutethimide frequently causes drowsiness: patients so affected should not drive or operate machinery.

Interactions

The rate of metabolism of some drugs is increased by aminoglutethimide; patients also taking warfarin or other coumarin anticoagulants, theophylline, tamoxifen, medroxyprogesterone, or oral hypoglycaemics, may require increased dosages of these drugs. The metabolism of dexamethasone is also accelerated, which limits its value for corticosteroid supplementation in patients receiving aminoglutethimide. Use with diuretics may lead to hyponatraemia, while alcohol may potentiate the central effects of aminoglutethimide.

For reference to aminoglutethimide's interactions with *digitoxin* (see p. 1353.2), *theophylline* (see p. 1235.2), *progestogens* (see p. 2302.2), *tamoxifen* (see Antineoplastics, p. 863.3), and *anticoagulants* (under Warfarin, p. 1532.2).

Pharmacokinetics

Aminoglutethimide is well absorbed after oral doses and peak plasma concentrations occur after 1 to 4 hours. It is metabolised in the liver, mainly to *N*-hydroxylaminoglutethimide and *N*-acetylaminoglutethimide, and appears to induce its own metabolism. The half-life, which is reported to be about 13 hours after a single dose, is decreased to around 9 hours after about 2 weeks of continuous therapy. Aminoglutethimide is excreted in urine, about half a dose being excreted unchanged and the remainder as metabolites. Only about 20 to 25% of a dose is bound to plasma protein.

Half-life. A study in 17 patients showed that the plasma half-life of aminoglutethimide had a mean value of 15.5 hours after single doses but fell to 8.9 hours during multiple-dose therapy.[1] This marked reduction could largely be attributed to a decrease in the volume of distribution; auto-induction of metabolism might be of less importance in decreasing half-life than had been previously suggested.

Uses and Administration

5-Aminolevulinic acid is a naturally occurring haem precursor that is metabolised in the body to protoporphyrin IX, a photosensitiser that accumulates in malignant cells, and then to haem. 5-Aminolevulinic acid and its derivatives are used in photodynamic diagnosis and therapy (see under Porfimer Sodium, p. 849.1). They may be used to treat actinic keratoses, Bowen's disease, and basal cell carcinoma. Some are used in the diagnosis of bladder cancer or for visualisation of malignant tissue during surgery for glioma (see Malignant Neoplasms, below).

Aminolevulinic acid hydrochloride is used to treat actinic keratoses. It is applied topically as a 20% solution in the treatment of mild to moderate non-hyperkeratotic actinic keratoses of the face or scalp. The solution is applied to the surface of the lesions, allowed to dry, and then applied again. This is followed, 14 to 18 hours later, by illumination with blue wavelength light sufficient to supply a dose of 10 J/cm². Treatment may be repeated once after 8 weeks if necessary. Alternatively, a gel containing aminolevulinic acid hydrochloride equivalent to aminolevulinic acid 7.8% may be used. It is applied to the roughened surface of the lesions and about 5 mm of the surrounding skin, allowed to dry, then covered with an occlusive light-tight dressing for 3 hours. After removal of the dressing and any gel, the area is illuminated with red light, from either a narrow spectrum source supplying a dose of 37 J/cm² or a broader and continuous spectrum supplying a dose of 75 to 200 J/cm². Residual lesions may be re-treated after 3 months.

Aminolevulinic acid hydrochloride is given orally for the visualisation of malignant tissue during surgery for glioma. A dose of 20 mg/kg is given 3 hours before anaesthesia, and blue light illumination is used during surgery.

Methyl aminolevulinate hydrochloride is a derivative of 5-aminolevulinic acid that is applied topically for the treatment of non-hyperkeratotic, non-pigmented actinic keratoses of the face or scalp when other therapies are considered inappropriate. In some countries, it is also used for the treatment of superficial and/or nodular basal cell carcinoma unsuitable for other therapies or for the treatment of Bowen's disease (squamous cell carcinoma *in situ*) when surgical excision is inappropriate. A cream containing the equivalent of 16% methyl aminolevulinate is applied to the lesions and covered with an occlusive dressing. After 3 hours the cream is removed and the lesions are exposed to red wavelength light; in the UK a dose of 75 J/cm² is used, whereas 37 J/cm² has been used in the USA. Exposure to the cream for more than 4 hours should be avoided. In the USA, two sessions of photodynamic therapy are given for actinic keratoses, a week apart. In the UK, one session is given for actinic keratoses, repeated after 3 months if necessary; for basal cell carcinoma or Bowen's disease two sessions are given a week apart.

Patients should avoid sunlight or bright light sources for about 2 days after topical application, and for 24 hours after oral administration.

Hexaminolevulinate hydrochloride is used for the detection of bladder cancer. A 50 mL solution containing hexaminolevulinate hydrochloride 100 mg (equivalent to about 85 mg of hexaminolevulinate) is instilled into the bladder and retained for 1 hour. After subsequent evacuation of the bladder, fluorescence cystoscopy using blue light should be started within 30 to 60 minutes.

Malignant neoplasms. The use of *topical* aminolevulinic acid or methyl aminolevulinate in the photodynamic therapy (PDT) of **actinic keratosis** and **basal cell carcinoma** (p. 714.2) has been reviewed.[1-6] Both aminolevulinic acid and methyl aminolevulinate are considered to be effective in clearing non-hyperkeratotic actinic keratoses of the face and scalp, with superior response rates and cosmetic outcome compared with cryotherapy.[7] More than 80% of lesions cleared completely after 2 treatments with aminolevulinic acid PDT; a recurrence rate of 19% was reported over 12 months.[8] Single treatment with methyl aminolevulinate is effective for thin lesions but thicker, non-responsive lesions may benefit from repeated treatment.[9] No significant differences in efficacy were seen between PDT with aminolevulinic acid or methyl aminolevulinate in the treatment of scalp actinic keratosis.[10] Topical PDT is less effective for acral lesions, although some consider that it may still offer therapeutic benefit.[7] Topical PDT with aminolevulinic acid was also found to prevent the development of new malignant lesions in patients with recurrent non-melanoma skin cancer.[11] A self-adhesive patch containing aminolevulinic acid (PD P 506 A) has been developed for easier application before therapy;[12] the patch also provides light protection. In one study, the majority of actinic keratosis lesions remained clear 12 months after a single patch-PDT treatment, and recurrence rates were superior to those of cryosurgery.[13] *Topical* PDT is considered effective for superficial basal cell carcinoma; it is less effective for nodular disease.[7] *Intralesional* use has been investigated to improve penetration of the photosensitiser, with good preliminary results.[14] Methyl aminolevulinate topical PDT may be preferable for difficult-to-treat basal cell carcinoma.[15,16]

Topical PDT is effective in **Bowen's disease** (squamous cell carcinoma *in situ*), with equivalence to cryotherapy, and equivalence or superiority to topical fluorouracil; cosmetic outcome is superior to standard therapy.[7] Topical PDT is not recommended for the treatment of invasive squamous cell carcinoma.[7] Topical methyl aminolevulinate PDT was more effective and cosmetically acceptable compared with topical 5-fluorouracil for pre-malignant skin disease in a small study in organ transplant recipients.[17]

PDT using *oral* 5-aminolevulinic acid as the photosensitiser, at doses of 30 or 60 mg/kg, has been used to treat **Barrett's oesophagus**, which is a major risk factor for oesophageal adenocarcinoma (p. 705.3).[18,19] A small study found similar clinical responses with low-dose (30 mg/kg) and high-dose (60 mg/kg) oral aminolevulinic acid protocols.[20] Good long-term results have been reported with aminolevulinic acid PDT in patients with early neoplasia or high-grade intraepithelial neoplasia.[21]

Aminolevulinic acid is given *orally* for the photodynamic detection of malignant tissue during **glioma** resection (see Malignant Neoplasms of the Brain, p. 701.2).[22,23] It has also been used for the fluorescence detection of **pleural malignancies**.[24]

An *intravesical* solution of hexaminolevulinate is used in the cystoscopic detection of non-muscle invasive **bladder cancer** (p. 700.2). Detection rates are higher compared with the use of standard white light cystoscopy,[25,26] although it may be less effective in patients previously treated with intravesical chemotherapy or immunotherapy.[26] Improvements in detection and associated complete resection are also thought to be related to lower recurrence rates.[25] Intravesical solutions of aminolevulinic acid have been studied as whole-bladder photodynamic therapy in the treatment of bladder tumours[27,28] and hexaminolevulinate is under investigation.

A *topical* application of 5-aminolevulinic acid 3% has been tried in the treatment of **cervical intraepithelial neoplasia**, with poor response.[29]

Skin disorders. 5-Aminolevulinic acid has been used topically in the photodynamic therapy (PDT) of skin condi-

tions such as psoriasis, recalcitrant viral warts, acne vulgaris, and cutaneous T-cell lymphoma.[1,2] Topical PDT is considered effective for clearing the lesions of cutaneous leishmaniasis, although further studies are needed. It also appears effective in the treatment of photoageing.[2] Variable results have been reported with this therapy in patients with plaque psoriasis. In one study therapy was generally well-tolerated,[3] but in another all patients reported stinging or burning during irradiation,[4] and topical PDT is not recommended for use in psoriasis.[2] PDT with 5-aminolevulinic acid has been reported to significantly improve an infected leg ulcer resistant to conventional therapies.[5] A topical 10% solution has been used with intraurethral PDT to treat condylomata acuminata.[6] Benefit has also been reported with topical PDT, using 5-aminolevulinic acid 20%, in 10 patients with actinic cheilitis, a common condition of the lower lip, which can progress to squamous cell carcinoma.[7] Topical PDT may potentially be beneficial in skin cancer prophylaxis, although further investigation is needed.[2]

PDT using topical aminolevulinic acid or methyl aminolevulinate can be effective in the treatment of inflammatory acne of the face and back.[2] However, the optimum regimen to achieve a sustained response with minimal adverse effect has not been established. A review[8] found that most studies reported on topical use of aminolevulinic acid 20% or methyl aminolevulinate 16%, but were small and of variable quality. The authors suggested that treatment for moderate to moderately severe inflammatory acne could consist of a short contact time of 15 to 60 minutes under occlusion, followed by broad spectrum yellow and/or red light. A course of therapy could consist of 2 to 4 treatments applied at intervals of 2 to 4 weeks.

Adverse Effects and Precautions

The mechanism of action of topical 5-aminolevulinic acid or its derivatives generally results in local phototoxicity, manifest as a localised burning or stinging sensation, erythema, oedema, pruritus, scabbing, or pain. Symptoms are usually mild to moderate, and transient. During treatment, patients should be advised to avoid sunlight or prolonged exposure to bright light.

Other common adverse effects on the skin include scaling or crusting, ulceration, suppuration, blistering, bleeding, sensation of heat, erosion or exfoliation, and skin infection. Urticaria, rash, and changes in skin pigmentation may also occur. Application site discharge, eczema, and allergic contact dermatitis have been reported. Systemic effects may occur with topical use. Paraesthesia and headache have been reported commonly; nausea, fatigue, eye swelling or eye pain, and wound haemorrhage have also occurred.

Bladder pain, cystitis, dysuria, haematuria, and abnormal urinalysis may occur with intravesical use. Anaphylactic shock has been reported. Widespread bladder inflammation should be excluded before instillation because of the potential for increased porphyrin accumulation resulting in an increased risk of local toxicity and false fluorescence.

Adverse effects associated with oral use include nausea, hypotension, and photosensitivity. Other reported effects include anaemia, thrombocytopenia, leucocytosis, and increases in bilirubin, liver enzyme, and amylase values.

Handling. US licensed product information warns that nitrile gloves should be worn during application and removal of methyl aminolevulinate hydrochloride cream; vinyl or latex gloves do not provide adequate protection.

Hypersensitivity. Allergic reactions to aminolevulinic acid[1] and methyl aminolevulinate[2] have been reported.

1. Gniadzowska B, *et al.* Allergic contact dermatitis from 5 -aminolevulinic acid used for photodynamic therapy. *Contact Dermatitis* 1998; 38: 348–9.
2. Wulf HC, Philipsen P. Allergic contact dermatitis to 5-aminolaevulinic acid methylester but not to 5-aminolaevulinic acid after photodynamic therapy. *Br J Dermatol* 2004; 150: 143–5.

Porphyria. Licensed product information states that the use of 5-aminolevulinic acid and its derivatives is contra-indicated in patients with porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies aminolevulinic acid given orally as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients. However, topical methyl aminolevulinate is classified as not porphyrinogenic because of insignificant systemic absorption; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/03/13)

Interactions

Use with other known photosensitisers such as griseofulvin, thiazide diuretics, sulfonylureas, phenothiazines, sulfonamides, and tetracyclines might increase the photosensitivity reaction commonly seen with 5-aminolevulinic acid or its derivatives.

St John's wort. A patient taking St John's wort had a pronounced phototoxic reaction consisting of an erythematous rash and swelling of the face, neck, and hands, 6 hours after receiving oral aminolevulinic acid. Although both drugs have been associated with photosensitivity, the authors suggested a synergistic effect had occurred. Tests *in vitro* appeared to confirm this.[1]

1. Ladner DP, *et al.* Synergistic toxicity of 5 -aminolaevulinic acid-induced protoporphyrin IX used for photodiagnosis and hypericum extract, a herbal antidepressant. *Br J Dermatol* 2001; 144: 916–8.

Pharmacokinetics

After intravenous and oral doses of aminolevulinic acid hydrochloride equivalent to 100 mg of aminolevulinic acid, the mean half-life of aminolevulinic acid is stated to be about 0.83 hours and 0.7 hours, respectively; oral bioavailability is about 50 to 60%. *In-vitro* studies of dermal absorption found that the mean cumulative absorption of methyl aminolevulinate through healthy human skin after 24 hours was 0.26% of a dose and a skin depot containing 4.9% of the dose was formed.

CAS — 618863-54-0.

UNII — U06Q37TEG.

NOTE. The name Xanafide has been used as a trade mark for amonafide malate

Profile

Amonafide is a topoisomerase inhibitor. Amonafide malate has been investigated for the treatment of acute myeloid leukaemia, but failed to improve the rate of complete remission. Amonafide hydrochloride has also been investigated, but some studies were stopped due to serious adverse effects.

Amrubicin (*USAN, rINN*)

Amrubicina; Amrubicine; Amrubicinum; SM-5887; Амрубицин.

(+)-(7*S*,9*S*)-9-Acetyl-9-amino-7-[(2-deoxy-β-D-*erythro*-pentopyranosyl)oxy]-7,8,9,10-tetrahydro-6,11-dihydroxy-5,12-naphthacenedione.

$C_{25}H_{25}NO_9$=483.5

CAS — 110267-81-7 (amrubicin); 110311-30-3 (amrubicin hydrochloride).

ATC — L01DB10.

ATC Vet — QL01DB10.

UNII — 93N13LB4Z2.

Profile

Amrubicin is a synthetic anthracycline derivative related to compounds such as doxorubicin (p. 782.3). Amrubicin hydrochloride is a potent topoisomerase II inhibitor that is used as an antineoplastic in the treatment of lung cancer.

4′-(Acridin-9-ylamino)methanesulphon-*m*-anisidide.

$C_{21}H_{19}N_3O_3S$=393.5

CAS — 51264-14-3.

ATC — L01XX01.

ATC Vet — QL01XX01.

UNII — 00DPD30SOY.

Incompatibility. Amsacrine is incompatible with sodium chloride 0.9% injection and with other chloride-containing solutions,[1,2] apparently because of the poor solubility of the hydrochloride salt in aqueous solution.[2] Amsacrine reacts with certain plastics.[1]

1. D'Arcy PF. Reactions and interactions in handling anticancer drugs. *Drug Intell Clin Pharm* 1983; 17: 532–8.
2. Trissel LA, *et al.* Visual compatibility of amsacrine with selected drugs during simulated Y-site injection. *Am J Hosp Pharm* 1990; 47: 2525–8.

Uses and Administration

Amsacrine is an antineoplastic agent that appears to act by intercalation with DNA and inhibition of nucleic acid synthesis. It may also exert an action on cell membranes. Cells in G_2 or S phases may be most sensitive to its actions.

It is used for the induction and maintenance of remission in adult acute leukaemias, particularly acute myeloid leukaemia.

Amsacrine is prepared as a solution in lactic acid and dimethylacetamide, and is given, diluted in glucose 5%, by intravenous infusion over 60 to 90 minutes.

For the induction of remission, amsacrine may be given at a dose of 90 mg/m² daily for 5 to 8 days, depending on clinical response. Courses may be repeated at 2- to 4-week intervals according to response, and the dose may be increased to 120 mg/m² daily in subsequent courses if tolerated. Maintenance doses of 150 mg/m² as a single dose or divided over 3 consecutive days have been given every 3 to 4 weeks, adjusted if necessary according to response.

Complete blood counts should be performed regularly, and cardiac, liver, kidney, and CNS function should be monitored.

Doses should be reduced in patients with hepatic or renal impairment (see p. 742.1).

Administration in hepatic impairment. In moderate to severe hepatic impairment, dosage of amsacrine may need to be reduced by up to 50%. Some licensed product information recommends an initial reduction of 20 to 30%, to a dose between 60 and 75 mg/m² daily.

Administration in renal impairment. In moderate to severe renal impairment, dosage of amsacrine may need to be reduced by up to 50%. Some licensed product information recommends an initial reduction of 20 to 30%, to a dose between 60 and 75 mg/m² daily.

Adverse Effects, Treatment, and Precautions

For a general outline see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bone-marrow depression is usually dose-limiting and may be severe. The nadir of the white cell count has been reported at about 12 days after treatment, with recovery usually by the 25th day. Pancytopenia and haemorrhage may develop. Nausea and vomiting (mild to moderate), stomatitis (mild to life-threatening), rashes, and alopecia may occur. Grand mal seizures, renal dysfunction, hepatotoxicity, and cardiotoxicity have also been reported. Amsacrine is irritant: there may be phlebitis and local tissue necrosis particularly when given in high concentrations.

Amsacrine should be given with caution to patients with liver or kidney disease, who may require dosage adjustments.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies amsacrine as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Use with diuretics or nephrotoxic drugs such as the aminoglycosides may theoretically increase the risk of cardiotoxicity with amsacrine by precipitating hypokalaemia.

Pharmacokinetics

Amsacrine is poorly absorbed after oral doses. When given intravenously it has a reported terminal half-life of about 5 to 8 hours. It is metabolised in the liver and excreted mainly in the bile, mostly as metabolites. It is reported to be about 98% protein bound.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Anastrozole). A white or almost white powder. Very slightly soluble in water; freely soluble in dehydrated alcohol; practically insoluble in cyclohexane. It shows polymorphism.

USP 36: (Anastrozole). A white to off-white crystalline powder. Freely soluble in alcohol, in methyl alcohol, in acetone, and in tetrahydrofuran; very soluble in acetonitrile.

Uses and Administration

Anastrozole is a potent and selective nonsteroidal inhibitor of the aromatase (oestrogen synthetase) system, which converts adrenal androgens to oestrogens in peripheral tissue. It is used in the treatment of advanced or locally advanced breast cancer, and as adjuvant treatment in hormone receptor-positive early breast cancer (p. 702.1), in postmenopausal women in an oral dose of 1 mg once daily. Responses are unlikely in patients with oestrogen receptor-negative disease, unless they had a previous positive clinical response to tamoxifen. For patients with advanced breast cancer, therapy may be continued until tumour progression. Adjuvant therapy may be continued for up to 5 years, although the optimum duration is uncertain.

Administration in hepatic impairment. UK licensed product information states that no dosage adjustment of anastrozole is required for patients with mild hepatic impairment, but contra-indicates its use in those with moderate or severe hepatic disease. US licensed product information states that no change in dose is required for those with mild to moderate hepatic impairment and that anastrozole has not been studied in those with severe hepatic impairment; dosage adjustment in patients with stable hepatic cirrhosis is not considered to be necessary.

Administration in renal impairment. US licensed product information allows for unchanged doses of anastrozole in renal impairment. However, UK licensed product information contra-indicates its use in patients with severe renal impairment (those with a creatinine clearance less than 20 mL/min).

Endometriosis. In a small, open-label study,[1] *oral* anastrozole 1 mg, given daily with a low-strength oral contraceptive for 6 months, reduced pelvic pain scores in women with refractory endometriosis (p. 2264.1). Adverse effects were mild, although most patients had breakthrough bleeding, which exacerbated pain. The authors supposed that a higher dose of oral contraceptive should be considered in future studies. A randomised, controlled study to investigate the efficacy of oral anastrozole with subcutaneous goserelin after surgery for endometriosis found the combination increased the pain-free interval and decreased recurrence rates compared with goserelin alone.[2]

There are also reports of success with oral letrozole 2.5 mg daily, given with calcium and vitamin D,[3] and also with norethisterone in some cases.[4] However, use with desogestrel in a small study of women with refractory endometriosis caused the development of functional ovarian cysts, necessitating interruption of treatment.[5]

In a small pilot study of patients with rectovaginal endometriosis,[6] anastrozole 250 micrograms was given *vaginally* once daily for 6 months. Dysmenorrhoea improved significantly although chronic pelvic pain was unchanged. Adverse effects were mild.

A review[4] on the use of aromatase inhibitors for endometriosis noted that, while they may be useful in reducing pain, the long-term course of pain symptoms after interruption of therapy remains to be evaluated, and that their superiority over hormonal therapy has yet to be proven. Furthermore, permanent inhibition of aromatase activity is contra-indicated in women with endometriosis who wish to preserve their fertility, and they should only be offered to selected women who have severe pain despite previous surgical and hormonal therapy; further studies were considered necessary before routine use could be recommended.

6. Hefler LA, *et al.* Role of the vaginally administered aromatase inhibitor anastrozole in women with rectovaginal endometriosis: a pilot study. *Fertil Steril* 2005; 84: 1033–6.

Growth hormone deficiency. Up to 3 years of adjuvant treatment with anastrozole in adolescent boys with growth hormone deficiency (see Growth Retardation, p. 1921.3) resulted in significant gains in predicted adult height compared with placebo; the drug was well tolerated and normal pubertal progression was maintained.[1]

1. Mauras N, *et al.* Anastrozole increases predicted adult height of short adolescent males treated with growth hormone: a randomized, placebo-controlled, multicenter trial for one to three years. *J Clin Endocrinol Metab* 2008; 93: 823–31.

Gynaecomastia. Anastrozole has been reported[1,2] to be under investigation for the treatment of gynaecomastia, but controlled studies suggest that it may be no better than placebo—see Gynaecomastia (p. 2264.3) and Gynaecomastia under Adverse Effects and Precautions of Flutamide (p. 799.1).

1. Grunmanis U, Braunstein GD. Treatment of gynecomastia. *Curr Opin Investig Drugs* 2001; 2: 643–9.
2. Mauras N, *et al.* Pharmacokinetics and pharmacodynamics of anastrozole in pubertal boys with recent-onset gynecomastia. *J Clin Endocrinol Metab* 2009; 94: 2975–8.

Infertility. Nonsteroidal aromatase inhibitors such as anastrozole and letrozole have been investigated for their ovulation-inducing effects, see Letrozole, p. 817.2.

Precocious puberty. For a report of the effective use of anastrozole with bicalutamide in the treatment of familial male precocious puberty (testotoxicosis), see Precocious Puberty, under Bicalutamide, p. 749.2.

Adverse Effects, Treatment, and Precautions

The most frequent adverse effects of anastrozole are gastrointestinal disturbances (including anorexia, nausea and vomiting, and diarrhoea), asthenia, hot flushes, dizziness, drowsiness, headache, and rash. Other commonly reported effects include hair thinning, vaginal dryness or bleeding, myalgia, arthralgia, carpal tunnel syndrome, and bone pain and/or fractures. Insomnia, depression, peripheral oedema, lymphoedema, increased cough, pharyngitis, dyspnoea, back pain, and hypertension are also common. An increased incidence of cardiovascular adverse events has been seen in women with pre-existing ischaemic heart disease and caution is advised in these patients. Abnormalities in liver enzyme values, hepatitis, thromboembolism, and hypercholesterolaemia can occur. Rare cases of erythema multiforme, Stevens-Johnson syndrome, and allergic reactions (including angioedema, urticaria, and anaphylaxis) have been reported. Other adverse reactions include thrombophlebitis, anaemia, leucopenia, anxiety, cataracts, and urinary-tract infections; bronchitis, rhinitis, and sinusitis have been reported.

Reductions in bone mineral density (BMD) can occur during use of anastrozole. Patients with or at risk of osteoporosis should therefore have their BMD assessed at the start of therapy and at regular intervals thereafter. Treatment or prophylaxis for osteoporosis should be started as appropriate and carefully monitored.

The use of aromatase inhibitors such as anastrozole is generally contra-indicated in premenopausal women (particularly in pregnancy).

Breast feeding. Licensed product information states that it is unknown whether anastrozole is distributed into human milk; in the UK its use during breast feeding is contra-indicated while in the USA a decision to use may be made based on clinical judgement. It has been suggested[1] that if only a single dose is given, breast feeding should be withheld for 10 days.

1. *et al.*, eds. *Drugs during pregnancy and lactation: treatment options and risk assessment.* 2nd ed. London: Elsevier, 2007.

Effects on blood lipids. For a comparison of the effects of anastrozole, letrozole, and exemestane on blood lipids see under Exemestane, p. 792.3.

Effects on the liver. A case of acute hepatitis was attributed to anastrozole, 3 weeks after starting therapy.[1] In another case[2] there was some evidence of an auto-immune mechanism.

1. de la Cruz L, *et al.* Severe acute hepatitis in a patient treated with anastrozole. *Lancet* 2007; 369: 23–4.
2. Inno A, *et al.* Anastrozole-related acute hepatitis with autoimmune features: a case report. *BMC Gastroenterol* 2011; 11: 32.

Effects on the musculoskeletal system. In a series of 77 postmenopausal women treated with anastrozole for metastatic breast cancer, 12 complained of joint pains within 2 months of beginning therapy. Based on this experience and the incidence of arthralgia reported during clinical studies, the authors estimated that arthralgia occurs in 10 to 15% of patients treated with anastrozole, possibly as a result of the very low oestrogen concentrations achieved.[1] It has been suggested that there may be modest differences between ethnic groups in the incidences of joint symptoms and bone fractures,[2] which seem to be lower in Japanese patients.

Adjuvant anastrozole therapy for postmenopausal women with early breast cancer was associated with accelerated bone loss, but the risk appeared to be confined to those with osteopenia at baseline.[3] A retrospective review[4] including 316 patients treated with aromatase inhibitors (anastrozole, letrozole, or exemestane) found that there was a significant association between musculoskeletal symptoms and bone mineral density (BMD) results; those with severe symptoms had an increased likelihood of having an abnormal BMD. Patients who were also taking calcium and bisphosphonates had fewer symptoms and fewer fractures, and those who had taken tamoxifen before aromatase inhibitors were less likely to develop musculoskeletal symptoms. Those taking steroidal aromatase inhibitors had significantly more arthralgia, generalised bone pain or myalgia, and bone fractures than those taking nonsteroidal aromatase inhibitors. The need to assess the risk of osteoporosis before starting therapy has been stressed.[5]

5. Chien AJ, Goss PE. Aromatase inhibitors and bone health in women with breast cancer. *J Clin Oncol* 2006; 24: 5305–12.

CARPAL TUNNEL SYNDROME. Carpal tunnel syndrome has been reported in postmenopausal women given anastrozole; in one study,[1] more than 3 times as many women taking anastrozole developed carpal tunnel syndrome than those taking tamoxifen, although the incidence was still low (2.6%). Most cases were of mild or moderate intensity and short duration; risk factors were an age of 60 years or younger, or previous treatment with hormone replacement therapy or chemotherapy.

1. Sestak I, *et al.* Aromatase inhibitor-induced carpal tunnel syndrome: results from the ATAC trial. *J Clin Oncol* 2009; 27: 4961–5.

Effects on the skin. A cutaneous eruption, diagnosed as subacute cutaneous lupus erythematosus, appeared 1 month after starting anastrozole. The patient was also taking an ACE inhibitor. The condition improved slightly after stopping anastrozole and replacing the ACE inhibitor with atenolol, but reappeared with greater intensity when anastrozole was restarted. Anastrozole was stopped again and the patient was treated with hydroxychloroquine and corticosteroids; after 4 months, signs had resolved and no recurrence was seen after 1 year.[1]

1. Trancart M, *et al.* Anastrozole-induced subacute cutaneous lupus erythematosus. *Br J Dermatol* 2008; 158: 628–9.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies anastrozole as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Interactions

Tamoxifen. In a study of postmenopausal women with breast cancer, use of *daily* tamoxifen with anastrozole reduced anastrozole concentrations by 27% compared with daily anastrozole monotherapy; however, the effect of anastrozole on estradiol suppression was similar whether used alone or with tamoxifen.[1] In another study of daily anastrozole, *weekly* tamoxifen, or the combination thereof, there was no difference in anastrozole concentration in the combination arm compared with the anastrozole monotherapy arm in the first year.[2] The authors hypothesised that when given at a daily dose, tamoxifen has a mainly oestrogenic effect in an oestrogen-deprived environment, whereas a weekly dose still provides desirable oestrogenic properties when added to anastrozole, but without impairing anastrozole bioavailability.[2]

1. Dowsett M, *et al.* ATAC Trialists' Group. Pharmacokinetics of anastrozole and tamoxifen alone, and in combination, during adjuvant endocrine therapy for early breast cancer in postmenopausal women: a sub-protocol of the 'Arimidex™ and tamoxifen alone or in combination' (ATAC) trial. *Br J Cancer* 2001; 85: 317–24.
2. Bonanni B, *et al.* Randomized biomarker trial of anastrozole or low-dose tamoxifen or their combination in subjects with breast intraepithelial neoplasia. *Clin Cancer Res* 2009; 15: 7053–60.

Pharmacokinetics

Anastrozole is rapidly and almost completely absorbed from the gastrointestinal tract after oral doses and peak plasma concentrations occur within about 2 hours. Food decreases the rate of absorption, though this is not considered clinically significant. Anastrozole is 40% bound to plasma proteins. It is metabolised in the liver by *N*-dealkylation, hydroxylation, and glucuronidation; the main metabolite is triazole, which lacks pharmacological activity (but see also Metabolism, below). Anastrozole is excreted in the urine, chiefly as metabolites. The terminal plasma elimination half-life is about 40 to 50 hours, and steady-state concentrations occur after about 7 days in patients receiving once-daily doses.

Metabolism. Anastrozole is mainly cleared by hepatic metabolism (see Pharmacokinetics, above); it has been hypothesised[1] that differences in metabolism may contribute to the interindividual variability in the drug's effects. A study to characterise anastrozole metabolism concluded that hydroxylation and *N*-glucuronidation are the main metabolic pathways.[1] *In vitro* and *in vivo* data suggested that anastrozole is hydroxylated to hydroxyanastrozole, mainly by the cytochrome P450 isoenzyme CYP3A4; there may be some involvement of CYP3A5. Hydroxyanastrozole is then rapidly and extensively conjugated probably by uridine diphosphate glucuronosyltransferases (UGTs). *N*-Glucuronidation of anastrozole to anastrozole glucuronide occurs mainly by UGT1A4, although the precise contribution of the enzyme to *in vivo* metabolism is unknown. Triazole or any *N*-dealkylated metabolites could not be detected in *in vitro* studies; the role of *N*-dealkylation in anastrozole metabolism could not be confirmed.

Antineoplaston A10

3-Phenylacetylamino-2,6-piperidinedione.
$C_{13}H_{14}N_2O_3$=246.3

Profile

Antineoplaston A10, one of a group of peptide derivatives isolated from blood and urine, has been investigated for the treatment of breast cancer, brain stem glioma, and other malignant neoplasms although its value has been questioned (see below).

A critical review of the antineoplastons[1] noted that most work had been done with antineoplaston A10, which is insoluble in aqueous solutions, and its derivatives antineoplaston AS2.5 (phenylacetylglutamine), and antineoplaston AS2.1 (a 4:1 mixture of phenylacetic acid and phenylacetylglutamine), which had not been independently shown to be active against cancer. However, some interest in the antineoplastons subsequently continued.[2-4]

AS-1411

AGRO-100.

Profile

AS-1411 is a selective oligonucleotide ligand (aptamer) that binds to the protein nucleolin, inducing apoptosis in cancer cells. It is under investigation for the treatment of renal cell carcinoma, pancreatic cancer, and acute myelogenous leukaemia.

Asparaginase *(USAN)*

L-Asparaginaasi; L-Asparaginas; Asparaginasa; L-Asparaginasa; L-Asparaginase; L-Asparaginasum; L-Asparaginaz; L-Asparagine Amidohydrolase; MK-965; NSC-109229; Re-82-TAD-15; Аспарагиназа.

CAS — 9015-68-3.
ATC — L01XX02.
ATC Vet — QL01XX02.
UNII — G4FQ3CKY5R.

NOTE. Asparaginase (*USAN*) is an enzyme isolated from *Escherichia coli*, or obtained from other sources. See also Colaspase and Crisantaspase, below.

Incompatibility. Asparaginase is incompatible with rubber. Licensed product information recommends that it should not be mixed with other drugs.

Storage. Asparaginase should be stored at 2 degrees to 8 degrees (see also Stability, p. 744.1).

Colaspase *(BAN)*

CAS — 9015-68-3.
ATC — L01XX02.
ATC Vet — QL01XX02.

NOTE. Colaspase (*BAN*) is asparaginase obtained from selected strains of *Escherichia coli*, such as ATCC 9637.

Pharmacopoeias. *Chin.* includes Asparaginase obtained from *Escherichia coli* ASI 357.

Crisantaspase *(BAN, pINN)*

Asparaginase *Erwinia chrysanthemi* (USAN); Crisantaspasa; Crisantaspasum; Erwinia L-asparaginase; Krisantaspaasi; Krisantaspas; Крисантаспаза.

CAS — 9015-68-3; 1349719-22-7.
ATC — L01XX02.
ATC Vet — QL01XX02.

NOTE. Crisantaspase (*BAN*) is asparaginase obtained from cultures of *Erwinia chrysanthemi* (*E. carotovora*).

Pegaspargase *(USAN, rINN)*

PEG-L-asparaginase; Pegaspargasa; Pégaspargase; Pegaspargasum; Пегаспаргаза.

A conjugate of colaspase with a polyethylene glycol of molecular weight 5000; Monomethoxypolyethylene glycol succinimidyl L-asparaginase.
CAS — 130167-69-0.
ATC — L01XX24.
ATC Vet — QL01XX24.
UNII — 7D96IR0PPM.

Stability. Although asparaginase was routinely kept under refrigeration,[1] information from a manufacturer (*Merck Sharp & Dohme*) indicated that it would remain stable for 48 hours at 15 degrees to 30 degrees. Licensed product information for pegaspargase states it should not be used if stored at room temperature for more than 48 hours.

1. Vogenberg FR, Souney PF. Stability guidelines for routinely refrigerated drug products. *Am J Hosp Pharm* 1983; **40:** 101–2.

Storage. Pegaspargase should be stored at 2 degrees to 8 degrees.

Units

One international unit of asparaginase splits 1 micromole of ammonia from L-asparagine in 1 minute under standard conditions.

Uses and Administration

Asparaginase is an enzyme that acts by breaking down the amino acid L-asparagine to aspartic acid and ammonia. It interferes with the growth of those malignant cells which, unlike most healthy cells, are unable to synthesise L-asparagine for their metabolism, but resistance to its action develops fairly rapidly. Its action is reportedly specific for the G_1 phase of the cell cycle.

Asparaginase and pegaspargase are used mainly in combination regimens for the induction of remissions in acute lymphoblastic leukaemia (p. 692.3). Pegaspargase may be used in patients who are hypersensitive to asparaginase (although hypersensitivity to pegaspargase can still occur, see Adverse Effects, below).

Crisantaspase may be given by intramuscular, intravenous, or subcutaneous injection. Colaspase may be given intramuscularly (maximum volume of 2 mL per injection), or intravenously over not less than 30 minutes into a running infusion of sodium chloride, or glucose 5%. Regimens vary, and dosage should follow local protocols, but a usual dose of asparaginase given as crisantaspase 6000 units/m² (200 units/kg) is given three times weekly for 3 weeks. Alternatively, pegaspargase may be given intramuscularly (maximum volume of 2 mL per injection) or intravenously diluted in 100 mL of sodium chloride, or glucose 5% and given over 1 to 2 hours into a running infusion, in a dose of 2500 units/m² no more frequently than every 14 days.

Asparaginase is not generally used alone as an induction agent but doses of 200 units/kg daily have been given intravenously as colaspase, for 28 days.

Many of the regimens using asparaginase or pegaspargase are for use in children; for further details see below.

Although not entirely reliable, an intradermal test dose of about 2 units has been recommended in the USA, to test for hypersensitivity before treatment with asparaginase or where more than a week has elapsed between doses. Desensitisation has been advocated in patients at increased risk of allergic reactions. The incidence of hypersensitivity is lower in patients given pegaspargase, and a test dose is not advocated.

Administration in children. Asparaginase and pegaspargase are used in children mainly in combination regimens for the induction of remission in acute lymphoblastic leukaemia. Pegaspargase may be used in children who are hypersensitive to asparaginase (although hypersensitivity to pegaspargase can still occur, see Adverse Effects, below). Regimens vary and dosage should follow local protocols, but doses are similar to those used in adults, see above. US licensed product information describes combination regimens using asparaginase with vincristine and prednisone for children with acute lymphoblastic leukaemia; typical asparaginase doses (given as colaspase) include:

- intravenous asparaginase 1000 units/kg daily for 10 days
- intramuscular asparaginase 6000 units/m² given every third day for 9 doses

Asparaginase toxicity is reported to affect children less than adults. A large study in children with acute lymphoblastic leukaemia also found that asparaginase derived from *Erwinia chrysanthemi* (crisantaspase) had a lower toxicity than that derived from *Escherichia coli* (colaspase); however, a lower survival rate was noted with crisantaspase over 5 years of treatment.[1]

1. Moghrabi A, *et al.* Results of the Dana-Farber Cancer Institute ALL Consortium Protocol 95-01 for children with acute lymphoblastic leukemia. *Blood* 2007; **109:** 896–904.

Adverse Effects

Asparaginase is a protein and may produce anaphylaxis and other hypersensitivity reactions including fever, rashes, bronchospasm, urticaria, hypotension, and laryngeal oedema. The risk of anaphylactic reactions increases with continued exposure to asparaginase, and may be increased on re-exposure to asparaginase after a drug-free interval. Patients who develop hypersensitivity to asparaginase derived from *Escherichia coli* may be able to continue treatment with that derived from *Erwinia chrysanthemi* as the enzymes are immunologically distinct. Hypersensitivity to pegaspargase is less common, but is still significant; about 30% of patients hypersensitive to asparaginase will be hypersensitive to pegaspargase too.

Liver function abnormalities occur in many patients, and there may be decreased blood concentrations of fibrinogen and clotting factors resulting in coagulopathy or thrombotic complications. There may also be alterations in blood lipids and cholesterol, and hypoalbuminaemia. Hyperammonaemia, due to the production of ammonia from asparagine, may occur. Uraemia, and occasionally renal failure, have been reported. Pancreatitis may occur and may be fatal: there may also be hyperglycaemia due to decreased insulin production, and death from ketoacidosis has occurred.

Gastrointestinal disturbances, including nausea and vomiting, and CNS disturbances, including drowsiness, depression, coma, hallucinations, seizures, and a Parkinson-like syndrome, have also been reported. Myalgia, reactive arthritis, and transient bone-marrow depression have occurred rarely, as has marked leucopenia. Fatal hyperthermia has been reported.

Effects on the blood. Central thrombosis or intracranial haemorrhage as well as peripheral thrombosis and haemorrhage have been reported after asparaginase therapy.[1–4] Although the precise mechanism for this effect remains unclear, asparaginase appears to deplete certain clotting factors as well as antithrombin III, plasminogen, and fibrinogen.[4] These decreases may be dependent on the formulation and resultant asparaginase activity of preparations,[5] and there is some suggestion that crisantaspase may affect coagulation factors less severely than colaspase.[6] A multicentre, retrospective survey[3] of paediatric patients with acute lymphoblastic leukaemia found that use of corticosteroids with colaspase may be an additional risk factor for thromboembolic events.

Precautions

Asparaginase is contra-indicated in patients with pancreatitis, and should be avoided in pregnancy. It should be given cautiously to patients with hepatic impairment; liver function should be measured regularly during treatment. Treatment should be stopped if an allergic reaction occurs and not restarted with the same type of asparaginase. Facilities for the management of anaphylaxis (see p. 1293.2) should be available during treatment. Some licensed product information recommends an intradermal test dose at the start of asparaginase treatment to check for hypersensitivity, as described under Uses, above, although such tests may not always be predictive. Careful observation is needed when re-treating with asparaginase after a break in therapy, as there may be an increased risk of allergic reactions. Desensitisation has been used in patients at increased risk of hypersensitivity, although it may itself be hazardous. Serum amylase and lipase concentrations should be monitored regularly as should blood glucose concentrations. Asparaginase has been reported to interfere with tests of thyroid function by transient reduction of concentrations of thyroxine-binding globulin. Routine screening of blood clotting factors should be carried out before starting treatment; if coagulopathy occurs, asparaginase should be withheld until recovery. Monitoring of blood count and bone marrow is also recommended. Measures to protect against the adverse effects of hyperuricaemia may be required (see p. 600.1).

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies asparaginase as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 14/11/11)

Interactions

Use of asparaginase with other drugs that affect liver function may increase the risk of hepatotoxicity and concomitant corticosteroid therapy may increase the risk of coagulation abnormalities. If asparaginase is given with methotrexate the activity of the latter may be reduced (see below). Vincristine neurotoxicity may possibly be increased by use with asparaginase (see p. 884.1).

Methotrexate. Asparaginase inhibits protein synthesis and cell replication, and therefore may interfere with the action of drugs such as methotrexate that require cell replication for their antineoplastic effect.[1] Licensed product information for asparaginase states that this effect persists as long as plasma-asparagine concentrations are suppressed and recommends that methotrexate should not be given with, or after asparaginase, while asparagine concentrations are below normal. It has been suggested that giving methotrexate 24 hours *before* asparaginase permits at least an additive therapeutic effect.[2]

1. Jolivet J, *et al.* Prevention of methotrexate cytotoxicity by asparaginase inhibition of methotrexate polyglutamate formation. *Cancer Res* 1985; **45:** 217–20.
2. Capizzi RL. Asparaginase-methotrexate in combination chemotherapy: schedule-dependent differential effects on normal versus neoplastic cells. *Cancer Treat Rep* 1981; **65** (suppl 4): 115–21.

Pharmacokinetics

After intravenous injection the plasma half-life of the native enzyme has varied from about 8 to 30 hours; half-lives of up to 49 hours may be seen after intramuscular dosage. The mean half-life of pegaspargase is reported to be between 6 and 14 days. Asparaginase is found in the lymph at about 20% of the concentration in plasma. There is virtually no diffusion into the CSF. Little is excreted in the urine.

Atiprimod (rINN)

Atiprimodum; Атипримод.
2-[3-(Diethylamino)propyl]-8,8-dipropyl-2-azaspiro[4.5]decane.

$C_{22}H_{44}N_2$=336.6.
CAS — 123018-47-3 (atiprimod); 130065-61-1 (atiprimod hydrochloride); 183063-72-1 (atiprimod maleate).
UNII — MG7D3QD743.

Profile

Atiprimod is an antineoplastic that is under investigation for the treatment of carcinoid tumours and multiple myeloma.

Atrasentan Hydrochloride *(USAN, rINNM)*

A-147627.1; Abbott-147627; ABT-627; Atrasentan, Chlorhydrate d'; Atrasentani Hydrochloridum; Hidrocloruro de atrasentán; Атразентана Гидрохлорид.
(2*R*,3*R*,4*S*)-1-[(Dibutylcarbamoyl)methyl]-2-(*p*-methoxyphenyl)-4-[3,4-(methylenedioxy)phenyl]-3-pyrrolidinecarboxylic acid hydrochloride.
$C_{29}H_{38}N_2O_6$,HCl=547.1
CAS — 173937-91-2 (atrasentan); 195733-43-8 (atrasentan hydrochloride).
UNII — E4G31X93ZA.

NOTE. The name Xinlay has been used as a trademark for atrasentan hydrochloride.

Profile

Atrasentan hydrochloride is a selective endothelin-A receptor antagonist that inhibits the effect of endothelin-1, a protein that may be involved in cancer progression. It is under investigation in the treatment of prostate cancer, and has been tried in other malignant neoplasms, as well as for complications of diabetes and the metabolic syndrome.

Axitinib *(USAN, rINN)*

AG-013736; Axitinibum; Акситиниб.
N-Methyl-2-({3-[(1*E*)-2-(pyridin-2-yl)ethenyl]-1*H*-indazol-6-yl}sulfanyl)benzamide.
$C_{22}H_{18}N_4OS$=386.5
CAS — 319460-85-0.
UNII — C9LVQ0YUXG.

Uses and Administration

Axitinib is an inhibitor of vascular endothelial growth factor (VEGF) receptor tyrosine kinases. It is given orally in the treatment of advanced renal cell carcinoma (p. 708.3). *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

The recommended initial dose is 5 mg twice daily, given at 12-hourly intervals. The dose may be increased in patients who tolerate axitinib for at least 2 consecutive weeks with no adverse effects above grade 2, are normotensive, and are not receiving antihypertensive therapy; an increase to 7 mg twice daily, and then to 10 mg twice daily may be considered. If the dose must be decreased because of adverse effects, it is suggested that 5 mg twice daily is reduced to 3 mg twice daily, and then to 2 mg twice daily, if necessary.

The use of strong inhibitors of the cytochrome P450 isoenzymes CYP3A4 and CYP3A5 should be avoided in patients given axitinib. If the combination must be used then the dose of axitinib should be halved, with further adjustments made according to patient response.

The dose of axitinib should be reduced in patients with hepatic impairment (see below).

Axitinib is also under investigation for the treatment of other cancers, including thyroid and liver cancers.

References.
1. Rini BI, *et al.* Phase II study of axitinib in sorafenib-refractory metastatic renal cell carcinoma. *J Clin Oncol* 2009; **27:** 4462–8.
2. Kelly RJ, Rixe O. Axitinib (AG-013736). *Recent Results Cancer Res* 2010; **184:** 33–44.
3. Rini BI, *et al.* Comparative effectiveness of axitinib versus sorafenib in advanced renal cell carcinoma (AXIS): a randomised phase 3 trial. *Lancet* 2011; **378:** 1931–9.

Administration in hepatic impairment. The starting dose of axitinib should be reduced in patients with moderate hepatic impairment (Child-Pugh class B) to about half the usual starting dose (see Uses and Administration, above). Further dose adjustment should be made based on individual response. Specific information on its use in severe hepatic impairment (Child-Pugh class C) is lacking.

References.
1. Tortorici MA, *et al.* Influence of mild and moderate hepatic impairment on axitinib pharmacokinetics. *Invest New Drugs* 2011; **29:** 1370–80.

Adverse Effects, Treatment, and Precautions

The most common adverse effects of axitinib include gastrointestinal disturbances, reduced appetite, weight loss, fatigue, asthenia, dysphonia, and palmar-plantar erythrodysesthesia.

Hypertension is also common and cases of hypertensive crisis have been reported. Blood pressure should be well-controlled before starting axitinib and monitored during therapy. Antihypertensive treatment may be needed but the dose of axitinib should be reduced if hypertension persists; axitinib should be stopped if hypertension is severe and persistent or there is evidence of hypertensive crisis. Arterial and venous thromboembolism have occurred in patients given axitinib. Reported haemorrhagic events have included cerebral haemorrhage, haematuria, and gastrointestinal bleeding. Gastrointestinal perforation and fistula formation have also been reported.

Other adverse effects include thyroid dysfunction, proteinuria, and elevations of liver enzymes values; patients should be assessed for these before starting axitinib and monitored during therapy. There have also been cases of reversible posterior leukoencephalopathy syndrome in patients given axitinib.

Axitinib should be stopped at least 24 hours before surgery, because of potential impairment of wound healing.

Interactions

Plasma concentrations of axitinib may be altered by the concomitant use of drugs that affect the cytochrome P450 isoenzymes CYP3A4 and CYP3A5. Strong inhibitors of these enzymes should be avoided, but if they must be used then the dose of axitinib should be reduced (see Uses and Administration, above). Grapefruit and grapefruit juice should also be avoided. Moderate and strong inducers of these enzymes can reduce axitinib concentrations and should therefore be avoided during axitinib therapy.

Pharmacokinetics

Axitinib is absorbed from the gastrointestinal tract. It has a bioavailability of about 58% and is highly bound to plasma proteins. Axitinib is metabolised mainly in the liver by the cytochrome P450 isoenzymes CYP3A4 and CYP3A5, and to a lesser extent by CYP1A2, CYP2C19, and UGT1A1. Most of the dose is excreted as metabolites in the urine and faeces; about 12% is excreted unchanged in the faeces.

Preparations

Proprietary Preparations (details are given in Volume B)

Azacitidine *(BAN, USAN, rINN)*

5-Azacitidina; Azacitidina; Azacitidinum; 5-Azacytidine; Ladakamycin; NSC-102816; U-18496; Азацитидин.
4-Amino-1-β-D-ribofuranosyl-1,3,5-triazin-2(1*H*)-one.
$C_8H_{12}N_4O_5$=244.2
CAS — 320-67-2.
ATC — L01BC07.
ATC Vet — QL01BC07.
UNII — M801H13NRU.

Uses and Administration

Azacitidine is an antimetabolite antineoplastic with general properties similar to those of cytarabine (p. 774.1). It also inhibits cellular pyrimidine synthesis. Azacitidine is used in myelodysplastic syndromes (p. 694.3); it is also used in the treatment of acute myeloid leukaemia (p. 693.1) and chronic myelomonocytic leukaemia.

Azacitidine is given subcutaneously or intravenously in a dose of 75 mg/m² daily for 7 days, in 4-week cycles. For myelodysplastic syndromes, if there is no benefit after 2 cycles, and no toxicity other than nausea and vomiting has occurred, the dose may be increased to 100 mg/m² daily.

Treatment for at least 4 to 6 cycles is usually recommended; treatment is continued as long as the patient benefits, or until disease progression. Doses may need to be adjusted for haematological toxicity. Azacitidine should be used with caution in renal impairment and doses adjusted accordingly (see below).

10. Gurion R, *et al.* 5-azacitidine prolongs overall survival in patients with myelodysplastic syndrome—a systematic review and meta-analysis. *Haematologica* 2010; **95:** 303–10.

Administration in renal impairment. Adverse renal effects of azacitidine include abnormalities in renal-function tests, renal tubular acidosis, renal failure, and death. Licensed product information recommends that if serum-bicarbonate concentrations fall to below 20 mmol/litre, the dose of azacitidine should be halved for the next course. If there are rises in serum concentrations of urea or creatinine, the next cycle of azacitidine should be delayed until these return to normal or baseline, and the dose should be halved on the next treatment course.

Adverse Effects and Precautions

The adverse effects of azacitidine are generally similar to those seen with cytarabine (p. 775.1). Hypokalaemia, dyspnoea, and bruising are common.

Pharmacokinetics

Azacitidine is rapidly absorbed after subcutaneous use; the bioavailability relative to intravenous use is about 89%. The mean plasma half-life after subcutaneous injection is about 40 minutes. Azacitidine and its metabolites are excreted mainly in the urine; about 50% and 85% is recovered after subcutaneous and intravenous dosing, respectively. The mean elimination half-life is about 4 hours after subcutaneous or intravenous use.

Bafetinib *(USAN, rINN)*

Bafétinib; Bafetinibum; INNO-406; NS-187; Бафетиниб.
N-(3-{[(4,5′-Bipyrimidin)-2-yl]amino}-4-methylphenyl)-4-[(3*S*)-3-(dimethylamino)pyrrolidin-1-yl]methyl-3-(trifluoromethyl)benzamide.

$C_{30}H_{31}F_3N_8O$=576.6
CAS — 859212-16-1; 887650-05-7.
UNII — NWA4Z03I9B.

Profile

Bafetinib is an orally active tyrosine kinase inhibitor active against BCR-ABL and Lyn (part of the SRC family) kinases. It is under investigation for the treatment of malignant neoplasms such as chronic myeloid leukaemia, chronic lymphocytic leukaemia, brain cancer, and prostate cancer.

Becatecarin *(USAN, rINN)*

Becatecarina; Bécatécarine; Becatecarinum; Betacatecarin; Betotecarin; BMS-181176; BMY-27557; DEAE-rebeccamycin; NSC-655649; XL-119; Бекатекарин.
1,11-Dichloro-6-[2-(diethylamino)ethyl]-12-(4-*O*-methyl-β-D-glucopyranosyl)-12,13-dihydro-5*H*-indolo[2,3-*a*]pyrrolo[3,4-*c*]carbazole-5,7(6*H*)-dione.
$C_{33}H_{34}Cl_2N_4O_7$=669.6
CAS — 119673-08-4.
UNII — A60X6MBU6G.

Profile

Becatecarin is a synthetic analogue of the antineoplastic antibiotic rebeccamycin. It is an inhibitor of the enzyme topoisomerase I, and is under investigation in the treatment of bile-duct and other tumours.

Belagenpumatucel-L *(USAN)*

NOTE. The name Lucanix has been used as a trade mark for belagenpumatucel-L.

Profile

Belagenpumatucel-L is an allogeneic cancer vaccine (p. 757.3) that is stated to produce improved antigen recognition because of its ability to block transforming growth factor β-2. It is under investigation for the treatment of non-small cell lung cancer.

Belinostat *(USAN, rINN)*

Belinostat; Belinostatum; PXD-101; Белиностат.
N-Hydroxy-3-[3-(phenylsulfamoyl)phenyl]prop-2-enamide.
$C_{15}H_{14}N_2O_4S$=318.3
CAS — 414864-00-9.
UNII — F4HP6P17NZ.

Profile

Belinostat is a histone deacetylase inhibitor that is under investigation for the treatment of peripheral T-cell lymphomas and other malignant neoplasms.

NOTE. The name Camtobell has been used as a trade mark for belotecan.

Belotecan Hydrochloride *(USAN, pINNM)*

Bélotécan, Chlorhydrate de; Belotecani Hydrochloridum; CKD-602; Hidrocloruro de belotecán; Бельотекана Гидрохлорид.
(4*S*)-4-Ethyl-4-hydroxy-11-[2-[(1-methylethyl)amino]ethyl]-1,12-dihydro-14*H*-pyrano[3′,4′:6,7]indolizino[1,2-*b*]quinoline-3,14(4*H*)-dione hydrochloride.
$C_{25}H_{27}N_3O_4$.HCl=470.0
CAS — 213819-48-8.
UNII — 01DZ4127G7.

Profile

Like irinotecan (p. 812.2), belotecan is a topoisomerase I inhibitor related to camptothecin. It is used for the treatment of ovarian cancer and small cell lung cancer. A liposomal formulation (S-CKD-602)is also under investigation.

References.

Bendamustine Hydrochloride

(BANM, USAN, rINNM)

Bendamustina, hidrocloruro de; Bendamustine, Chlorhydrate de; Bendamustinhydrochlorid; Bendamustini Hydrochloridum; Cytostasan; Hidrocloruro de bendamustina; IMET-3393; SDX-105; SyB-L-0501; Бендамустина Гидрохлорид.
5-[Bis(2-chloroethyl)amino]-1-methyl-2-benzimidazolebutyric acid hydrochloride.
$C_{16}H_{21}Cl_2N_3O_2$.HCl=394.7
CAS — 16506-27-7 (bendamustine); 3543-75-7 (bendamustine hydrochloride).
ATC — L01AA09.
ATC Vet — QL01AA09.
UNII — 981Y8SX18M.

Stability. US licensed product information for bendamustine hydrochloride states that, once reconstituted as directed and further diluted with sodium chloride 0.9%, the final infusion solution is stable for 24 hours when refrigerated (2 degrees to 8 degrees) or for 3 hours when stored at room temperature (15 degrees to 30 degrees) and exposed to light.

Uses and Administration

Bendamustine is an antineoplastic alkylating agent used for the treatment of chronic lymphocytic leukaemia (p. 693.3) as well as for non-Hodgkin's lymphoma (p. 696.3) that has progressed during, or within 6 months of, treatment with rituximab. It may be given with prednisone for the treatment of multiple myeloma (p. 699.2) in patients older than 65 years of age who are not eligible for stem-cell transplantation and who cannot be treated with thalidomide or bortezomib. It may also be used for Hodgkin's disease and breast cancer.

Bendamustine is given intravenously as the hydrochloride. After reconstitution, it is usually diluted in 500 mL of sodium chloride 0.9%; the final concentration of bendamustine hydrochloride should be between 200 and 600 micrograms/mL. Doses should be modified or delayed in the event of toxicity until the patient has recovered, and until neutrophils and platelets have reached acceptable concentrations (see Bone-Marrow Depression, p. 730.3).

For the treatment of **chronic lymphocytic leukaemia**, bendamustine hydrochloride is given in a dose of 100 mg/m², infused over 30 to 60 minutes on days 1 and 2 of a 28-day cycle, for up to 6 cycles. For severe haematological or non-haematological toxicity, dose should be reduced to 50 mg/m² on days 1 and 2 of each cycle. If severe haematological toxicity recurs, the dose should be further reduced to 25 mg/m² on days 1 and 2 of each cycle. Dose re-escalation in subsequent cycles may be considered.

The recommended dose for **non-Hodgkin's lymphoma** is 120 mg/m², infused over 30 to 60 minutes on days 1 and 2 of a 21-day cycle, for up to 8 cycles. For severe haematological or non-haematological toxicity, dose should be reduced to 90 mg/m² on days 1 and 2 of each cycle. If severe toxicity recurs, the dose should be further reduced to 60 mg/m² on days 1 and 2 of each cycle.

For the treatment of **multiple myeloma**, bendamustine hydrochloride is given in a dose of 120 to 150 mg/m² infused over 30 to 60 minutes on days 1 and 2 of a 28-day cycle; intravenous or oral prednisone at a dose of 60 mg/m² is given on days 1 to 4 of the cycle.

8. Hoy SM. Bendamustine: a review of its use in the management of chronic lymphocytic leukaemia, rituximab-refractory indolent non-Hodgkin's lymphoma and multiple myeloma. *Drugs* 2012; 72: 1929–50.

Administration in hepatic impairment. US licensed product information states that, although no meaningful effect on the pharmacokinetics of bendamustine was seen in mild hepatic impairment, data are limited, and therefore caution should be exercised when using bendamustine in these patients. Bendamustine should not be used in moderate or severe hepatic impairment due to a lack of data.

Administration in renal impairment. Although no meaningful effect on the pharmacokinetics of bendamustine was seen in renal impairment, US licensed product information states that data are limited, and that caution should be exercised in patients with mild or moderate renal impairment. Bendamustine should not be used in patients with creatinine clearance less than 40 mL/minute, due to a lack of data.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bendamustine commonly causes myelosuppression and doses may need to be reduced (see Uses and Administration, above); patients are therefore susceptible to infection. Other common adverse effects include gastrointestinal disturbances, fever, asthenia, fatigue, malaise, dry mouth, somnolence, cough, headache, mucosal inflammation, and stomatitis. Infusion reactions are common; symptoms include fever, chills, pruritus, and rash. Anaphylactic reactions have been reported rarely, especially during the second and subsequent cycles of therapy. Prophylactic antihistamines, antipyretics, and corticosteroids should be considered. If severe infusion reactions occur, therapy should be stopped. Tumour lysis syndrome has been reported, usually within the first treatment cycle, and may lead to acute renal failure and death. Adequate volume status should be maintained and potassium and uric acid concentrations should be monitored; allopurinol may be used in patients at high risk. Skin reactions such as bullous exanthema can occur with bendamustine; therapy may need to be withheld or stopped. Worsening hypertension, including hypertensive crisis, has also occurred. Increases in creatinine concentrations and liver enzyme values have been reported; bendamustine should be used with caution in patients with renal or hepatic impairment.

Interactions

Bendamustine is extensively metabolised by cytochrome P450 isoenzyme CYP1A2. Inhibitors of CYP1A2, such as fluvoxamine and ciprofloxacin, may increase exposure to bendamustine. Conversely, CYP1A2 inducers, such as omeprazole, can reduce exposure to bendamustine; tobacco smoking also may increase exposure to bendamustine.

Pharmacokinetics

Bendamustine is about 95% bound to plasma proteins; data suggest it is not likely to displace nor to be displaced by highly protein-bound drugs. Bendamustine distributes freely into human red blood cells. It is mainly metabolised by hydrolysis via the cytochrome P450 isoenzyme CYP1A2. Little or no accumulation in plasma is anticipated for intravenous doses of bendamustine given on days 1 and 2 of a 28-day cycle. About 90% of the drug is eliminated, mainly via the faeces.

Bevacizumab *(rINN)*

Bevacizumab; Bevacizumabum; R-435; rhuMAb-VEGF; Бевацизумаб.

Immunoglobulin G1 (human-mouse monoclonal rhuMAb-VEGF γ-chain anti-human vascular endothelial growth factor), disulfide with human-mouse monoclonal rhuMAb-VEGF light chain, dimer.

CAS — 216974-75-3.
ATC — L01XC07.
ATC Vet — QL01XC07.
UNII — 2S9ZZM9Q9V.

Stability. UK licensed product information states that bevacizumab is chemically and physically stable for 48 hours at 2 degrees to 30 degrees in sodium chloride 0.9%, although immediate use is recommended from a microbiological point of view. If the solution is not used immediately, storage for longer than 24 hours at 2 degrees to 8 degrees cannot be recommended, unless dilution has taken place in controlled and validated aseptic conditions. In the USA, licensed product information states that bevacizumab solutions for infusion may be stored at 2 degrees to 8 degrees for up to 8 hours.

Bevacizumab should not be mixed with glucose.

A study tested the concentration change in bevacizumab when the drug was drawn up into 1-mL latex-free syringes, using a 20-gauge needle, and then capped with a 30-gauge needle, and stored at 4 degrees for varying times; 1 syringe was frozen at -10 degrees. Results were compared with an unopened vial of bevacizumab stored at 4 degrees and protected from light. Bevacizumab concentrations decreased by 1.6% at 1 week, 0% at 3 weeks, 8.8% at 3 months, and 15.9% at 6 months; the concentration in the frozen syringe decreased by 12% at 6 months.[1]

Uses and Administration

Bevacizumab is a recombinant humanised monoclonal antibody that binds to vascular endothelial growth factor (VEGF), thereby inhibiting the angiogenesis that occurs during tumour growth. Bevacizumab is used with fluoropyrimidine-based chemotherapy in the treatment of metastatic colorectal cancer (p. 706.3). It has also been used with a taxane such as paclitaxel, for the first-line treatment of patients with metastatic breast cancer (p. 702.1). Bevacizumab may be used with platinum-based chemotherapy in the first-line treatment of patients with unresectable, locally advanced, recurrent or metastatic, non-squamous, non-small cell lung cancer (p. 710.2). Bevacizumab is used with interferon alfa for the first-line treatment of advanced and/or metastatic renal cell cancer (p. 708.3). Bevacizumab is also used for the treatment of progressive glioblastoma (see Malignant Neoplasms of the Brain, p. 701.2).

Bevacizumab is usually given diluted in 100 mL of sodium chloride 0.9%; the final concentration should be kept within the range of 1.4 to 16.5 mg/mL. The first dose should be given as an intravenous infusion over 90 minutes; if this is well tolerated the second dose should be given over 60 minutes, and if this is well tolerated then subsequent doses may be given over 30 minutes.

In the treatment of **colorectal cancer**, bevacizumab is given in a dose of 5 or 10 mg/kg once every 2 weeks, or 7.5 or 15 mg/kg once every 3 weeks; doses depend on the combination of drugs used in the regimen.

For **breast cancer**, the recommended dose of bevacizumab is 10 mg/kg given once every 2 weeks, or 15 mg/kg given once every 3 weeks.

For **non-small cell lung cancer**, the recommended dose of bevacizumab is 7.5 or 15 mg/kg given once every 3 weeks. In the UK, combination therapy is given for up to 6 cycles, followed by bevacizumab monotherapy until disease progression.

For **renal cell carcinoma**, bevacizumab is given in a dose of 10 mg/kg once every 2 weeks.

For **glioblastoma**, the recommended dose of bevacizumab is 10 mg/kg once every 2 weeks.

There are no recommended dose reduction regimens should adverse effects occur with bevacizumab; therapy should either be permanently stopped or temporarily suspended.

Bevacizumab is under investigation for various other neoplasms, including gastric, ovarian, and prostate cancer. A related monoclonal antibody, ranibizumab (p. 2602.1) has been developed for the treatment of neovascular (wet) age-related macular degeneration, and it has been suggested that bevacizumab might also be of benefit.

A drug-eluting stent containing bevacizumab is under investigation.

Administration. It has been suggested that bevacizumab may be safely given at an infusion rate of 500 micrograms/kg per minute; this means a dose of 5 mg/kg could be given over 10 minutes.[1]

1. Reidy DL, *et al.* Bevacizumab 5 mg/kg can be infused safely over 10 minutes. *J Clin Oncol* 2007; **25**: 2691–5.

Eye disorders. In addition to the conditions discussed below, bevacizumab is being tried in many eye disorders, mostly those associated with choroidal or retinal neovascularisation, or with macular oedema, but the number of patients is mostly small, with evidence limited to case reports or small case series.[1]

1. Gunther JB, Altaweel MM. Bevacizumab (Avastin) for the treatment of ocular disease. *Surv Ophthalmol* 2009; **54**: 372–400.

AGE-RELATED MACULAR DEGENERATION. Promising short-term results with intravenous[1,2] or intravitreal[3-9] bevacizumab to treat age-related macular degeneration (p. 880.2) or its complications were reported, and a controlled study[10] found its intravitreal use to be superior to pegaptanib or to photodynamic therapy with verteporfin. However, bevacizumab is unlicensed for this use and has been associated with adverse effects (see Effects on the Eyes, p. 748.1). Ranibizumab (p. 2602.1) is a humanised antibody fragment derived from bevacizumab that is licensed for the treatment of this disease. A multicentre comparative study[11] found that ranibizumab and bevacizumab, both given according to the same intravitreal schedule, had equivalent effects on visual acuity during 1 year of follow-up. No significant differences were seen between the 2 drugs in rates of death or thrombotic events, although the rate of serious systemic adverse events (mainly hospitalisation) was higher with bevacizumab.

GLAUCOMA. Neovascular glaucoma is a severe complication in patients affected by proliferative diabetic retinopathy or central retinal vein occlusion, and can result in complete loss of vision; treatment is unsatisfactory, and early diagnosis with aggressive control of intra-ocular pressure is crucial. In a small study of patients who had already undergone standard retinal ablative treatment, a total of 3 intravitreal injections of bevacizumab were given, at intervals of 4 weeks. Regression of corneal oedema with significant pain reduction was seen after the first injection, without any notable improvement in visual acuity; however, after the third injection, regression of iris neovascularisation as well as significant improvement of visual acuity was seen in most cases.[1]

1. Costagliola C, *et al.* Intravitreal bevacizumab (Avastin) injection for neovascular glaucoma: a survey on 23 cases throughout 12-month follow-up. *Br J Clin Pharmacol* 2008; **66**: 667–73.

PTERYGIUM. Bevacizumab has been investigated in the management of pterygium.[1]

RETINOPATHY OF PREMATURITY. For reference to the investigational use of bevacizumab in infants with retinopathy of prematurity see p. 2120.3.

Reperfusion and revascularisation procedures. Restenosis is a particular problem after percutaneous coronary revascularisation procedures (p. 1259.2) and various drugs have been tried for its prevention. Bevacizumab has been reported to be effective.[1]

1. Stefanadis C, *et al.* Avastin-eluting stent: long-term angiographic and clinical follow up. *Hellenic J Cardiol* 2008; **49**: 188–90.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bevacizumab may impair wound healing; therapy should not be started for at least 28 days after major surgery or until the surgical incision is fully healed; it should also be withheld before elective surgery. Gastrointestinal perforation complicated by intra-abdominal abscesses or fistula formation is more common in patients receiving bevacizumab; fatalities have been reported. Serious, and sometimes fatal, non-gastrointestinal fistulas can also occur, usually within the first 6 months of therapy. Bevacizumab should be stopped permanently in patients who develop gastrointestinal perforation, or fistulas, or wound dehiscence needing medical intervention. Very rare cases of nasal septum perforation have been reported.

Leucopenia, anaemia, neutropenia, thrombocytopenia, and febrile neutropenia have also occurred; severe neutropenia with infection has caused fatalities. Bevacizumab can cause two distinct patterns of bleeding. Minor

haemorrhage such as epistaxis may occur; severe or fatal bleeding including CNS haemorrhage and pulmonary haemorrhage presenting as haemoptysis has been reported. There is an increased risk of serious arterial and venous thromboembolic events associated with the use of bevacizumab including pulmonary embolism, stroke, transient ischaemic attacks, myocardial infarction, angina, and death. Bevacizumab may cause congestive heart failure; the risk is higher in those patients who have concurrent or previous treatment with anthracyclines. Hypertension, possibly dose-dependent, has occurred; blood pressure should be monitored, and therapy stopped in patients who develop hypertensive crisis or hypertensive encephalopathy.

Proteinuria may develop; bevacizumab should be stopped in patients who develop nephrotic syndrome. Other adverse effects include asthenia, pain, abdominal pain, gastrointestinal disturbances, stomatitis, headache, taste alteration, dyspnoea, lachrymation disorder, and exfoliative dermatitis. Peripheral sensory neuropathy, syncope, somnolence, supraventricular tachycardia, palmar-plantar erythrodysesthesia syndrome, myalgia, arthralgia, and muscular weakness have been commonly reported. Mucosal inflammation, dry skin, and skin discoloration are also common. Laboratory abnormalities reported include hyperglycaemia, decreased haemoglobin, hypokalaemia, hyponatraemia, and increased INR. Infusion reactions, manifesting as hypertension, hypoxia, wheezing, chest pain, headaches, rigors, and diaphoresis may occur rarely with the first dose of bevacizumab; treatment should be interrupted.

There have been rare reports of reversible posterior leukoencephalopathy syndrome, a neurological disorder; this may present as seizures, headache, altered mental status, visual disturbance, or cortical blindness, with or without associated hypertension. Bevacizumab therapy should be stopped, and patients treated symptomatically.

Effects on the cardiovascular system. For a discussion of the incidence of hypertension associated with use of bevacizumab, see Effects on the Kidneys, below.

Effects on the eyes. As of November 2008, the UK manufacturer of bevacizumab (*Roche, UK*) reported on 25 Canadian cases of adverse events after the unlicensed intravitreal use of the drug; symptoms included ocular irritation, photophobia, blurred vision, and floaters associated with mild to moderate anterior and posterior cellular inflammation.[1] The US manufacturer (*Genentech, USA*) reported that, as of December 2008, there had been 36 Canadian reports of intra-ocular adverse effects, of which 32 were serious intra-ocular inflammatory reactions, after intravitreal use of bevacizumab.[2] Other adverse reactions reported after intravitreal use include retinal pigment epithelial tear[3] and submacular haemorrhage[4] after use for age-related macular degeneration, and macular ischaemia[5] after use for central retinal vein occlusion in patients with diabetes and vascular disease; retinal detachment has occurred after use for proliferative diabetic retinopathy, when used as an adjunct to vitrectomy[6] and when used for neovascular glaucoma in one patient,[7] where it was associated with macular hole.

7. Mitamura Y, *et al.* Retinal detachment with macular hole following intravitreal bevacizumab in patient with severe proliferative diabetic retinopathy. *Br J Ophthalmol* 2008; 92: 717–18.

Effects on the kidneys. A systematic review and subsequent meta-analysis of 7 studies in 1850 patients with various cancers estimated the incidence and risk of developing hypertension and proteinuria with bevacizumab therapy.[1] The relative risk (RR) of developing proteinuria was 1.4 with low-dose bevacizumab (95% confidence interval 1.1 to 1.7) and even higher with high-dose therapy (RR 2.2; 95% confidence interval 1.6 to 2.9). For hypertension, the RR was 3.0 for low-dose bevacizumab (95% confidence interval 2.2 to 4.2) and 7.5 for high-dose therapy (95% confidence interval 4.2 to 13.4). US licensed product information states that hypertension can persist after stopping bevacizumab; therapy should be stopped permanently in those with hypertensive crisis or hypertensive encephalopathy. (For the suggestion that hypertension is a problem with angiogenesis inhibitors in general see Effects on the Cardiovascular System in Sorafenib, p. 858.2.) The safety of continued treatment in patients with moderate to severe proteinuria has not been evaluated; therapy should be interrupted if proteinuria is equal to or greater than 2 g per 24 hours, and may be resumed when it is less than this.

Nephrotic syndrome has also been reported with use of bevacizumab;[2,3] therapy should be stopped in these patients. In one case,[3] there was evidence of a haemolytic-uraemic syndrome; renal biopsy revealed a glomerular thrombotic microangiopathy. Bevacizumab was stopped, with favourable response; however, sunitinib therapy was started but had to be stopped due to a recurrence of severe haemolytic-uraemic syndrome.

A patient who received 3 doses of bevacizumab was diagnosed with acute renal failure secondary to interstitial nephritis. His renal function resolved slowly after stopping therapy; haemodialysis was required.[4]

Effects on the musculoskeletal system. Osteonecrosis of the jaw (similar to that seen with the bisphosphonates, see under Bisphosphonates, p. 1176.3) has been reported in 2 patients after bevacizumab therapy; neither patient had been treated with bisphosphonates.[1] Other cases have occurred when bevacizumab and bisphosphonates were given together; it has been postulated that anti-angiogenic agents such as bevacizumab and sunitinib (see also Effects on the Musculoskeletal System, under Sunitinib, p. 859.2) contribute to oral mucosal breakdown and subsequent development of osteonecrosis of the jaw.[2]

1. Estilo CL, *et al.* Osteonecrosis of the jaw related to bevacizumab. *J Clin Oncol* 2008; 26: 4037–8.
2. Ayllon J, *et al.* Osteonecrosis of the jaw under bisphosphonate and antiangiogenic therapies: cumulative toxicity profile? *Ann Oncol* 2009; 20: 600–1.

Effects on the nervous system. There are reports of reversible posterior leukoencephalopathy syndrome (RPLS) attributed to bevacizumab.[1,2] Presenting symptoms included lethargy, seizures, hypertension, acute bilateral loss of vision, headache, and confusion. Recovery was rapid after symptomatic treatment.

The symptoms of RPLS may be difficult to distinguish from those of uncontrolled hypertension, and patients presenting with the above signs and symptoms should be examined neurologically.[3]

3. Health Canada. Association of AVASTIN(bevacizumab) with hypertensive encephalopathy and reversible posterior leukoencephalopathy syndrome (RPLS) (issued 24th October 2006). Available at: http://www.hc-sc.gc.ca/dhp-mps/medeff/advisories-avis/public/_2006/avastin_pc-cp-eng.php (accessed 30/07/08)

Effects on the spleen. Splenic infarction has been reported in a patient given bevacizumab, fluorouracil, folinic acid, and irinotecan. Bevacizumab was stopped. Four further chemotherapy cycles were given. The splenic infarcts partially regressed, although the patient died from metastatic progression. The authors attributed the splenic infarction to bevacizumab, which has been associated with arterial thromboembolic events.[1]

1. Malka D, *et al.* Splenic infarction and bevacizumab. *Lancet Oncol* 2006; 7: 1038.

Fistula formation. US licensed product information for bevacizumab states that the incidence of gastrointestinal perforation, including fistula formation and/or intra-abdominal abscess, in bevacizumab-treated patients with colorectal cancer or non-small cell lung cancer was 2.4% and 0.9%, respectively. Reports of other types of fistulas such as bronchopleural, urogenital, and biliary fistulas, across various indications and mostly within the first 6 months of therapy, are less common; however, reports of tracheo-oesophageal fistula formation include some fatalities.[1,2] Therapy should be permanently stopped in patients with tracheo-oesophageal or gastrointestinal fistulas.

1. Roche, Canada. Health Canada endorsed Important safety information on AVASTIN (bevacizumab): association of AVASTIN (bevacizumab) with tracheo-esophageal fistula (issued June 2007). Available at: http://www.hc-sc.gc.ca/dhp-mps/alt_formats/hpfb-dgpsa/pdf/medeff/avastin_hpc-cps_2_e.pdf (accessed 13/06/07)
2. Genentech, USA. Important drug warning regarding AVASTIN (bevacizumab) (issued April 2007). Available at: http://www.fda.gov/downloads/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicinalProducts/ucm153953.pdf (accessed 21/07/10)

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies bevacizumab as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

The US manufacturer of bevacizumab has recommended that it should not be used with *sunitinib* after several patients receiving the combination had developed microangiopathic haemolytic anaemia.[1] UK licensed product information states that this was reversible upon stopping the 2 drugs.

1. Genentech, USA. Important drug warning subject: microangiopathic hemolytic anemia (MAHA) in patients treated with Avastin (bevacizumab) and sunitinib malate (issued July 2008). Available at: http://www.fda.gov/downloads/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicinalProducts/ucm126434.pdf (accessed 21/07/10)

Pharmacokinetics

Bevacizumab has a half-life of about 20 days. The predicted time to steady state is about 100 days. Male patients and those with a higher tumour burden have higher clearances of bevacizumab than females and those with tumour burdens below the median, respectively; although no evidence of lesser efficacy has been seen due to this higher clearance, the relationship between exposure to bevacizumab and clinical outcome is not known.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Avastin; *Austral.*: Avastin; *Austria*: Avastin; *Belg.*: Avastin; *Braz.*: Avastin; *Canad.*: Avastin; *Chile*: Avastin; *China*: Avastin (安维汀); *Cz.*: Avastin; *Denm.*: Avastin; *Fin.*: Avastin; *Fr.*: Avastin; *Ger.*: Avastin; *Gr.*: Avastin; *Hong Kong*: Avastin; *Hung.*: Avastin; *Indon.*: Avastin; *Irl.*: Avastin; *Israel*: Avastin; *Ital.*: Avastin; *Jpn*: Avastin; *Malaysia*: Avastin; *Mex.*: Avastin; *Neth.*: Avastin; *Norw.*: Avastin; *NZ*: Avastin; *Philipp.*: Avastin; *Pol.*: Avastin; *Port.*: Avastin; *Rus.*: Avastin (Авастин); *S.Afr.*: Avastin; *Singapore*: Avastin; *Spain*: Avastin; *Swed.*: Avastin; *Switz.*: Avastin; *Thai.*: Avastin; *Turk.*: Altuzan; *UK*: Avastin; *Ukr.*: Avastin (Авастин); *USA*: Avastin.

Bexarotene *(BAN, USAN, rINN)*

Beksaroteeni; Beksaroten; Bexaroten; Bexarotène; Bexaroteno; Bexarotenum; LG-100069; LGD-1069; Бексаротен.

p-[1-(5,6,7,8-Tetrahydro-3,5,5,8,8-pentamethyl-2-naphthyl)vinyl]benzoic acid.

$C_{24}H_{28}O_2$=348.5

CAS — 153559-49-0.

ATC — L01XX25.

ATC Vet — QL01XX25.

UNII — A61RXM4375.

Uses and Administration

Bexarotene is an agonist at the retinoid X receptor, which is involved in the regulation of cell differentiation and proliferation. It is used in the treatment of cutaneous T-cell lymphoma (see Mycosis Fungoides, p. 698.3), in a usual initial oral dose of 300 mg/m² daily as a single dose taken with a meal. Dosage is adjusted according to toxicity. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

For the topical treatment of refractory disease a 1% gel may be applied on alternate days for the first week, gradually increased at weekly intervals to up to 4 times daily, depending on tolerance.

Adverse Effects and Precautions

The main adverse effects noted after oral therapy with bexarotene include hyperlipidaemia, hypothyroidism, leucopenia, headache, oedema, altered liver function, rash, and pruritus. Exfoliative dermatitis, alopecia, and skin disorders may occur. Other common adverse effects include anaemia, insomnia, dizziness, eye or ear disorders, gastrointestinal disturbances, arthralgia, and myalgia. Acute pancreatitis has been associated with hypertriglyceridaemia, and patients with risk factors for pancreatitis should generally not be given bexarotene. If triglyceride concentrations rise during therapy, dose reductions are recommended, and lipid-lowering therapy may be instituted (with the exception of gemfibrozil, see below). The most common adverse events associated with topical therapy are rash, pruritus, and pain. Bexarotene capsules and gel should not be used during pregnancy because of the risk of fetal malformation.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies bexarotene as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

Gemfibrozil. Gemfibrozil inhibits clearance of bexarotene, resulting in extremely high triglyceride levels and pancreatitis.[1]

CAS — 90357-06-5.

ATC — L02BB03.

ATC Vet — QL02BB03.

UNII — A0Z3NAU9DP.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Bicalutamide). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in dehydrated alcohol and in dichloromethane; freely soluble in acetone.

USP 36: (Bicalutamide). A fine, white to off-white powder. Sparingly to slightly soluble in alcohol; freely soluble in acetone and in tetrahydrofuran; soluble in acetonitrile. Store in airtight containers.

Uses and Administration

Bicalutamide is a nonsteroidal anti-androgen with actions and uses similar to those of flutamide (p. 798.2). It is used orally in the treatment of prostatic cancer (p. 712.3). When used with a gonadorelin analogue in the palliative treatment of advanced prostatic cancer the usual dose is 50 mg daily. In the UK treatment is started at least 3 days before starting the gonadorelin analogue to suppress any flare reaction, but in the USA treatment is started at the same time. A similar dose is used with surgical castration, starting on the same day as surgery.

Bicalutamide in a dose of 150 mg daily may be given as monotherapy or adjuvant therapy to surgery or radiotherapy in men with locally advanced disease at high risk for disease progression. It has been used as monotherapy in localised disease, but there is some evidence to suggest that in men without high risk of disease progression, who would otherwise be managed with watchful waiting, the immediate use of bicalutamide may increase the risk of death.

Precocious puberty. Bicalutamide, with either anastrozole or letrozole, has been reported to be effective in the treatment of familial male precocious puberty (p. 2254.1); in 2 boys the combination therapy was well tolerated, stabilised bone-age advancement while allowing for continued normal linear growth, and prevented progression of virilisation.[1]

1. Lenz AM, *et al.* Bicalutamide and third-generation aromatase inhibitors in testotoxicosis. *Pediatrics* 2010; 126: e728–e733.

Adverse Effects and Precautions

As for Flutamide, p. 798.3. Pruritus, asthenia, alopecia, hair regrowth, and dry skin occur commonly with bicalutamide. Hypersensitivity reactions, including angioedema and urticaria, have been reported infrequently.

Cardiovascular effects including angina, heart failure, arrhythmias, and ECG changes have been reported rarely. Interstitial pneumonitis and pulmonary fibrosis have also been reported rarely.

Effects on the gastrointestinal tract. There is some evidence that bicalutamide is associated with a lower incidence of diarrhoea than flutamide.[1]

1. Schellhammer P, *et al.* A controlled trial of bicalutamide versus flutamide, each in combination with luteinizing hormone-releasing hormone analogue therapy, in patients with advanced prostate cancer. *Urology* 1995; 45: 745–52.

Effects on the liver. Fulminant hepatotoxicity has been reported with bicalutamide treatment. Despite stopping the drug the patient developed secondary multiorgan failure and died.[1]

1. O'Bryant CL, *et al.* Bicalutamide-associated fulminant hepatotoxicity. *Pharmacotherapy* 2008; 28: 1071–5.

Effects on the lungs. For a review of cases of pneumonitis associated with anti-androgens including bicalutamide, see under Flutamide, p. 798.3.

Gynaecomastia. For a discussion of gynaecomastia, a frequent adverse effect of anti-androgen therapy, and its management, see under Flutamide, p. 799.1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies bicalutamide as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Interactions

Bicalutamide inhibits various cytochrome P450 isoenzymes, particularly CYP3A4, *in vitro*, and licensed product information recommends that terfenadine, astemizole, and cisapride should not be given with bicalutamide, and that other drugs with a narrow therapeutic index that are metabolised by cytochrome P450 isoenzymes should be used with caution. *In vitro* studies have shown that bicalutamide can displace warfarin from its protein binding sites (see also Antineoplastics, p. 1532.2).

Pharmacokinetics

Bicalutamide is well absorbed after oral doses. It undergoes extensive metabolism in the liver, the active *R*-enantiomer mainly by oxidation, the inactive *S*-enantiomer mainly by glucuronidation. It is excreted as metabolites in urine and faeces. The half-life of the *R*-enantiomer is about 6 to 7 days, and may be prolonged still further in severe hepatic impairment. The *S*-enantiomer is cleared more rapidly. Bicalutamide is about 96% bound to plasma proteins.

Pharmacopoeial Preparations
BP 2014: Bicalutamide Tablets;
USP 36: Bicalutamide Tablets.

Bleomycin Sulfate *(BANM, USAN, pINNM)*

Bleomicina, sulfato de; Bleomicino sulfatas; Bleomicin-szulfát; Bleomycin Sulphate; Bleomycine, Sulfate de; Bleomycini Sulfas; Bleomycinsulfat; Bleomycin-sulfat; Bleomysinisulfaatti; Sulfato de bleomicina; Блеомицина Сульфат.

CAS — 11056-06-7 (bleomycin); 67763-87-5 (bleomycin hydrochloride); 9041-93-4 (bleomycin sulfate).

ATC — L01DC01.

The symbol † denotes a preparation no longer actively marketed

ATC Vet — QL01DC01
UNII — 7DP3NTV15T

Pharmacopoeias. In *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Int. and *Jpn* also include Bleomycin Hydrochloride. *Chin.* includes Bleomycin A5 Hydrochloride for Injection.

Ph. Eur. 8: (Bleomycin Sulfate). The sulfate of a mixture of glycopeptides obtained by the growth of *Streptomyces verticillus* or by any other means; the two principal components of the mixture are *N*-[3-(dimethylsulphonio) propyl]bleomycinamide (bleomycin A_2) and *N*-[4-(carbamimidoylamino)butyl]bleomycinamide (bleomycin B_2). A white or yellowish-white, very hygroscopic powder. It loses not more than 3% of its weight when dried. Very soluble in water; slightly soluble in dehydrated alcohol; practically insoluble in acetone. A 0.5% solution in water has a pH of 4.5 to 6.0. Store in airtight containers at a temperature of 2 degrees to 8 degrees.

USP 36: (Bleomycin Sulfate). The sulfate salt of a mixture of basic cytotoxic glycopeptides, produced by the growth of *Streptomyces verticillus* or produced by other means. It has a potency of not less than 1.5 units and not more than 2.0 units/mg. It contains between 55 and 70% of bleomycin A_2 and between 25 and 32% of bleomycin B_2; the content of bleomycin B_4 is not more than 1%. The combined percentage of bleomycin A_2 and B_2 is not less than 90%. A cream-coloured, amorphous powder. It loses not more than 6% of its weight when dried. Very soluble in water. A solution in water containing 10 units/mL has a pH of 4.5 to 6.0. Store in airtight containers.

Incompatibility. A loss of bleomycin activity was reported when bleomycin sulfate solutions were mixed with solutions of carbenicillin, cefazolin or cefalotin sodium, nafcillin sodium, benzylpenicillin sodium, methotrexate, mitomycin, hydrocortisone sodium succinate, aminophylline, ascorbic acid, or terbutaline.[1] The interactions of bleomycin have been summarised as the chelation of divalent and trivalent cations (especially copper), inactivation by compounds containing sulfhydryl groups, and precipitation by hydrophobic anions; solutions of bleomycin should not be mixed with solutions of essential amino acids, riboflavin, dexamethasone, or furosemide.[2]

2. D'Arcy PF. Reactions and interactions in handling anticancer drugs. *Drug Intell Clin Pharm* 1983; 17: 532–8.

Stability. Bleomycin sulfate solutions appear to be equally stable in plastic or glass,[1,2] despite some earlier studies suggesting loss of potency in plastic.[3,4] There is some evidence[5] that bleomycin is more stable in sodium chloride 0.9% than glucose 5%, and sodium chloride 0.9% is the diluent recommended by the licensed product information. UK licensed product information states that bleomycin sulfate is chemically and physically stable, once reconstituted and diluted as directed, for 10 days when refrigerated at 2 degrees to 8 degrees and protected from light. From a microbiological point of view, solutions should be used immediately; storage for longer than 24 hours at 2 degrees to 8 degrees is not recommended, unless prepared under controlled and validated aseptic conditions.

Units

8910 units of bleomycin complex A_2/B_2 are contained in 5 mg of bleomycin complex in one ampoule of the first International Reference Preparation (1980). The Ph. Eur. 8 specifies a potency of not less than 1500 international units per mg, calculated with reference to the dried substance. These units differ from those used by the USP: Bleomycin Sulfate (USP 36) contains 1.5 to 2.0 units of bleomycin in each mg. A change in the labelling of preparations in the UK, from units equivalent to those of the USP to international units in line with the Ph. Eur., resulted in an apparent but artefactual increase in UK doses by a factor of 1000.

In some countries doses were *formerly* described in terms of mg-potency, where 1 mg-potency corresponded to 1 unit. In the original preparation 1 mg-potency was equivalent to 1 mg-weight but improvements in purification of the product led to a situation in which ampoules labelled as containing 15 mg (i.e. 15 units) contained far fewer mg-weight of bleomycin.

Uses and Administration

Bleomycin is an antineoplastic antibiotic that binds to DNA and causes strand scissions, and is probably most effective in the G_2 and M phases of the cell cycle. It is widely used to treat malignant disease; particularly squamous cell carcinomas, including those of the cervix and external genitalia, oesophagus, skin, and head and neck; Hodgkin's disease and other lymphomas; malignant neoplasms of the testis, and malignant effusions. It has also been tried in other malignancies, including carcinoma of the bladder, lung, and thyroid, and some sarcomas, including Kaposi's sarcoma.

Bleomycin is often used with other antineoplastics, notably with doxorubicin, vinblastine, and dacarbazine (ABVD) for Hodgkin's disease, and with etoposide and cisplatin (BEP) in testicular tumours. Bleomycin is given as the sulfate by either the intramuscular, intravenous, or subcutaneous route. It may also be given intra-arterially or instilled intrapleurally or intraperitoneally. If intramuscular injections are painful they may be given in a 1% solution of lidocaine.

Doses are calculated in terms of the base, and are given in units, but the units used for preparations in the UK, which were formerly equivalent to those of the USP, are now international units equivalent to those of the Ph. Eur. (see Units, above). Since 1000 international units is equivalent to 1 USP unit, UK doses now appear to be 1000 times greater than those previously in use, or than those in use in the USA, and care is recommended in evaluating the literature.

In the UK the licensed dose as a single agent for **squamous cell** or **testicular tumours** is 15 000 international units (15 USP units) three times a week, or 30 000 international units twice a week, by intramuscular or intravenous injection, although in practice treatment of malignancy will generally be with combination regimens. This may be repeated, at usual intervals of 3 to 4 weeks, up to a total cumulative dose of 500 000 international units. The dose and total cumulative dose should be reduced in those over 60 years of age (see below). Doses should be adjusted according to tolerance, and may need to be adjusted as part of combination chemotherapy. Continuous intravenous infusion at a rate of 15 000 international units per 24 hours for up to 10 days or 30 000 international units per 24 hours for up to 5 days may also be used. In patients with **lymphoma** a dose of 15 000 international units once or twice weekly by intramuscular injection has been suggested, to a total dose of 225 000 international units. Again, dosage should be reduced in older patients and in combination regimens if necessary. In the treatment of **malignant effusions** a solution of 60 000 international units in 100 mL of sodium chloride 0.9% may be instilled into the affected serous cavity. Treatment may be repeated as necessary up to a total cumulative dose of 500 000 international units depending on the patient's age. Local anaesthetics or analgesics are given concomitantly.

In the USA licensed doses for **lymphomas** as well as **squamous cell** and **testicular** neoplasms are 250 to 500 international units/kg (0.25 to 0.5 USP units/kg), or 10 000 to 20 000 international units/m^2 (10 to 20 USP units/m^2), given once or twice weekly by slow intravenous, intramuscular, or subcutaneous injection. In view of the risk of an anaphylactoid reaction it has been suggested that patients with lymphomas should receive two test doses of 2000 international units (2 USP units) or less initially (but see Administration, below). In patients with Hodgkin's disease, once a 50% response has been achieved it may be maintained with 1000 international units (1 USP unit) of bleomycin daily, or 5000 international units (5 USP units) weekly by slow intravenous or intramuscular injection.

In the UK, licensed product information suggests that a **total dose** of 500 000 international units (500 USP units) should not be exceeded. Total cumulative dose should not exceed 300 000 international units in those aged 60 to 69 years, 200 000 international units in those 70 to 79, and 100 000 international units in those 80 and over; the weekly dose should be no more than 60 000, 30 000 and 15 000 international units respectively. In the USA the recommended maximum total dose is 400 000 international units (400 USP units); it is generally agreed that patients receiving 400 000 international units or more are at increased risk of pulmonary toxicity (see Adverse Effects, p. 751.1).

Dosage should be reduced in patients with renal impairment (see below).

Bleomycin hydrochloride has also been given parenterally for malignant neoplasms, and bleomycin sulfate has been applied topically for the local treatment of skin tumours.

Administration. Although test doses have been suggested as a way of avoiding anaphylactoid reactions in patients with lymphoma being treated with bleomycin, a review[1] of the literature concluded that the evidence did not support such a strategy, since the onset of the reaction was unpredictable, and not associated with any particular dose. It had also been suggested that reactions were less frequent with intramuscular rather than intravenous dosage, but evidence for this was conflicting.

There is some suggestion that giving bleomycin by intravenous infusion rather than bolus injection in combination regimens may result in reduced pulmonary toxicity.[2,3]

Intralesional bleomycin is generally well tolerated; its uses by this route, which include malignancies and non-malignant skin conditions such as warts (p. 751.1) have been reviewed.[4]

4. Saitta P, *et al.* Bleomycin in dermatology: a review of intralesional applications. *Dermatol Surg* 2008; 34: 1299–1313.

Administration in renal impairment. A significant portion of a dose of bleomycin is excreted largely unchanged in the urine, and dose reduction should be considered in patients with renal impairment. UK licensed product information suggests a 50% dose reduction when the serum creatinine concentration is between 20 and 40 micrograms/mL and further reduction for serum creatinine above this. US licensed product information gives the following proposed percentages of the initial dose, based on creatinine clearance (CC):

- CC 5 to 10 mL/minute: 40%
- CC 10 to 20 mL/minute: 45%
- CC 20 to 30 mL/minute: 55%
- CC 30 to 40 mL/minute: 60%
- CC 40 to 50 mL/minute: 70%
- CC 50 mL/minute and above: 100%

Leucoplakia. Leucoplakia is used to describe a white patch or plaque in the mouth which cannot be otherwise characterised. Such lesions are of concern because they may be pre-malignant, and patients with evidence of dysplasia may be at higher risk of transformation (see also Malignant Neoplasms of the Head and Neck, p. 708.1). Leucoplakia must be distinguished from other conditions such as candidiasis, lichen planus, and oral hairy leucoplakia which is associated with HIV infection.[1]

Leucoplakia is often associated with tobacco smoking, and smoking cessation can result in regression.[1] Where active treatment is desirable, small and easily accessible lesions can be removed surgically or by laser therapy, although they may recur.[1] For extensive patches or those in which surgery would be difficult, the treatments described include topical bleomycin 1%, dissolved in dimethylsulfoxide and applied for 5 minutes daily for 14 consecutive days. In a group of 19 patients with dysplastic leucoplakia improvement in the appearance of lesions and histological evidence of remission of the dysplasia occurred in the majority of patients. Sustained effects were also found on long-term follow-up for up to 10 years.[2]

There have been reports of partial or complete remission of leucoplakia in studies of vitamin A or betacarotene given orally long-term,[3-5] but lesions have recurred when supplementation was stopped.[4] Topical treatment with retinoids such as tretinoin or isotretinoin has also been tried, with similar results to those of oral vitamin A and retinoid treatments.[6,7] A small open study has also suggested that topical calcipotriol may be effective.[8]

A systematic review of treatments for leucoplakia found that there were few controlled studies, and that although these treatments might be effective in the resolution of lesions, the rate of relapse was high, and there was no evidence that they prevent malignant transformation.[9]

Malignant effusions. Bleomycin is used for the sclerotherapy of malignant pleural and pericardial effusions (p. 700.1).

Malignant neoplasms. Bleomycin is used in regimens for the management of Hodgkin's disease (p. 696.1), non-Hodgkin's lymphomas such as AIDS-related lympho-

mas (see p. 697.2), and for germ-cell tumours of the ovary and testis (see p. 711.2, and p. 715.1), as well as for some other malignancies including those of the head and neck, (p. 708.1), and Kaposi's sarcoma (p. 718.1).

Pneumothorax. In a patient with AIDS and pneumocystis pneumonia who developed pneumothorax, instillation of bleomycin into each pleural cavity was successful in resolving the pneumothorax after tetracycline sclerotherapy failed to do so.[1]

1. Knatiuk OW, *et al.* Bleomycin sclerotherapy for bilateral pneumothoraces in a patient with AIDS. *Ann Intern Med* 1990; 113: 988–90.

Warts. Several studies have examined the local use of bleomycin sulfate to treat severe or resistant warts (p. 1689.3) of the common, plane, plantar, eponychial, and mosaic types, usually by intralesional injection.[1-4] At the doses used, adverse effects, other than pain at the injection site,[1-3] do not seem to be common; however, nail dystrophy and Raynaud's phenomenon have been reported (see under Effects on the Skin, Hair, and Nails and Effects on the Vascular System, under Adverse Effects, below). Bleomycin has also been applied as a pressure-sensitive adhesive tape,[5] and various techniques for better intralesional use have been investigated.[6-8]

Adverse Effects and Treatment

For a general outline see Antineoplastics, p. 726.1 and p. 730.2.

The most frequent adverse effects with bleomycin involve the skin and mucous membranes and include rash, erythema, pruritus, vesiculation, hyperkeratosis, nail changes, alopecia, hyperpigmentation, striae, and stomatitis. Fever is also common, and acute anaphylactoid reactions with hyperpyrexia and cardiorespiratory collapse have been reported in about 1% of patients with lymphoma. There is little depression of the bone marrow. Local reactions and thrombophlebitis may occur at the site of parenteral dosage.

The most serious delayed effect is pulmonary toxicity; interstitial pneumonitis occurs in about 10% of patients and progresses to fibrosis and death in about 1% of patients treated with bleomycin. Pulmonary toxicity is more likely in elderly patients and those given total doses greater than 400 000 international units (400 USP units). It is also more likely in patients who have had previous radiotherapy to the chest.

Effects on the lungs. Pneumonitis induced by bleomycin can progress to fatal pulmonary fibrosis. The presentation is often delayed; clinical manifestations include non-productive cough, dyspnoea, and sometimes fever (see Effects on the Lungs, p. 729.1). Pneumomediastinum has also been reported as an initial manifestation of fatal pulmonary toxicity due to bleomycin.[1] Risk factors for toxicity include increased age,[2,3] deteriorating renal function,[2] and concurrent or previous radiotherapy. The reaction is dose-related, and maximum doses have been set (see Uses and Administration, p. 750.2). Other factors that may be implicated include the regimen used, concomitant oxygen supplementation, smoking history, underlying lung disease, and growth factor support.[2,3] For further details of some of these risk factors, see under Interactions, below. There is no standard treatment for bleomycin-induced pneumonitis. Bleomycin therapy is usually stopped, and corticosteroids may be given[3] although strong evidence to support their use is lacking.[2] There is some suggestion that giving bleomycin by intravenous infusion rather than bolus injection may reduce pulmonary toxicity.[2]

2. Sleijfer S. Bleomycin-induced pneumonitis. *Chest* 2001; 120: 617–24.
3. Martin WG, *et al.* Bleomycin pulmonary toxicity has a negative impact on the outcome of patients with Hodgkin's lymphoma. *J Clin Oncol* 2005; 23: 7614–20.

Effects on the skin, hair, and nails. Permanent nail loss and nail loss followed by regrowth with dystrophy have been reported after intralesional injection of bleomycin for periungual warts.[1-3] In 2 cases this was preceded by blistering and ulceration,[1] or swelling, severe pain, and a burning sensation.[2] All 3 patients had received injections on one or two previous occasions when 2 patients had reported only mild pain.[1,3] Other reported cutaneous adverse effects of bleomycin include flagellate erythema, Raynaud's phenomenon, gangrene, fibrotic or sclerotic skin changes, hyperpigmentation, and neutrophilic eccrine hidradenitis (an inflammatory dermatosis with erythematous plaques and nodules, neutrophilic infiltrates of eccrine glands, and degeneration of eccrine cells). Acute generalised exanthematous pustulosis and alopecia have also been reported.[4]

Effects on the vascular system. Although thromboembolic disorders and Raynaud's syndrome have been associated with use of bleomycin in combination regimens, particularly with cisplatin and the vinca alkaloids or etoposide (see Effects on the Cardiovascular System, p. 727.2) there is some evidence for an association of Raynaud's syndrome with the use of bleomycin alone.[1,2]

There have also been cases of Raynaud's phenomenon reported after intralesional injection of bleomycin for treatment of warts on the hands and feet.[3-6] See also Effects on the Skin, Hair, and Nails, above.

Precautions

For reference to the precautions necessary with antineoplastics, see p. 732.2.

Bleomycin should be used with caution in the elderly, in patients with renal impairment or pulmonary infection or pre-existing impairment of pulmonary function, and in those who have received radiotherapy, particularly to the thorax. Patients should undergo regular chest X-rays. If these show infiltrates, or if breathlessness occurs, bleomycin should be stopped.

In view of the risk of an anaphylactoid reaction it has been suggested that patients with lymphomas should receive two test doses of 2000 international units (2 USP units) or less initially (but see Administration, p. 750.2).

AIDS. Cutaneous adverse effects occurred in 12 of 50 patients being treated with bleomycin for AIDS-associated Kaposi's sarcoma and increased in severity until bleomycin was withdrawn.[1] Bleomycin should be stopped in people with AIDS if cutaneous adverse effects are seen, and rechallenge should be avoided. However, the incidence of adverse effects did not appear to be higher in these patients than in cancer patients, and patients with AIDS seem to be less sensitive to bleomycin than to antibacterials such as co-trimoxazole and penicillins.

1. Caumes E, *et al.* Cutaneous side-effects of bleomycin in AIDS patients with Kaposi's sarcoma. *Lancet* 1990; 336: 1593.

Diving. Since the partial pressure of oxygen in the inspired air of a scuba diver increases with increasing depth, a theoretical possibility exists of a toxic [pulmonary] reaction to oxygen in bleomycin-treated patients who subsequently go diving, and such a risk would increase with the depth and duration of each dive.[1] However, the risks associated with diving after uncomplicated bleomycin-based treatment have been questioned;[2] the authors considered that resuming diving was acceptable 6 to 12 months after completing treatment with BEP (bleomycin, etoposide, and cisplatin), and recommended caution only in those who developed pulmonary function impairment when given bleomycin.

Handling and disposal. *Urine* produced for up to 72 hours after a dose of bleomycin should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies bleomycin as not porphyrinogenic: it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pregnancy. For a report of use of a bleomycin-containing chemotherapy regimen in a pregnant woman and subsequent adverse effects on the infant, see Pregnancy, under Cisplatin, p. 768.2. No adverse effects were reported in another infant whose mother was treated with combination chemotherapy containing bleomycin, see Pregnancy, under Teniposide, p. 867.2.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. There may be an increased risk of pulmonary toxicity in patients given bleomycin who receive oxygen, for example as part of a general anaesthetic procedure; a reduction in inspired oxygen concentration has been recommended.

Antineoplastics. Enhanced pulmonary toxicity, in some cases fatal, has been reported in patients given bleomycin and *cisplatin*,[1-4] presumably because cisplatin-induced renal impairment led to a decrease in bleomycin elimination. It seems reasonable to assume that similar interactions might occur if bleomycin were given with other nephrotoxic agents. It has been suggested that apart from a decrease in bleomycin dosage if nephrotoxicity occurs with such a combination, giving bleomycin by constant infusion rather than intermittent bolus might be less toxic.[1,5]

A study to investigate whether substitution of etoposide with *gemcitabine* would lead to a less leukaemogenic BEACOPP regimen was stopped early because of unexpectedly common pulmonary toxicity; one patient died. This toxicity was considered to be due to the use of gemcitabine with bleomycin.[6]

Bredenfeld H, *et al.* Severe pulmonary toxicity in patients with advanced-stage Hodgkin's disease treated with a modified bleomycin, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone, and gemcitabine (BEACOPP) regimen is probably related to the combination of gemcitabine and bleomycin: a report of the German Hodgkin's Lymphoma Study Group. *J Clin Oncol* 2004; 22: 2424–9.

Colony-stimulating factors. An increased incidence of pulmonary toxicity has been reported in patients receiving bleomycin as part of the ABVD regimen (with doxorubicin, vinblastine, and dacarbazine) who were given granulocyte colony-stimulating factor to alleviate neutropenia.[1] Another case of rapidly developing and fatal pneumonitis in a patient given BEP (bleomycin, etoposide, and cisplatin) with granulocyte colony-stimulating factor has been reported.[2]

Analyses of study data failed to show increased pulmonary toxicity when granulocyte colony-stimulating factor was added to bleomycin-containing regimens in patients with germ cell tumours or non-Hodgkin's lymphomas.[3-5] In a retrospective review of patients with Hodgkin's lymphoma, however, use of bleomycin with granulocyte colony-stimulating factor was associated with a statistically significant increase of pulmonary toxicity.[6]

6. Martin WG, *et al.* Bleomycin pulmonary toxicity has a negative impact on the outcome of patients with Hodgkin's lymphoma. *J Clin Oncol* 2005; 23: 7614–20.

Oxygen. Because bleomycin is thought to cause pulmonary toxicity partly by induction of free radicals, use with high concentrations of oxygen could be hazardous,[1] and reductions in inspired oxygen concentration have been recommended by licensed product information where oxygen supplementation is unavoidable. *Animal* studies show an increased risk of mortality with use of bleomycin and oxygen, although data in humans are lacking. The

need for oxygen restriction in bleomycin-treated patients has, however, been questioned.[2]

1. Sleijfer S. Bleomycin-induced pneumonitis. *Chest* 2001; 120: 617–24.
2. Donat SM, Levy DA. Bleomycin associated pulmonary toxicity: is perioperative oxygen restriction necessary? *J Urol (Baltimore)* 1998; 160: 1347–52.

Pharmacokinetics

Bleomycin is thought to be poorly absorbed from the gastrointestinal tract. Absorption is rapid after parenteral, intraperitoneal, or intrapleural use. Bioavailability is 100% and 70% after intramuscular and subcutaneous dosage, respectively. A bioavailability of 45% has been reported after intraperitoneal or intrapleural use. Plasma protein binding is low. Enzymic degradation by bleomycin hydrolase occurs, mainly in plasma, the liver and other organs, and to a much lesser extent in skin and lungs. Elimination is biphasic: mean initial and terminal half-lives of 0.5 and 4 hours respectively have been reported after an intravenous bolus. Elimination may be more prolonged after continuous intravenous infusion and mean half-lives of 1.3 and 9 hours respectively have been reported. About two-thirds of a dose is excreted unchanged in the urine; the rate of excretion is determined by renal function. Drug concentrations in the CSF are low. Bleomycin crosses the placenta.

Genetic factors. Bleomycin is inactivated by bleomycin hydrolase (BLMH). Since response to chemotherapy may be determined by gene polymorphisms involved in metabolism, a study investigated whether the single nucleotide polymorphism (SNP) A1450G of the BLMH gene was associated with survival in patients with testicular cancer treated with bleomycin-containing chemotherapy. The homozygous variant G/G of this SNP was found to be associated with reduced survival and a higher prevalence of early relapses. The authors cautioned that this finding was hypothesis-generating and not yet clinically applicable.[1]

CAS — 179324-69-7

ATC — L01XG32

ATC Vet — QL01XG32

UNII — 69G8BD63PP

Uses and Administration

Bortezomib is a reversible inhibitor of the 26S proteasome, a large protein complex in cells that is responsible for breaking down regulatory proteins of the cell cycle. Such inhibition disrupts tumour cell turnover and induces apoptosis. Bortezomib is used for the treatment of multiple myeloma (p. 699.2), either in combination with melphalan and prednisone for previously untreated patients or as monotherapy in relapsed/refractory multiple myeloma. In the USA, it is also used for mantle cell lymphoma in patients given at least one previous therapy.

In previously untreated multiple myeloma, an initial dose of bortezomib 1.3 mg/m² is given intravenously on days 1, 4, 8, 11, 22, 25, 29, and 32 of a 42-day cycle for 4 cycles. For the next 5 cycles, bortezomib is given at the same dose on days 1, 8, 22, and 29. Melphalan (9 mg/m²) and prednisone (60 mg/m²) are given orally on days 1 to 4 of each cycle.

For relapsed/refractory multiple myeloma and mantle cell lymphoma, bortezomib is given in initial bolus doses of 1.3 mg/m² intravenously on days 1, 4, 8, and 11 of a 21-day cycle. At least 72 hours should elapse between consecutive doses of bortezomib. In the UK, licensed product information recommends that patients with a confirmed complete response should receive 2 additional cycles of bortezomib, and that those who respond but do not achieve complete remission receive a total of 8 cycles. In the USA, extended therapy of more than 8 cycles may be given, either on the standard schedule recommended above, or on a maintenance schedule of one dose weekly for 4 weeks (days 1, 8, 15, and 22 of a 35-day cycle).

Before combination treatment, the platelet count should be ≥70 000 cells/mm³ and the absolute neutrophil count should be ≥1000 cells/mm³. Whether used in combination or as monotherapy, the bortezomib dose should be withheld, reduced, or treatment withdrawn, according to toxicity, particularly when peripheral neuropathy, neuropathic pain, and haematological toxicity occur (see Administration in Subsequent Cycles, below).

See also below for use in patients with hepatic impairment.

Bortezomib is under investigation for the treatment of other malignancies including non-Hodgkin's lymphoma. A subcutaneous formulation is also under investigation.

Administration. Although licensed product information recommends no dose reduction of bortezomib for the elderly on the basis of age alone, toxicity often limits its use and reduced-intensity regimens have been investigated.[1-3] In combination treatment for elderly patients with untreated multiple myeloma, use of a once-weekly bortezomib regimen was well-tolerated without apparent detriment to efficacy (compared with the conventional initial twice-weekly schedule, see Uses and Administration, above).[1,2] In a retrospective review of elderly patients with relapsed disease, a once-weekly regimen of bortezomib was given with dexamethasone to patients with a median age of 80 years; toxicity and efficacy were comparable to a control cohort (median age 61 years) who were given the standard initial twice-weekly regimen (see Uses and Administration, above).[3]

Mateos M-V, *et al.* Bortezomib, melphalan, and prednisone versus bortezomib, thalidomide, and prednisone as induction therapy followed by maintenance treatment with bortezomib and thalidomide versus bortezomib and prednisone in elderly patients with untreated multiple myeloma: a randomised trial. *Lancet Oncol* 2010; 11: 934–41.
2. Bringhen S, *et al.* Efficacy and safety of once-weekly bortezomib in multiple myeloma patients. *Blood* 2010; 116: 4745–53.
3. Parrish C, *et al.* Feasibility and efficacy of administration of bortezomib-containing regimens to patients over the age of 70 years. *Br J Haematol* 2011; 153: 273–5.

ROUTE. A randomised study in patients with relapsed multiple myeloma found that subcutaneous bortezomib had similar efficacy to intravenous use.[1] The subcutaneous route also seemed to have a better systemic safety profile than intravenous bortezomib; peripheral neuropathy (of all grades) was significantly less, and overall rates of gastrointestinal disorders, respiratory, and nervous system disorders were also lower with subcutaneous use. Systemic exposure was similar between routes; peak plasma concentrations were lower but more sustained with subcutaneous use.

1. Moreau P, *et al.* Subcutaneous versus intravenous administration of bortezomib in patients with relapsed multiple myeloma: a randomised, phase 3, non-inferiority study. *Lancet Oncol* 2011; 12: 431–40.

Administration in hepatic impairment. Bortezomib exposure is increased in patients with moderate or severe hepatic impairment and close monitoring is recommended. In the UK and USA, specific recommendations are made according to the severity of impairment, defined by bilirubin and aspartate aminotransferase (AST/SGOT) concentrations:

- mild impairment, bilirubin ≤ the upper limit of normal (ULN) with AST > the ULN, or bilirubin > the ULN up to 1.5 times the ULN with any AST concentration: no dose modification required.
- moderate and severe impairment, bilirubin > 1.5 times the ULN with any AST concentration: reduce dose in the first cycle to bortezomib 700 micrograms/m² intravenously; in subsequent cycles doses can be increased up to 1 mg/m² or reduced to 500 micrograms/m² depending on tolerance.

See Uses and Administration, above for further details of dosing regimens.

Administration in subsequent cycles. When intravenous bortezomib is used *with melphalan and prednisone* for previously untreated multiple myeloma patients:

- if prolonged grade 4 neutropenia or thrombocytopenia, or thrombocytopenia with bleeding is seen in one cycle: consider reduction of the *melphalan* dose by 25% in the next cycle
- if the platelet count ≤ 30 000 cells/mm³ or absolute neutrophil count ≤ 750 cells/mm³ on a bortezomib dosing day (other than day 1): withhold bortezomib
- if several bortezomib doses in a cycle (≥ 3 doses during twice weekly dosing, or ≥ 2 doses during weekly dosing) or consecutive cycles are withheld: the bortezomib dose should be reduced by 25% (1.3 mg/m² to 1 mg/m²; 1 mg/m² to 700 micrograms/m²)

For grade 3 or more severe non-haematological toxicity (excluding neuropathy), dose modifications are as for patients on monotherapy, below

When used as *monotherapy* in relapsed/refractory multiple myeloma and mantle cell lymphoma, bortezomib should be withheld at the onset of any grade 3 non-haematological (excluding neuropathy) or grade 4 haematological toxicities. Once the toxicity has resolved, bortezomib may be restarted at a dose reduced by 25% (1.3 mg/m² to 1 mg/m²; 1 mg/m² to 700 micrograms/m²)

For those who have neuropathic pain and/or peripheral (sensory or motor) neuropathy, *whether treated with bortezomib monotherapy or as part of a combination regimen* the following dose modifications are recommended:

- grade 1 with pain, or grade 2: reduce bortezomib dose to 1 mg/m²
- grade 2 with pain, or grade 3: withhold bortezomib until toxicity resolves; restart with a reduced dose of 700 micrograms/m² and change treatment schedule to once weekly
- grade 4 (disabling sensory neuropathy or life-threatening motor neuropathy or paralysis): stop bortezomib

Adverse Effects, Treatment, and Precautions

For a general outline see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Very common adverse effects of bortezomib include haematological toxicities (especially transient thrombocytopenia, neutropenia, and anaemia), decreased appetite, gastrointestinal disturbances, peripheral neuropathy, fatigue, fever, headache, dyspnoea, and rash. Complete blood counts including platelet counts should be monitored and therapy withheld or given at reduced doses if necessary. Peripheral neuropathy may also be dose-limiting.

Other common adverse effects include hyperglycaemia, hypokalaemia, insomnia, anxiety, confusion, depression, dry mouth, blurred vision, eye pain, vertigo, dizziness, dysgeusia, tremor, epistaxis, cough, rhinorrhoea, pruritus, urticaria, erythema, and oedema. Orthostatic hypotension is also common and may require treatment; caution is advised in patients with a history of syncope, those who are dehydrated, or those who take antihypertensives. Dizziness, orthostatic hypotension, fatigue, or blurred vision can affect the performance of tasks such as driving. Hypertension is also common. Musculoskeletal adverse effects such as myalgia, arthralgia, bone pain, and cramps are often reported.

Tachycardia, arrhythmias, palpitations, angina pectoris, atrial fibrillation, and myocardial infarction have occurred. There have been isolated cases of QT-interval prolongation but causality has not been confirmed. Congestive heart failure may develop or be exacerbated and pulmonary oedema has been reported. There are rare reports of pericarditis. Pulmonary disease such as pneumonitis has

occurred, and there have been rare reports of acute respiratory distress syndrome, some of them fatal. Bortezomib should not be used in patients with acute diffuse pulmonary or pericardial disease. Renal impairment is common in patients with multiple myeloma and acute renal failure has developed in patients on bortezomib. Dysuria is also common; urinary frequency or incontinence, urinary retention, haematuria, proteinuria, and haemorrhagic cystitis have been reported. Hepatotoxicity, which may be reversible, has included increases in liver enzyme values, hyperbilirubinaemia, and acute liver failure; bortezomib should be used with caution in hepatic impairment.

Tumour lysis syndrome may occur during bortezomib treatment, and those with a high tumour burden should be monitored closely. Immune-mediated reactions such as anaphylaxis, angioedema, serum-sickness-type reactions, polyarthritis with rash, and proliferative glomerulonephritis have been reported; bortezomib should be stopped if serious reactions occur. Reversible posterior leukoencephalopathy syndrome has occurred rarely and therapy should again be stopped; symptoms include seizures, hypertension, headache, blindness, and confusion. Bacterial, viral, and fungal infections have been reported in patients on bortezomib. Reactivation of latent herpes zoster infection can occur and prophylaxis with antivirals is recommended.

Other adverse effects that have been reported include injection site reactions, electrolyte disturbances, paralysis, disseminated intravascular coagulation, hearing impairment, thrombotic or bleeding events, ischaemic colitis, paralytic ileus, acute pancreatitis, pulmonary hypertension, Sweet's syndrome (acute febrile neutrophilic dermatosis), Stevens-Johnson syndrome, and toxic epidermal necrolysis. Photosensitivity reactions, alopecia, and erectile dysfunction have also been reported.

Effects on the nervous system. Treatment with bortezomib is often associated with peripheral neuropathy, mainly sensory, although cases of motor neuropathy have been reported. A review[1] identified risk factors for bortezomib-induced peripheral neuropathy as pre-existing neuropathy and comorbidities that cause nerve damage such as diabetes. The incidence of neuropathy with bortezomib is also higher in patients with multiple myeloma compared with solid tumours. Furthermore, high rates of peripheral neuropathy have been reported in newly diagnosed multiple myeloma patients before treatment. Results from an analysis[2] in relapsed and/or refractory multiple myeloma patients also found that the peripheral neuropathy associated with bortezomib seemed to be cumulative and dose-related, and increased in prevalence through the first 5 treatment cycles. Prolonged bortezomib exposure beyond this time did not seem to increase the incidence or severity of neuropathy. Development of neuropathy appeared to be independent of previous neurotoxic therapy. In most patients, neuropathic pain resolved or improved after dose modification or upon completion of therapy. Recovery is reported to take a median of 3 months after stopping bortezomib,[1] although some cases have taken up to 2 years for neuropathic symptoms to resolve.

Analgesics may be given symptomatically (see Choice of Analgesic, p. 4.2). For reference to use of topical menthol to relieve bortezomib-induced neuropathic pain, see p. 2553.3.

1. Argyriou AA, *et al.* Bortezomib-induced peripheral neuropathy in multiple myeloma: a comprehensive review of the literature. *Blood* 2008; 112: 1593–9. Correction. *ibid.*; 113: 4478.
2. Richardson PG, *et al.* Frequency, characteristics, and reversibility of peripheral neuropathy during treatment of advanced multiple myeloma with bortezomib. *J Clin Oncol* 2006; 24: 3113–20.

Effects on the skin. In 3 studies of bortezomib in patients with non-Hodgkin's lymphoma, 26 of 140 patients developed an erythematous maculopapular rash. Six patients underwent biopsy; all cases revealed a small vessel necrotising vasculitis. Although some patients had dosage reductions implemented or therapy interrupted upon development of the rash, others were treated continuously without dose reduction, with no apparent adverse clinical consequences. In fact, analysis of the data supported a strong relationship between bortezomib-associated cutaneous vasculitis and a positive clinical response in patient with non-Hodgkin's lymphoma.[1] A macular brown-red eruption developed in a patient at the site of bortezomib infusions; abundant venous flushing was given from the fourth infusion, and the eruption did not recur, although hyperpigmentation persisted for several months.[2]

2. Matalx J, *et al.* Persistent supravenous eruption induced by intravenous bortezomib therapy. *Br J Dermatol* 2008; 158: 863–4.

Infection. A retrospective analysis[1] of data from a study in relapsed multiple myeloma revealed an increase in herpes zoster infections with bortezomib treatment compared with dexamethasone. An incidence of 13% was reported which was comparable with that reported by other studies in relapsed multiple myeloma. Similarly, a herpes zoster incidence of 13% was found in newly diagnosed multiple myeloma patients treated with bortezomib (plus melphalan and prednisone),[2] compared with 4% in the control group (melphalan and prednisone only). The incidence of herpes zoster was reduced to 3% in the bortezomib group when antiviral prophylaxis was used. A retrospective review[3] found that prophylactic use of antivirals resulted in no cases of herpes zoster in 125 multiple myeloma patients treated with bortezomib. Most patients were given aciclovir 400 mg daily, or a reduced dose of 200 mg daily in renal impairment; famciclovir 500 mg daily or valaciclovir 250 to 500 mg daily were also used.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies bortezomib as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

Bortezomib is both metabolised by, and a weak inhibitor of, cytochrome P450 isoenzymes, see below. Ketoconazole (a potent CYP3A4 inhibitor) increased exposure to bortezomib, but omeprazole (a potent CYP2C19 inhibitor) did not increase exposure to bortezomib. Patients should be closely monitored for toxicities or reduced efficacy when bortezomib is given with inhibitors or inducers of CYP3A4. Although melphalan plus prednisone increased exposure to bortezomib, the increase is not thought to be clinically relevant. Hypoglycaemia and hyperglycaemia have occurred in diabetic patients receiving oral antidiabetics who were given bortezomib.

Pharmacokinetics

After a single intravenous dose of bortezomib, plasma concentrations decline in a biphasic manner; a distribution phase of less than 10 minutes is followed by a longer elimination phase of about 5 to 15 hours. Clearance decreases after multiple doses. Protein binding has been reported to be about 83%. Bortezomib has a large volume of distribution suggesting it is widely distributed to peripheral tissues. Peak proteasome inhibition occurs about 1 hour after a dose, with a mean of 61% inhibition and a half-life of about 24 hours. *In-vitro* studies indicate that bortezomib is mainly oxidatively metabolised via the cytochrome P450 isoenzymes CYP3A4, CYP2C19, and CYP1A2; minor metabolism via CYP2D6 and CYP2C9 also occurs. Bortezomib is also a weak inhibitor of CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. The major metabolic pathway is deboronation to inactive metabolites.

Bosutinib *(USAN, rINN)*

Bosutinibum, SKI-606, Бозутиниб.

4-[(2,4-Dichloro-5-methoxyphenyl)amino]-6-methoxy-7-[3-(4-methylpiperazin-1-yl)propoxy]quinoline-3-carbonitrile.

$C_{26}H_{29}Cl_2N_5O_3$=530.4

CAS — 380843-75-4.
UNII — 5018V4AEZ0.

Uses and Administration

Bosutinib is an orally active dual SRC family and BCR-ABL tyrosine kinase inhibitor. It is indicated in patients with chronic, accelerated, or blast phase Philadelphia chromosome-positive chronic myeloid leukaemia (p. 694.2) that is resistant to prior therapy or in those who are intolerant to other therapies. An oral dose of 500 mg is taken once daily with food. In the absence of grade 3 adverse effects, this dose may be increased to 600 mg once daily in patients who have an incomplete haematological response by week 8 or an incomplete cytogenetic response by week 12. The dose is reduced in those with hepatic impairment, see Administration in Hepatic Impairment below, and may need to be modified if toxicities occur, see Administration in Subsequent Cycles below. Treatment may be continued until there is disease progression or intolerance to bosutinib. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Bosutinib is also being investigated in solid tumours and for polycystic kidney disease.

References.

3. Boschelli F, *et al.* Bosutinib: a review of preclinical studies in chronic myelogenous leukaemia. *Eur J Cancer* 2010; 46: 1781–9.
4. Cortes JE, *et al.* Bosutinib versus imatinib in newly diagnosed chronic-phase chronic myeloid leukemia: results from the BELA trial. *J Clin Oncol* 2012; 30: 3486–92.

Administration in hepatic impairment. Exposure to bosutinib is increased in those with hepatic impairment, and a reduced oral dose of 200 mg once daily is recommended in patients with chronic myeloid leukaemia and any degree of hepatic impairment.

Dose adjustments are required if hepatotoxicity occurs during treatment, see Administration in Subsequent Cycles, below.

Administration in subsequent cycles. In chronic myeloid leukaemia, oral bosutinib dosage may need to be modified if toxicities occur.

If myelosuppression occurs, bosutinib should be withheld until the absolute neutrophil count is ≥1000 cells/mm^3 and the platelets are ≥50 000 cells/mm^3. Bosutinib is resumed at the same dose if recovery occurs within 2 weeks; if recovery takes longer than 2 weeks, the daily dose is reduced by 100 mg. If cytopenia recurs the daily dose should be reduced by a further 100 mg upon recovery.

For an increase in liver transaminases >5 times the upper limit of normal (ULN), bosutinib should be withheld until recovery to ≤2.5 times the ULN; the dose should be resumed at 400 mg once daily thereafter. Bosutinib treatment should be stopped if recovery takes longer than 4 weeks or if liver transaminases increase to ≥3 times the ULN with a bilirubin increase >2 times the ULN and alkaline phosphatase <2 times the ULN.

If grade 3 or 4 diarrhoea occurs (≥7 stools/day more than usual), bosutinib should be withheld until recovery to grade 1 or better and the dose restarted at 400 mg once daily.

For other moderate or severe non-haematological toxicities, bosutinib should be withheld until the toxicity has resolved and then resumed at a dose of 400 mg once daily. If appropriate, this may be increased to 500 mg once daily if this higher dose was previously used.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The most commonly reported adverse effects with bosutinib are diarrhoea, nausea, vomiting, abdominal pain, thrombocytopenia, anaemia, rash, pyrexia, and fatigue. The gastrointestinal toxicity with bosutinib can be dose-limiting; diarrhoea may be severe. Antidiarrhoeals, antiemetics, and fluid replacement may be required to manage symptoms. Gastritis and gastrointestinal haemorrhage have also been reported.

Myelosuppression (neutropenia, anaemia, and thrombocytopenia) can occur and full blood counts should be undertaken weekly for the first month and then monthly thereafter. Increased liver enzyme values and hepatotoxicity has been seen with bosutinib and liver function tests should be carried out monthly for the first three months of treatment.

Fluid retention occurs with bosutinib and may manifest as pericardial or pleural effusion, pulmonary oedema, or peripheral oedema.

Treatment may need to be modified for gastrotoxicity, myelosuppression, hepatotoxicity, and fluid retention, see Administration in Subsequent Cycles, above.

Hypersensitivity reactions include urticaria and anaphylactic shock, and dermatological effects include pruritus, acne, erythema multiforme, exfoliative rash, and drug eruption. Chest pain, pericarditis, and a prolonged QT interval have also been reported, as have dyspnoea, respiratory failure, and pulmonary hypertension. Increases in blood creatinine levels and acute renal failure have occurred.

Other adverse effects include acute pancreatitis, arthralgia, myalgia, back pain, headache, dizziness, dysgeusia, tinnitus, cough, and hyperkalaemia.

Exposure to bosutinib is increased in patients with hepatic impairment.

Interactions

Bosutinib is metabolised by the cytochrome P450 isoenzyme CYP3A4 and is an inhibitor and substrate for P-glycoprotein. Potent or moderate inhibitors of CYP3A4 or P-glycoprotein should be avoided as an increased plasma concentration of bosutinib is expected. Potent or moderate inducers of CYP3A4 should also be avoided as a reduction in the plasma concentration of bosutinib is expected.

Bosutinib may increase exposure to drugs that are P-glycoprotein substrates.

The bioavailability of bosutinib is pH-dependent and concomitant use with the proton pump inhibitor lansoprazole reduced exposure to bosutinib. If possible, short-acting antacids or H_2-antagonists should be used in place of proton pump inhibitors, and bosutinib doses should be separated from gastric-acid suppressants by at least 2 hours.

References.
1. Abbas R, *et al.* Effect of ketoconazole on the pharmacokinetics of oral bosutinib in healthy subjects. *J Clin Pharmacol* 2011; 51: 1721–7.

Pharmacokinetics

Peak plasma concentrations of bosutinib occur around 4 to 6 hours after a single oral dose. Exposure increases when taken with a high-fat meal. Bosutinib is highly protein bound at around 96%, and is a P-glycoprotein inhibitor and substrate. Metabolism is mainly via the cytochrome P450 isoenzyme CYP3A4 to inactive metabolites. Over 90% of an oral dose is excreted in the faeces and 3% in the urine. The terminal elimination half-life is about 22.5 hours after a single oral dose.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *UK*: Bosulif; *USA*: Bosulif.

Brentuximab Vedotin *(rINN)*

Brentuximab Vedotina; Brentuximab Védotine; Brentuximaburn Vedotinum; cAC10-vcMMAE; SGN-35; Брентуксимаб Ведотин.

CAS — 914088-09-8.
UNII — 7XL5I5S668.

Uses and Administration

Brentuximab vedotin is an antibody-drug conjugate consisting of the chimeric CD30-specific monoclonal antibody cAC10 conjugated to monomethyl auristatin E (MMAE), a microtubule disrupting agent. Brentuximab vedotin is used for the treatment of patients with Hodgkin's disease (p. 696.1) after failure of autologous haematopoietic stem cell transplantation or after failure of at least two treatment regimens (in those deemed unsuitable for transplantation). It is also used for the treatment of patients with systemic anaplastic large cell lymphoma after failure of at least one combination chemotherapy regimen.

The recommended dose is 1.8 mg/kg (up to a maximum body-weight of 100 kg) given as an intravenous infusion over 30 minutes every 3 weeks. Treatment may be continued for a maximum of 16 cycles or until disease progression or unacceptable toxicity occurs. The dose may need to be delayed or reduced (see Administration in Subsequent Cycles, below). Brentuximab vedotin is diluted before infusion to obtain a final concentration ranging from 400 micrograms/mL to 1.8 mg/mL; appropriate infusion fluids include sodium chloride 0.9%, glucose 5%, or Lactated Ringer's solution.

Brentuximab vedotin is under investigation in the treatment of cutaneous T-cell lymphoma.

3. Younes A, *et al.* Results of a pivotal phase II study of brentuximab vedotin for patients with relapsed or refractory Hodgkin's lymphoma. *J Clin Oncol* 2012; 30: 2183–9.
4. Gopal AK, *et al.* Safety and efficacy of brentuximab vedotin for Hodgkin lymphoma recurring after allogeneic stem cell transplantation. *Blood* 2012; 120: 560–8.
5. van de Donk NW, Dhimolea E. Brentuximab vedotin. *MAbs* 2012; 4: 458–65.

Administration in subsequent cycles. Brentuximab vedotin therapy may need to be delayed or the intravenous dose reduced if toxicity occurs. Licensed product information makes the following recommendations.

In the event of peripheral neuropathy:
- new or worsening grade 2 or 3 toxicity: treatment should be withheld until neuropathy improves to grade 1 or baseline, then brentuximab vedotin restarted at 1.2 mg/kg
- grade 4 toxicity: treatment is stopped

For neutropenia:
- grade 3 or 4 toxicity: treatment should be withheld until neutropenia improves to baseline or grade 2 or lower; growth factor support should be considered for subsequent cycles
- recurrent grade 4 neutropenia despite the use of growth factors: treatment should be stopped or the dose reduced to 1.2 mg/kg

Adverse Effects, Treatment, and Precautions

Bone marrow depression occurs commonly with brentuximab vedotin, especially neutropenia, anaemia, and thrombocytopenia. Neutropenia may be severe and prolonged and force doses to be delayed or reduced, or therapy to be stopped (see Administration in Subsequent Cycles, above). Complete blood counts should be monitored before each dose, and more frequently if neutropenia is severe. Infections occur, and can be serious; opportunistic infections have also been reported. Peripheral neuropathy is common and is mainly sensory, although cases of peripheral motor neuropathy have also been reported. Neuropathy may be cumulative and patients should be monitored for symptoms such as hypoaesthesia or hyperaesthesia, paraesthesia, burning sensations, or neuropathic pain or weakness. Therapy may need to be delayed or stopped, or a dose reduction may be warranted (see Administration in Subsequent Cycles, above).

Other common adverse effects include fatigue, gastrointestinal disturbances, cough, dyspnoea, fever, chills, lymphadenopathy, rash, pruritus, alopecia, headache, dizziness, insomnia, anxiety, myalgia, arthralgia, muscle spasms, peripheral oedema, hyperglycaemia, night sweats, and dry skin. Pain in the back, abdomen, or oropharyngeal area is also common; pain in an extremity can be serious.

Infusion-related reactions have occurred; associated symptoms include chills, nausea, dyspnoea, pruritus, fever, and cough. The infusion should be interrupted and the patient should be pre-medicated for subsequent infusions; premedication may include paracetamol, an antihistamine, and a corticosteroid. If anaphylaxis occurs, the infusion should be immediately and permanently stopped. Tumour lysis syndrome has been reported, especially in those with a high tumour burden, or rapidly proliferating disease. Stevens-Johnson syndrome has occurred; therapy should be stopped. There have been reports of fatal progressive multifocal leukoencephalopathy. Other serious adverse effects that have been reported include pulmonary embolism, pneumonitis, pneumothorax, pyelonephritis, septic shock, and supraventricular arrhythmia.

Interactions

Brentuximab vedotin contains monomethyl auristatin E (MMAE), which is mainly metabolised by cytochrome P450 isoenzyme CYP3A. Use of brentuximab vedotin with ketoconazole increased exposure to MMAE by about 30 to 70% and patients taking strong CYP3A4 inhibitors should be monitored closely for adverse reactions. Use with rifampicin, a potent CYP3A4 inducer, reduced exposure to MMAE by about 30 to 45%.

Pharmacokinetics

Brentuximab vedotin consists of a monoclonal antibody conjugated with monomethyl auristatin E (MMAE); the pharmacokinetic profile of brentuximab vedotin was similar to that of the monoclonal antibody. Peak concentrations of brentuximab vedotin were seen soon after the end of an infusion; time to peak concentrations of MMAE ranged from 1 to 3 days. Steady-state concentrations of brentuximab vedotin and MMAE occurred within 21 days when the drug was given every 3 weeks. No accumulation of brentuximab vedotin was seen with multiple dosing, and MMAE exposure decreased with continued use. Binding of MMAE to plasma proteins *in vitro* ranged from 68 to 82%. *In vivo*, only a small fraction of MMAE released from brentuximab vedotin is metabolised; this metabolism is mainly via oxidation by cytochrome P450 isoenzyme CYP3A4/5. The terminal half-life of brentuximab vedotin is about 4 to 6 days. About 24% of MMAE is recovered in both urine and faeces over a 1-week period; of this recovered MMAE, about 72% is in the faeces, and the majority of the excreted MMAE is unchanged.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Belg.*: Adcetris; *Switz.*: Adcetris; *UK*: Adcetris; *USA*: Adcetris.

Brostallicin *(rINN)*

Brostalicina; Brostallicine; Brostallicinum; PNU-166196 (hydrochloride); Бростальлицин.

4-(2-Bromoacrylamido)-*N*‴-(2-guanidinoethyl)-1,1′,1″,1‴-tetramethyl-*N*,4′:*N*′,4″:*N*″,4‴-quater[pyrrole-2-carboxamide].

$C_{30}H_{35}BrN_{12}O_5$=723.6

CAS — 203258-60-0.
UNII — RPC6R41K4I.

Profile

Brostallicin is an antineoplastic that binds to DNA. It is under investigation for the treatment of soft-tissue sarcomas.

Broxuridine *(rINN)*

Bromodeoxyuridine; Broxuridina; Broxuridinum; BUDR; NSC-38297; Броксуридин.

5-Bromo-2′-deoxyuridine; 5-Bromo-1-(2-deoxy-β-D-ribofuranosyl)pyrimidine-2,4(1*H*,3*H*)-dione.

$C_9H_{11}BrN_2O_5$=307.1

CAS — 59-14-3.
UNII — G34N38R2N1.

Profile

Broxuridine is a thymidine analogue which acts as a radiosensitiser to enhance the effects of radiotherapy. It is also reported to possess antiviral activity. A related compound brivudine (p. 970.1) is used as an antiviral.

Broxuridine is used as a research tool for measuring DNA synthesis. It has been given by intra-arterial infusion, with radiotherapy and other antineoplastic agents, in the treatment of tumours of the brain, head, and neck; it has also been used diagnostically.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Busulfan). A white or almost white, crystalline powder. Very slightly soluble in water and in alcohol; freely soluble in acetone and in acetonitrile. Store in airtight containers. Protect from light.

USP 36: (Busulfan). A white, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol; soluble 1 in 45 of acetone. Store in airtight containers.

Uses and Administration

Busulfan is an antineoplastic with a cell-cycle non-specific alkylating action unlike that of the nitrogen mustards, and having a selective depressant action on bone marrow. In small doses, it depresses granulocytopoiesis and to a lesser extent thrombocytopoiesis but has little effect on lymphocytes. With larger doses, severe bone-marrow depression eventually ensues.

Because of its selective action, busulfan has been used in the palliative treatment of chronic myeloid leukaemia (p. 694.2). It provides symptomatic relief with a reduction in spleen size and a general feeling of well-being. The fall in leucocyte count is usually accompanied by a rise in the haemoglobin concentration. Permanent remission is not induced and resistance to its beneficial effects gradually develops.

Busulfan may be used in patients with polycythaemia vera (p. 695.2) and in some patients with myelofibrosis and primary thrombocythaemia (p. 695.2). It is also used at high doses as part of a conditioning regimen to prepare patients for haemaatopoietic stem cell transplantation, see p. 1937.1.

Busulfan may be given orally or intravenously. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

The licensed initial oral dosage of busulfan in **chronic myeloid leukaemia** is 60 micrograms/kg or 1.8 mg/m² daily, with a usual maximum single daily dose of 4 mg. This is continued until the white cell count has fallen to between 15 000 and 25 000 cells/mm³ (typically 12 to 20 weeks). It should be stopped earlier if the platelet count falls below 100 000 cells/mm³. Higher doses may be given if the response after 3 weeks is inadequate but this increases the risk of irreversible damage to the bone marrow and calls for special vigilance. Complete blood counts should be made at least every week and the trends followed closely; if haemorrhagic tendencies occur or there is a steep fall in the white cell count indicating severe bone-marrow depression, busulfan should be withdrawn until marrow function has returned.

Once an initial remission has been attained treatment is stopped and not resumed until the white cell count returns to 50 000 cells/mm³. If this occurs within 3 months, continuous maintenance treatment with a usual dose of 0.5 to 2 mg daily may be given; doses equating to less than 1 whole tablet may be achieved by including busulfan-free days between the treatment days.

In patients with **polycythaemia vera** the usual oral dose is 4 to 6 mg daily, continued for 4 to 6 weeks with careful monitoring of blood counts. Further courses are given when relapse occurs; alternatively, maintenance therapy may be given at half the dose required for induction. Doses of 2 to 4 mg daily have been given for **primary thrombocythaemia** or myelofibrosis.

In conditioning regimens for **haematopoietic stem cell transplantation** busulfan is given in *oral* doses of 1 mg/kg every 6 hours for 4 days, starting 7 days before transplantation; cyclophosphamide is usually given for 2 days, starting 24 hours after the final dose of busulfan. When given by *intravenous* infusion, the recommended dose is 800 micrograms/kg ideal body-weight every 6 hours for 4 days starting 7 days before transplantation. Cyclophosphamide is usually given for 2 days: UK licensed product information states that cyclophosphamide dosing should not be started for at least 24 hours after the last dose of busulfan, while US information permits earlier use although no sooner than 6 hours after the last busulfan dose. Actual body-weight is used for the calculation if it is less than the ideal weight and dose calculations for obese patients should be based on adjusted ideal body weight. Each dose should be diluted in sodium chloride 0.9% or glucose 5% to a final concentration of about 500 micrograms/mL, and given over 2 hours through a central venous catheter using an infusion pump.

For doses in children, see below.

4. Ciurea SO, Andersson BS. Busulfan in hematopoietic stem cell transplantation. *Biol Blood Marrow Transplant* 2009; 15: 523–36.

Administration in children. Busulfan may be given in conditioning regimens to prepare children for **haematopoietic stem cell transplantation**. UK licensed product information states that it may be given *orally* to children less than 18 years of age, in accordance with local protocols, up to a maximum dose of 37.5 mg/m² every 6 hours for 4 days, starting 7 days before transplantation; cyclophosphamide is usually given for 2 days, starting 24 hours after the final dose of busulfan. When given *intravenously*, busulfan is licensed for use with cyclophosphamide or melphalan. The recommended dose of busulfan for children up to 17 years of age is weight-based as follows:

- less than 9 kg: busulfan 1 mg/kg
- 9 to 16 kg: busulfan 1.2 mg/kg
- 16 to 23 kg: busulfan 1.1 mg/kg
- 23 to 34 kg: busulfan 950 micrograms/kg
- greater than 34 kg: busulfan 800 micrograms/kg

This dose is given every 6 hours over 4 days to a total of 16 doses, diluted and infused as for adults (see Uses and Administration, above); cyclophosphamide or melphalan should not be started for at least 24 hours after the final dose of busulfan.

For the treatment of **chronic myeloid leukaemia** busulfan may be given orally to paediatric patients in the same dose as that used for adults (see Uses and Administration, above).

Adverse Effects and Treatment

For a general outline see Antineoplastics, p. 726.1 and p. 730.2.

The major adverse effect of busulfan with standard doses is bone-marrow depression, manifest as leucopenia, thrombocytopenia, and sometimes, anaemia. The nadir of the granulocyte count usually occurs after about 10 to 30 days with recovery occurring over up to 5 months, but busulfan has sometimes caused irreversible or extremely-prolonged bone-marrow depression.

Hyperpigmentation is common, and in a few cases after long-term therapy may be part of a syndrome simulating Addison's disease.

Rarely, progressive interstitial pulmonary fibrosis, known as 'busulfan lung', can occur on prolonged treatment. Gastrointestinal disturbances are rare at usual therapeutic doses but may be dose-limiting where high doses are given before bone marrow transplantation. Other rare adverse effects include dry skin and other skin reactions, liver damage, gynaecomastia, cataract formation, and, at high doses, CNS effects including convulsions.

Busulfan may result in impaired fertility and gonadal function. As with other alkylating agents, it is potentially carcinogenic, mutagenic, and teratogenic.

Effects on the bladder. Haemorrhagic cystitis occurred in a patient who had received prolonged therapy with busulfan.[1] High-dose busulfan used in conditioning regimens for haematopoietic stem cell transplantation may increase the risk of late-onset haemorrhagic cystitis.[2,3]

1. Pode D, *et al.* Busulfan-induced hemorrhagic cystitis. *J Urol (Baltimore)* 1983; 130: 347–8.

3. Leung AYH, *et al.* Clinicopathological features and risk factors of clinically overt haemorrhagic cystitis complicating bone marrow transplantation. *Bone Marrow Transplant* 2002; 29: 509–13.

Effects on the liver. Jaundice in the terminal phase of chronic myeloid leukaemia in a 31-year-old man was attributed to busulfan which had been taken for 6 years.[1] Busulfan toxicity involving the liver was also reported in a patient who had taken busulfan for 54 months,[2] while hepatitis possibly associated with busulfan therapy has also been described.[3] Dose-dependent veno-occlusive disease (VOD) has been reported in 20 to 40% of patients receiving high-dose busulfan before bone marrow transplantation.[4] Previous radiotherapy, progenitor cell transplantation, three cycles of chemotherapy or more, the use of multiple alkylating agents, or total doses of busulfan in excess of 16 mg/kg can increase the risk of hepatic VOD. A reduced incidence of hepatic VOD has been seen in those patients given high-dose busulfan and cyclophosphamide when the first dose of cyclophosphamide has been delayed for more than 24 hours after the last dose of busulfan.

Effects on the nervous system. High-dose busulfan, used in conditioning regimens for bone marrow transplantation, has been associated with the development of convulsions,[1-4] both generalised[1,3,4] and myoclonic.[2,4] As a result, the use of prophylactic antiepileptic therapy has been suggested as a component of such regimens.[1,3,4] However, some have not considered the routine use of prophylactic antiepileptics justified.[5]

If an antiepileptic is given, the best drug to choose is uncertain. Many studies have used phenytoin, but the potential for phenytoin to increase the metabolism of busulfan, thereby possibly decreasing its myeloablative efficacy, has been pointed out.[6] In addition, phenytoin plasma concentrations have been found to be subtherapeutic in patients who developed convulsions despite a standard prophylactic dose,[4] and the regimen was subsequently adjusted to take account of plasma concentrations. Clobazam has been suggested as an alternative to phenytoin for prophylaxis of busulfan-induced seizures.[7] A review[8] on the optimal prevention of seizures with high-dose busulfan considered that phenytoin was not the best choice, given its adverse effects and the induction of busulfan metabolism; it was suggested that a benzodiazepine such as clonazepam or lorazepam ought to be considered, and that levetiracetam also showed some promise.

Licensed product information from one manufacturer *Otsuka, USA* states that the recommended dose of their parenteral product is based on studies in which phenytoin was given; since phenytoin increases the clearance of busulfan by 15% or more, exposure should be monitored if other anticonvulsants are used, as an increase in plasma-busulfan might be expected, with increased risk of toxicity.

8. Eberly AL, *et al.* Optimal prevention of seizures induced by high-dose busulfan. *Pharmacotherapy* 2008; 28: 1502–10.

Effects on the skin and hair. For the effect of radiotherapy in precipitating skin lesions in busulfan-treated patients, see under Precautions, below.

Permanent alopecia has been reported after use of busulfan.[1]

1. Tosti A, *et al.* Permanent alopecia after busulfan chemotherapy. *Br J Dermatol* 2005; 152: 1056–8.

Precautions

For reference to the precautions necessary with antineoplastics, see p. 732.2. Careful attention should be given to monitoring blood counts during therapy. This should be done at least weekly at the start of standard dose therapy. With high dose therapy blood counts should be monitored daily, as should liver function. Prophylactic anticonvulsants should be used during high dose therapy (see Effects on the Nervous System, above).

Busulfan should be stopped if lung toxicity develops. The use of oxygen may exacerbate possible lung toxicity; if anaesthesia is required the concentration of oxygen should be minimised.

Handling. Busulfan is irritant; avoid contact with skin and mucous membranes.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies busulfan as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Radiotherapy. Severe cutaneous reactions occurred in patients given radiotherapy at least 30 days after combined chemotherapy with high-dose busulfan.[1]

It is possible that radiotherapy could worsen subclinical lung injury caused by busulfan.

1. Vassal G, *et al.* Radiosensitisation after busulphan. *Lancet* 1987; i: 371.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Phenytoin increases the metabolism of busulfan (see Effects on the Nervous System, above).

Antifungals. Giving *itraconazole* with busulfan resulted in a decrease in the clearance of busulfan; *fluconazole* had no such effect.[1] Busulfan doses may need to be decreased if itraconazole is also given.

1. Buggia I, *et al.* Itraconazole can increase systemic exposure to busulfan in patients given bone marrow transplantation. *Anticancer Res* 1996; 16: 2083–8.

Antineoplastics. When *tioguanine* was given with busulfan for chronic myeloid leukaemia, several cases of hepatic nodular regenerative hyperplasia, with abnormal liver function tests, portal hypertension, and oesophageal varices were noted. There were no cases in patients given busulfan alone, and the mechanism of this possible interaction is unclear.[1,2]

1. Key NS, *et al.* Oesophageal varices associated with busulfan-thioguanine combination therapy for chronic myeloid leukaemia. *Lancet* 1987; ii: 1050–2.
2. Shepherd PCA, *et al.* Thioguanine used in maintenance therapy of chronic myeloid leukaemia causes non-cirrhotic portal hypertension. *Br J Haematol* 1991; 79: 185–92.

Antiprotozoals. In patients who received either high-dose oral or intravenous busulfan as part of a myeloablative regimen before stem cell transplantation, the use of *metronidazole* significantly increased plasma concentrations of busulfan and the degree of associated toxicity, including elevation of liver function tests, veno-occlusive disease, and/or mucositis.[1,2]

1. Nilsson C, *et al.* The effect of metronidazole on busulfan pharmacokinetics in patients undergoing hematopoietic stem cell transplantation. *Bone Marrow Transplant* 2003; 31: 429–35.
2. Gulbis AM, *et al.* Busulfan and metronidazole: an often forgotten but significant drug interaction. *Ann Pharmacother* 2011; 45: e39.

Pharmacokinetics

Busulfan is well absorbed after oral dosage, although intra- and interpatient bioavailability vary widely. Busulfan is lipophilic and crosses the blood-brain barrier; concentrations in the CSF have been reported as being comparable to those in plasma. About 30% of circulating drug is irreversibly bound to plasma proteins, mainly to albumin; the level of reversible binding has been variably reported to be insignificant at around 7%, or to be about 55%. The plasma elimination half-life is about 2 to 3 hours. Busulfan is extensively metabolised in the liver, mainly by conjugation with glutathione, either spontaneously or mediated by the enzyme glutathione-S-transferase. About 12 inactive metabolites have been identified, which are excreted in the urine. About 1% of busulfan is excreted unchanged. Elimination in the faeces is considered to be negligible.

References.

Genetic factors. Busulfan is metabolised in the liver via conjugation with glutathione; this can be mediated via the enzyme glutathione-S-transferase (GST). Genetic variants can result in altered enzymatic activity, and affect busulfan metabolism. A pharmacokinetic study in children given intravenous busulfan found that carriers of GSTA1*B allele had a higher exposure to busulfan than non-carriers; busulfan clearance in carriers was reduced by about 30%. While genetic status may provide some explanation for pharmacokinetic variability, busulfan exposure is also dependent on age and body-weight; GSTA1*B carriers were also significantly younger and weighed less, confounding the interpretation. Nonetheless, genotype may be useful in dosing decisions.[1]

1. Johnson L, *et al.* Glutathione S-transferase A1 genetic variants reduce busulfan clearance in children undergoing hematopoietic cell transplantation. *J Clin Pharmacol* 2008; 48: 1052–62.

Metabolism. In a study of the pharmacokinetics of high-dose busulfan in 5 patients receiving 1 mg/kg orally every six hours for 4 days, the mean elimination half-life decreased from about 3.4 hours after the first dose to about 2.3 hours after the final dose, suggesting that busulfan may induce its own metabolism.[1]

Genetic factors may also affect metabolism of busulfan, see above.

1. Hassan M, *et al.* Pharmacokinetic and metabolic studies of high-dose busulphan in adults. *Eur J Clin Pharmacol* 1989; 36: 525–30.

Therapeutic drug monitoring. The value of therapeutic drug monitoring for busulfan in conditioning regimens for haematopoietic stem cell transplantation has been reviewed,[1,2] and suggested to maximise engraftment and minimise toxicity and relapse. In regimens using busulfan with cyclophosphamide, steady-state plasma concentrations of busulfan above 600 micrograms/litre appeared to favour engraftment.[1] A pharmacokinetic analysis found that in patients with graft rejections, busulfan trough concentrations were below 150 nanograms/mL; steady-state concentrations also tended to be lower in this group but not significantly so.[3]

The bioavailability of oral busulfan is variable, particularly in children; intravenous conditioning regimens, adjusted on the basis of first-dose pharmacokinetics and therapeutic drug monitoring, have been used to overcome this problem.[4,5] A study found a significant correlation between busulfan concentration in plasma and saliva after oral dosing in children; busulfan saliva analysis may therefore be a useful, non-invasive alternative to plasma analysis.[6]

Cabazitaxel *(USAN, rINN)*

Cabazitaxelum; RPR-116258A; XRP-6258; Кабазитаксел.
1-Hydroxy-7β,10β-dimethoxy-9-oxo-5β,20-epoxytax-11-ene-2α,4,13α-triyl 4-acetate 2-benzoate 13-((2*R*,3*S*)-3-[[(*tert*-butoxy)carbonyl]amino]-2-hydroxy-3-phenylpropanoate).
$C_{45}H_{57}NO_{14}$=835.9
CAS — 183133-96-2.
UNII — 51F690397J.

Uses and Administration

Cabazitaxel is a semisynthetic taxane similar to paclitaxel (see p. 839.3) that is manufactured from a taxane precursor derived from the needles of the yew tree. It is used with prednisone or prednisolone in the treatment of hormone-refractory metastatic prostate cancer (p. 712.3), in patients previously treated with a docetaxel-containing regimen.

Cabazitaxel is given by intravenous infusion over 1 hour diluted in at least 250 mL sodium chloride 0.9% or glucose 5% to a final concentration of between 100 to 260 micrograms/mL; infusion is via a 0.22 micrometre in-line filter and PVC containers and polyurethane infusion sets should not be used. Cabazitaxel 25 mg/m² is given every 3 weeks, with oral prednisone or prednisolone 10 mg given daily.

At least 30 minutes before each dose of cabazitaxel, an intravenous dose of an antihistamine (diphenhydramine 25 mg or equivalent), a corticosteroid (dexamethasone 8 mg or equivalent), and a histamine H_2-antagonist (ranitidine 50 mg or equivalent) should be given. Prophylaxis with an antiemetic is also recommended and can be given orally or intravenously as needed. Patients at high risk of neutropenia may need granulocyte colony-stimulating factor, see Adverse Effects, Treatment, and Precautions, below.

Toxicity may require the cabazitaxel dose to be modified, see Administration in Subsequent Cycles, below.

Administration in subsequent cycles. Intravenous dose of cabazitaxel should be modified for the following toxicities:

- febrile neutropenia, or neutropenia of grade 3 or above for more than 1 week despite treatment including granulocyte colony-stimulating factor: delay cabazitaxel until neutrophil count is above 1500 cells/mm³ and fever has improved or resolved, then reduce dose to 20 mg/m².
Secondary prophylaxis with a granulocyte colony-stimulating factor is recommended.
- persistent diarrhoea (despite treatment), or diarrhoea of grade 3 or above: delay cabazitaxel until improvement or resolution of symptoms, then reduce dose to 20 mg/m².
- peripheral neuropathy of grade 2 or above: delay cabazitaxel until improvement or resolution of symptoms, then reduce dose to 20 mg/m².

If a patient continues to have any of the above adverse effects while on the reduced dose, cabazitaxel treatment should be stopped.

Adverse Effects, Treatment, and Precautions

For a general outline see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Neutropenia is common during cabazitaxel treatment and fatalities have been reported. Granulocyte colony-stimulating factor may be given to reduce the risk, and prophylaxis and/or treatment should be considered in high-risk patients such as those aged 65 years and over, those with poor performance status, those with extensive prior radiotherapy, or those with previous episodes of febrile neutropenia. Cabazitaxel should not be started or continued while neutrophil counts are 1500 cells/mm³ or below if counts increase above this level then use may be continued using a modified dose (see Uses and Administration, above). Blood counts should be monitored every week during the first treatment cycle of cabazitaxel, and before each cycle thereafter.

To prevent hypersensitivity reactions, all patients should be given premedication with an antihistamine, corticosteroid, and histamine H_2-antagonist (see Uses and Administration, above). If a severe hypersensitivity reaction occurs cabazitaxel should be stopped immediately and not restarted; symptoms include hypotension, bronchospasm, and rash, that may occur within a few minutes of the infusion. Cabazitaxel should not be used in patients hypersensitive to polysorbate 80, which is present in the formulation.

Peripheral neuropathy and gastrointestinal disturbances are common; diarrhoea may be severe and fatalities have been reported. Treatment should be delayed or the dose reduced for peripheral neuropathy, or severe or persistent diarrhoea (see Uses and Administration, above). Other common adverse effects include anaemia, leucopenia, thrombocytopenia, fatigue, haematuria, dyspnoea, dysgeusia, cough, arthralgia, myalgia, alopecia, anorexia, dehydration, hyperglycaemia, hypokalaemia, anxiety, confusion, sciatica, conjunctivitis, increased lachrymation, tinnitus, vertigo, tachycardia, hypotension or hypertension, deep-vein thrombosis, flushing, dry skin, and urinary disorders. Arrhythmias, peripheral oedema, increases in liver enzymes, urinary-tract infection, dizziness, headache, pyrexia, muscle spasms, and pain including chest pain have also been reported. Renal failure, occasionally fatal, has occurred. Other rare adverse effects that have led to death include cardiac arrest or cardiac failure, ventricular fibrillation, and cerebral haemorrhage.

Some adverse effects such as neutropenia, fatigue, pyrexia, dizziness, dehydration, and urinary-tract infections occurred more frequently in elderly patients (65 years and over), who may require additional monitoring.

Cabazitaxel is metabolised in the liver and so should not be used in patients with hepatic impairment (defined as total bilirubin > the upper limit of normal, or aspartate aminotransferase and/or alanine aminotransferase ≥ 1.5 times the upper limit of normal).

Interactions

For a general discussion of antineoplastic drug interactions, see p. 733.3.

Cabazitaxel is mainly metabolised via the cytochrome P450 isoenzyme CYP3A4. Potent inhibitors or inducers of this enzyme may affect exposure to cabazitaxel, and their use together should be avoided. Caution is advised when cabazitaxel is used with moderate inhibitors.

In vitro studies suggest that the potential for cabazitaxel to inhibit or induce CYP isoenzymes is low.

Pharmacokinetics

Cabazitaxel is equally distributed between blood and plasma *in vitro*; binding to plasma proteins is about 90%, mainly to albumin and lipoproteins. Cabazitaxel is extensively metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP3A4 and CYP3A5, and to a lesser extent by CYP2C8. Renal excretion of cabazitaxel and its metabolites accounts for a small portion of the dose (about 4%); most of the dose (76%) is excreted via the faeces as metabolites. After a one-hour intravenous infusion, cabazitaxel follows a three-compartment pharmacokinetic model with α, β, and γ half-lives of 4 minutes, 2 hours, and 95 hours, respectively.

Cabazitaxel crosses the blood-brain barrier and the placenta.

$C_{28}H_{24}FN_3O_5.C_4H_6O_5$=635.6

CAS — 1140909-48-3.

UNII — DR7ST46X58.

Uses and Administration

Cabozantinib is a tyrosine kinase inhibitor that targets multiple receptor kinases including MET (mesenchymal-epithelial transition factor, hepatocyte growth factor receptor/HGFR), RET (rearranged during transfection), and VEGF (vascular endothelial growth factor). It is used in the treatment of progressive, metastatic medullary thyroid cancer (p. 716.1). Doses are given as the s-malate but expressed as the base; 177.4 mg of cabozantinib s-malate is equivalent to about 140 mg cabozantinib.

The usual oral dose is the equivalent of cabozantinib 140 mg once daily; capsules should be taken on an empty stomach and swallowed whole. A missed dose should not be taken within 12 hours of the next dose. Dose adjustments may be required for toxicities, see Administration in Subsequent Cycles, below. Treatment is continued until disease progression or unacceptable toxicity occurs. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

For patients who must also take a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, the daily dose of cabozantinib should be reduced by 40 mg. The original dose of cabozantinib may be restarted 2 or 3 days after the inhibitor has been stopped. For patients who must take a potent CYP3A4 inducer, the daily dose of cabozantinib should be increased by 40 mg to a maximum dose of 180 mg daily. The original dose of cabozantinib may be restarted 2 or 3 days after the inducer has been stopped.

Cabozantinib is also under investigation for the treatment of other solid neoplasms including prostate cancer and renal cell carcinoma.

References.

4. Hart CD, De Boer RH. Profile of cabozantinib and its potential in the treatment of advanced medullary thyroid cancer. *Onco Targets Ther* 2013; 6: 1–7.

Administration in subsequent cycles. Cabozantinib treatment may need to be modified if toxicities occur. It should be withheld for grade 4 haematological adverse effects, for grade 3 or higher non-haematological reactions, or for intolerable grade 2 reactions. When reactions have resolved or improved to grade 1, the oral daily dose of cabozantinib should be reduced as follows:

- in those previously taking 140 mg: resume treatment at 100 mg
- in those previously taking 100 mg: resume treatment at 60 mg
- in those previously taking 60 mg: resume treatment at 60 mg if tolerated, otherwise stop treatment

Adverse Effects and Precautions

The most commonly reported adverse effects with cabozantinib are diarrhoea or constipation, stomatitis, nausea and vomiting, abdominal pain, dysgeusia, oral pain, anorexia and decreased body weight, palmar-plantar erythrodysesthesia syndrome, fatigue, hair colour changes, and hypertension. Other less common adverse effects include other gastrointestinal disorders such as dyspepsia or dysphagia, arthralgia, muscle spasms, musculoskeletal chest pain, dizziness, peripheral neuropathy, anxiety, dysphonia, rash, dry skin, alopecia, and hypotension. Reversible posterior leucoencephalopathy syndrome has been reported, and any patients reporting seizures, headache, visual disturbances, confusion, or altered mental state should be evaluated for this. Increased concentrations of thyroid-stimulating hormone, increased liver enzyme values, hyperbilirubinaemia, neutropenia, thrombocytopenia, lymphopenia, hypocalcaemia, hypophosphataemia, hypomagnesaemia, hypokalaemia, and hyponatraemia have also been noted. Proteinuria has sometimes occurred; monitoring is recommended.

Gastrointestinal perforations and fistulas have occurred, as have tracheal or oesophageal fistulas. Serious haemorrhage has been reported and cabozantinib should not be used in patients with recent haemorrhage or haemoptysis. An increased incidence of thrombotic events, including venous and arterial thromboembolism, has also been associated with cabozantinib.

Osteonecrosis of the jaw has occurred with cabozantinib and an oral examination should be carried out before starting treatment and periodically thereafter. Wound complications have also been reported and treatment should be stopped at least 28 days before scheduled surgery, including invasive dental procedures; it may be restarted when healing is deemed adequate. Where dehiscence or wound healing complications occur during treatment, cabozantinib should be withheld.

Cabozantinib should be permanently stopped for visceral perforation or fistula formation, severe haemorrhage, serious arterial thromboembolism, nephrotic syndrome, malignant hypertension, hypertensive crisis, persistent uncontrolled hypertension despite medical management, osteonecrosis of the jaw, or reversible posterior leucoencephalopathy syndrome.

Interactions

Cabozantinib is a substrate of the cytochrome P450 isoenzyme CYP3A4. Exposure to cabozantinib was increased by 38% when it was given with the CYP3A4 inhibitor ketoconazole, and potent CYP3A4 inhibitors should be avoided during treatment. Conversely, exposure to cabozantinib was decreased by 77% when it was given with the CYP3A4 inducer rifampicin and prolonged use of potent CYP3A4 inducers should avoided. The dose cabozantinib may need to be adjusted if CYP3A4 inhibitors or inducers must be used, see Uses and Administration, above.

Pharmacokinetics

Peak plasma concentrations of cabozantinib occur between 2 to 5 hours after an oral dose, and steady-state concentrations are seen by day 15. Exposure is increased when it is taken with a high-fat meal. Cabozantinib is highly-bound to plasma proteins (over 99%). It is metabolised by the cytochrome P450 isoenzyme CYP3A4; CYP2C9 is a minor route. It is excreted via the faeces and urine.

Cancer Vaccines

Vacunas contra el cáncer.

Profile

Vaccines are under investigation for many neoplastic diseases including breast, colorectal, head and neck, lung, ovarian, pancreatic, prostate, and renal cancers, lymphoma, and melanoma. Vaccines can be either preventative or therapeutic. Vaccines for the treatment of cancer are designed to stimulate an antibody response and can be allogeneic or autologous and based on dendritic cells, peptides or proteins, whole tumour cells, RNA or DNA, bacterial or viral vectors, or heat shock proteins.

BCG vaccine can be used as immunotherapy to treat bladder cancer (see p. 2378.2), and a human papillomavirus (HPV) vaccine for the prevention of cervical cancer is available in some countries (see p. 2392.2). A therapeutic vaccine targeting epidermal growth factor is used in some countries for non-small cell lung cancer. Sipuleucel-T (p. 857.1) and vitespen (p. 887.1) are examples of personalised cancer vaccines.

Pharmacopoeias. In *US.*

USP 36: (Capecitabine). A white to off-white crystalline powder. Sparingly soluble in water; soluble in alcohol and in acetonitrile; freely soluble in methyl alcohol. Store in airtight containers at a temperature of 20 degrees to 25 degrees, excursions permitted between 15 degrees and 30 degrees.

Uses and Administration

Capecitabine is a prodrug that is converted to fluorouracil (p. 795.3) in body tissues. It is given orally for the treatment of metastatic colorectal cancer (p. 706.3) and is also used for the adjuvant treatment of patients after surgery for Dukes C colon cancer. Capecitabine is given with docetaxel for the treatment of locally advanced or metastatic breast cancer (p. 702.1) after failure of anthracycline-containing chemotherapy. It may be given as monotherapy after failure of taxanes and anthracycline-containing regimens for patients with breast cancer and for whom further anthracycline-containing therapy is not indicated. Capecitabine with lapatinib (p. 815.1) is used for the treatment of patients with advanced or metastatic breast cancer whose tumours overexpress human epidermal receptor type 2 (HER2). Capecitabine is also used with a platinum-based regimen for the first-line treatment of gastric cancer (p. 706.1).

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

For *monotherapy* in **colon, colorectal,** or in **breast** cancer, the recommended initial oral dose is 1.25 g/m^2 given twice daily (for the suggestion that lower initial doses may be favoured in the USA see Administration, p. 758.1). Doses are given for 14 days, followed by a 7-day rest period.

Adjuvant treatment for colon cancer is recommended for a total of 6 months.

For *combination* therapy in **breast** cancer, when given with docetaxel, capecitabine is given in the same dose as listed above; docetaxel is given at 75 mg/m² as a 1-hour intravenous infusion every 3 weeks. However, when used with lapatinib tosilate, a different regimen is used, see Uses and Administration, under Lapatinib Tosilate, p. 815.1.

In *combination* therapy in **colorectal** or **gastric** cancer, the recommended initial oral dose of capecitabine is 0.8 to 1 g/m² twice daily for 14 days, followed by a 7-day rest period. Alternatively, capecitabine 625 mg/m² twice daily is given continuously.

Capecitabine tablets should be swallowed with water within 30 minutes after a meal. Doses should be modified in subsequent cycles according to toxicity. Capecitabine doses should be reduced in patients with renal impairment (see below).

Capecitabine is also under investigation in the treatment of other malignancies.

Administration. Severe toxicity has been reported when capecitabine was given after a fluorouracil and folinic acid regimen to patients with colorectal cancer; a comparable effect was not seen when the treatments were given in the reverse order.[1] Although the mechanism of this sequence-specific toxicity was not determined, the authors suggested that an interaction with intracellularly retained folate was a possible cause.

Interestingly, it has been suggested that aggressive dietary folate supplementation policies in the USA may also contribute to the increased rate of major toxicity seen with capecitabine in phase III studies there, compared with Europe and Asia. In contrast to European practice, oncologists in the USA therefore rarely prescribed the recommended initial oral dose of 1.25 g/m² twice daily, tending to prefer a dose of 1 g/m² twice daily.[2]

1. Hennig IM, *et al.* Severe sequence-specific toxicity when capecitabine is given after fluorouracil and leucovorin. *J Clin Oncol* 2008; 26: 3411–17.
2. Midgley R, Kerr DJ. Capecitabine: have we got the dose right? *Nat Clin Pract Oncol* 2009; 6: 17–24.

Administration in the elderly. A review noted that the pharmacokinetics of capecitabine were not affected by age in those patients with normal renal function. However, toxicity may be increased in some elderly patients, and reduced doses may be used.[1]

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; 25: 1832–43.

Administration in renal impairment. Renal impairment increases systemic exposure to 5′-deoxy-5-fluorouridine, a metabolite of capecitabine. An increase in the severity of adverse effects appears to correlate with decreased renal function and increased exposure to this metabolite.[1]

Licensed product information suggests the following dosage adjustments based on creatinine clearance (CC):

- mild renal impairment, CC 51 to 80 mL/minute: no dosage adjustment necessary
- moderate renal impairment, CC 30 to 50 mL/minute: when the starting dose is 1.25 g/m² twice daily, a dose reduction of 25%, to about 950 mg/m² twice daily is recommended; however, when the starting dose is 1 g/m² twice daily, no dose reduction is required
- severe renal impairment, CC below 30 mL/minute: capecitabine is contra-indicated

1. Poole C, *et al.* Effect of renal impairment on the pharmacokinetics and tolerability of capecitabine (Xeloda) in cancer patients. *Cancer Chemother Pharmacol* 2002; 49: 225–34.

Adverse Effects, Treatment, and Precautions

As for Fluorouracil, p. 797.1. Diarrhoea (which may be severe), nausea and vomiting, abdominal pain, stomatitis, and palmar-plantar erythrodysesthesia syndrome (erythema and desquamation of hands and feet) occur commonly with capecitabine, and may be dose-limiting. Other common adverse effects include fatigue, asthenia, and anorexia. Rashes, alopecia, erythema, dryness of the skin, pruritus, skin pigmentation disorders, and nail disorders can occur. Other adverse effects are fever, pain, arthralgia, constipation, dyspepsia, paraesthesia, headache, dizziness, insomnia, depression, eye irritation, hypo- or hypercalcaemia, and dehydration. Encephalopathy, cardiotoxicity, thromboembolism, and bone-marrow depression have all been reported. Hyperbilirubinaemia has occurred. Severe toxicity has been seen in patients with dihydropyrimidine dehydrogenase deficiency.

Doses of capecitabine should be reduced in patients with moderate renal impairment and its use is contra-indicated in those with severe renal or hepatic impairment.

Effects on blood lipids. Severe hypertriglyceridaemia has been reported with oral capecitabine;[1] patients had high baseline triglyceride concentrations at the start of capecitabine. Despite the introduction of lipid-lowering therapy, triglyceride concentrations remained above baseline, and only decreased several weeks after stopping capecitabine. A prospective study suggested an incidence of hypertriglyceridaemia of 3.7% in patients treated with capecitabine, either as monotherapy or with oxaliplatin, for colorectal cancer.[2]

2. Michie CO, *et al.* The frequency and severity of capecitabine-induced hypertriglyceridaemia in routine clinical practice: a prospective study. *Br J Cancer* 2010; 103: 617–21.

Effects on the eyes. A report of severe ocular irritation with corneal deposits and impaired visual acuity in 2 patients given capecitabine.[1] Symptoms resolved within several weeks of stopping the drug.

1. Waikhom B, *et al.* Severe ocular irritation and corneal deposits associated with capecitabine use. *N Engl J Med* 2000; 343: 740–1. Correction. *ibid.*: 1428.

Effects on the heart. Acute ischaemic chest pain has been reported, usually within a few days of starting capecitabine.[1-3] Symptoms from case reports[1] and incidence in Phase III studies[4] were similar to those in patients given fluorouracil. While symptoms have generally been reported to be reversible, fatal myocardial infarction has occurred.[2] One patient had also had cardiotoxicity with fluorouracil treatment,[1] but others had no apparent risk factors.[2] Capecitabine-induced cardiotoxicity without chest pain has also been reported;[5] myocardial ischaemia and a significant decrease in ejection fraction were apparent on exertion.

4. Lam MSH, *et al.* Capecitabine-associated cerebellar ataxia. *Am J Health-Syst Pharm* 2008; 65: 2032–5.

Effects on the skin and nails. While hand-foot syndrome appears to be common in patients treated with capecitabine (see Palmar-plantar Erythrodysesthesia Syndrome, below), other skin eruptions have been rarely reported.[1] Onychomadesis (total separation of the nail-bed) and onycholysis have occurred.[2,3] Pyogenic granuloma has been seen with the use of capecitabine,[1] as has re-pigmentation of chemotherapy-induced vitiligo.[4] Stevens-Johnson syndrome has also been reported.[5]

Hypersensitivity. A patient was successfully given fluorouracil by continuous infusion despite previous hypersensitivity to capecitabine. The authors supposed that the hypersensitivity was likely to have been caused by capecitabine or intermediate metabolites, and suggested a lack of cross-sensitivity between capecitabine and fluorouracil.[1]

Palmar-plantar erythrodysesthesia syndrome. Hand-foot syndrome (palmar-plantar erythrodysesthesia syndrome, p. 730.1) has been reported to be common with use of capecitabine given either as monotherapy[1] or as part of combination chemotherapy regimens.[2,3] The syndrome developed within the first 2 cycles of monotherapy,[1] but within the first 3 cycles in combination therapy,[3] which was attributed to dose modifications of capecitabine in the latter case. Use with docetaxel, and previous chemotherapy-induced stomatitis were found to be significant risk factors for its occurrence.[3] The only effective management is treatment interruption and dose modification.[4] Supportive measures to reduce pain and discomfort and prevent secondary infection are important.[5] General recommended strategies include submersion of hands and feet in cold water, wound care, and avoidance of extreme temperature changes, tight-fitting clothing, or skin friction. Emollient creams may be of benefit for both prophylaxis and treatment. Other strategies that have been proposed include the use of amifostine, topical or systemic corticosteroids, and nicotine patches; however, use of these drugs for capecitabine-induced hand-foot syndrome remains unproven. While pyridoxine cannot be recommended for prophylaxis, some consider it a reasonable choice for treatment, since benefit has been reported with its use with topical emollients.[4] Concurrent treatment with celecoxib has been reported to reduce the incidence of hand-foot syndrome induced by capecitabine.[6,7] For reference to the use of vitamin E to alleviate palmar-plantar erythrodysesthesia syndrome caused by capecitabine and docetaxel, see Chemotherapy-induced Toxicity, under Uses of Vitamin E, p. 2120.1.

As a result of capecitabine-induced hand-foot syndrome, fingerprint misidentification has been reported.[8,9]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies capecitabine as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Toxicity. Sequence-specific toxicity has been reported when capecitabine was given after fluorouracil and folinic acid, see Administration, above.

Tumour lysis syndrome. A fatal case of tumour lysis syndrome (p. 730.2) has been reported after the use of capecitabine.[1]

1. Kurt M, *et al.* Tumor lysis syndrome following a single dose of capecitabine. *Ann Pharmacother* 2004; 38: 902.

Interactions

As for Fluorouracil, p. 797.3. Altered coagulation parameters and bleeding have occurred in patients on warfarin or phenprocoumon given capecitabine. Increased phenytoin plasma concentrations and symptoms of toxicity during use with capecitabine have been reported. Antacids containing aluminium or magnesium hydroxides cause a small increase in capecitabine plasma concentration. The maximum tolerated dose of capecitabine is reduced when it is given with either folinic acid or interferon alfa. Use with sorafenib increased exposure to capecitabine.

Antivirals. For reference to a fatal interaction between capecitabine and *brivudine*, see Antivirals, under Interactions of Fluorouracil, p. 797.3.

Folate. For the suggestion that an interaction between capecitabine and intracellularly retained folate led to increased toxicity in patients with colorectal cancer, see Administration, above.

Pharmacokinetics

Capecitabine is readily absorbed from the gastrointestinal tract and peak plasma concentrations occur at about 1.5 hours. Food reduces the rate and extent of absorption. Plasma protein binding of capecitabine is less than 60%. Capecitabine is hydrolysed in the liver to 5'-deoxy-5-fluorocytidine (5'-DFCR), which is then converted to 5'-deoxy-5-fluorouridine (5'-DFUR; doxifluridine—p. 782.3) and subsequently to the active 5-fluorouracil in body tissues, via the enzyme thymidine phosphorylase. 5-Fluorouracil is further metabolised, as discussed on p. 798.1. About 3% of a dose of capecitabine is excreted in the urine unchanged.

Pharmacopoeial Preparations
USP 36: Capecitabine Tablets.

Carboplatin *(BAN, USAN, rINN)*

Carboplatine; Carboplatino; Carboplatinum; CBDCA; JM-8; Karboplatiini; Karboplatin; Karboplatina; Karboplatyna; NSC-241240; Карбоплатин.

cis-Diammine(cyclobutane-1,1-dicarboxylato)platinum.

$C_6H_{12}N_2O_4Pt$=371.3

CAS — 41575-94-4.

ATC — L01XA02.

ATC Vet — QL01XA02.

UNII — BG3F62OND5.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Ph. Eur. 8: (Carboplatin). A colourless, crystalline powder. Sparingly soluble in water; very slightly soluble in alcohol and in acetone. Protect from light.

USP 36: (Carboplatin). A 1% solution in water has a pH of 5.0 to 7.0. Store in airtight containers. Protect from light.

Incompatibility. Carboplatin reacts with aluminium causing loss of potency and forming a precipitate. Needles, syringes, catheters or giving sets that contain aluminium should not be used for preparing or giving carboplatin.

Stability. About 5% of the initial carboplatin concentration was lost over 24 hours when solutions were diluted in sodium chloride 0.9% and stored at 25 degrees; lesser amounts of degradation were seen at lower sodium chloride concentrations, but carboplatin was apparently stable over this period if diluted with glucose 5%.[1] The authors suggested that chloride-containing infusion solutions are not suitable for carboplatin, not only because of the loss of active drug but because of the possibility that conversion to cisplatin may be occurring, with a risk of increased toxicity.[1] This has been contested by the manufacturers (*Bristol-Myers, USA*), who found that only 0.5% or 0.7%, depending on formulation, of a carboplatin solution in sodium chloride 0.9%, had been converted to cisplatin after 24 hours.[2] However, the total degradation of carboplatin was not measured. In another study, the authors calculated the time to 5% degradation of carboplatin at 25 degrees as 29.2 hours in sodium chloride 0.9% compared with 52.7 hours in water.[3] They concluded that carboplatin should not be diluted in sodium chloride 0.9% when intended for continuous infusion over a prolonged period.[3] Carboplatin in glucose 5% was reported to be stable for 7 days at 25 degrees in PVC bags when protected from light.[4]

Uses and Administration

Carboplatin is an analogue of cisplatin with similar actions and uses (see p. 766.2). It is used in the treatment of advanced ovarian cancers and of small-cell lung cancer, both alone and combined with other antineoplastics. It has also been tried as an alternative to cisplatin in other solid tumours (see below).

Carboplatin is given by intravenous infusion over 15 minutes to 1 hour. In the UK an initial dose of 400 mg/m^2 is licensed for use as a single agent in previously untreated patients with normal renal function, reduced by 20 to 25% (to 300 to 320 mg/m^2) in patients who have previously been treated with myelosuppressive therapy or who have poor performance status. In the USA an initial dose of 360 mg/m^2 is licensed as a single agent in previously treated patients with recurrent disease, and an initial dose of 300 mg/m^2 when used with cyclophosphamide in previously untreated patients.

Dosage adjustments are necessary in patients with renal impairment (see below) and when carboplatin is given as part of a combination regimen. The dose in mg may be calculated using the Calvert formula as described under Administration, below. Subsequent doses should be adjusted according to the nadir of the white cell and platelet counts (see also Bone-marrow Depression, p. 730.3), and should not be given more frequently than every 4 weeks.

Administration. Pharmacokinetic studies by Calvert and colleagues[1] have indicated that the dose of carboplatin to produce a desired area under the concentration-time curve (AUC) could be calculated, based on the patient's glomerular filtration rate (GFR), as:

$$\text{Dose in mg} = \text{target AUC} \times (\text{GFR} + 25)$$

It should be noted that the resultant dose is given in mg and not in mg/m^2. This formula was found to be useful in patients with higher than normal as well as reduced GFR. Suggested target AUCs were 5 mg/mL per minute in previously treated patients and 7 mg/mL per minute in those who had not previously received chemotherapy. In combination therapy the appropriate AUC value depended on the other drugs used: an AUC of 4.5 mg/mL per minute gave acceptable results when carboplatin was used with bleomycin and etoposide for testicular teratoma.

However, determination of GFR may be a problem: clearance of technetium-99m-labelled diethylenetriamine penta-acetic acid (DTPA) or chromium-51-labelled edetic acid is more accurate than 24-hour creatinine clearance, with the first of these more convenient than the second.[2] (It has been suggested that creatinine clearance should not be used to estimate GFR for the Calvert equation.[3]) Nonetheless, radioisotopic determination of GFR is still an elaborate procedure, and may be less accurate in children than adults.[4,5] Chatelut and colleagues have proposed formulas[4,6,7] for determining clearance of carboplatin in both adults and children.

It has been suggested that the Calvert and Chatelut formulas are not sufficiently accurate for use in **children**, or in adults with very severe renal impairment. Bayesian methods are the technique of choice where serum carboplatin concentrations can be monitored.[3] However, a study in children showed that dosage based on determination of the GFR results in more consistent carboplatin exposure than dosage based on body-surface.[8] A comparison of calculation methods for carboplatin dosing in children found marked differences with the use of different GFR formulas.[5] GFR calculations according to Léger with the dose formula of Newell, or dose calculation by the method of Chatelut were considered to have low bias and only small age-dependent differences, whereas calculation methods with several steps or conversion procedures were prone to considerable error; the authors stated that the usefulness of dose calculations based solely on the serum creatinine should be critically questioned, and recommended the use of limited sampling strategies, therapeutic drug monitoring, and the precise determination of GFR.[5] There has also been a report of the successful use of the Calvert formula in 2 Japanese patients undergoing haemodialysis.[9]

Administration in the elderly. A review[1] found no data to support dose reduction of carboplatin based on age alone and noted that the use of the Calvert and Chatelut formulas (see Administration, above) allows for safe and accurate dosing by taking into account renal function changes associated with age.

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; 25: 1832–43.

Administration in renal impairment. The initial dose of carboplatin is usually determined using a formula (see Administration, above). If this approach is not adopted, US licensed product information suggests the following initial intravenous dose of carboplatin, based on creatinine clearance (CC):

- CC 41 to 59 mL/minute: 250 mg/m^2
- CC 16 to 40 mL/minute: 200 mg/m^2

The incidence of severe leucopenia, neutropenia, or thrombocytopenia has been about 25% in renally-impaired patients who received single-agent carboplatin therapy at the above doses. The data for patients with more severe renal impairment are too limited to allow dosage recommendations.

Malignant neoplasms. A preliminary review[1] of carboplatin, concluded that it was active in ovarian cancer (p. 711.2), with similar responses to those seen with cisplatin; its activity in small-cell lung cancer (p. 710.2), seminoma, and squamous cell carcinomas of the head and neck seemed likely to be comparable, whereas results in gastrointestinal and breast cancers, lymphomas and leukaemias, melanoma, mesothelioma, renal carcinoma, and sarcoma were, generally unimpressive. A subsequent review[2] suggested that in testicular cancer, where there was a prospect of cure, cisplatin, which appeared to give better results in some studies should be preferred. However, in ovarian cancer, where treatment was largely palliative, carboplatin had the advantage of being better tolerated. A further review[3] of randomised studies concurred that carboplatin was equivalent to cisplatin in suboptimally debulked ovarian cancer and extensive-stage small-cell lung cancer, and was inferior to cisplatin in testicular cancer. It was also concluded that carboplatin was inferior to cisplatin in head and neck and oesophageal cancers. There was insufficient comparative evidence for other cancers for which cisplatin has a role.

Adverse Effects, Treatment, and Precautions

The adverse effects of carboplatin are similar to those of cisplatin (p. 767.1); nephrotoxicity and gastrointestinal toxicity are less severe than with cisplatin and reversible myelosuppression is the dose-limiting toxicity; platelet counts reach a nadir between 14 and 21 days after a dose, with recovery within 35 days, but recovery from leucopenia may be slower. Myelosuppression may be more severe and prolonged in patients with impaired renal function. Carboplatin should therefore be given at reduced doses to these patients and should be avoided if creatinine clearance is 20 mL/minute or less. Weekly blood counts and regular renal and hepatic function tests are recommended in all patients during therapy. Neurological function including assessment of hearing should also be monitored.

Incidence of adverse effects. The manufacturers analysed the adverse effects of carboplatin in studies involving 710 patients.[1] Myelosuppression was the dose-limiting toxicity: leucopenia occurred in 55% of the evaluable patients. Leucopenia and thrombocytopenia result in symptomatic events such as infection or bleeding in a minority of patients. Anaemia was frequent (59%) and required transfusional support in about one-fifth of the patients. Nephrotoxicity and serum electrolyte loss were much less of a problem; no high-volume fluid hydration or electrolyte supplementation was given during treatment. Vomiting occurred in about half the patients, and a further 25% had nausea without vomiting. Peripheral neurotoxi-

city was reported in 6% of evaluable patients and clinical ototoxicity occurred in only 8 cases or about 1% (but see also Effects on the Ears, below). Increases in liver enzyme values have also been reported, as well as, more rarely, alopecia, rash, a flu-like syndrome, and local effects at the injection site.

1. Canetta R, *et al.* Carboplatin: the clinical spectrum to date. *Cancer Treat Rev* 1985; **12** (suppl A): 125–36.

Effects on the ears. Carboplatin is less ototoxic than cisplatin, but ototoxicity is still common with carboplatin when used in high doses, for example, as part of conditioning regimens for bone marrow transplantation.[1,2] Long-term audiometric follow-up has been advised in young children given carboplatin-based chemotherapy, as ototoxicity may only be evident some years after treatment.[3] There was some evidence that sodium thiosulfate reduced carboplatin-induced hearing loss, when carboplatin was used for CNS malignancy.[4,5]

1. Frellich RJ, *et al.* Hearing loss in children with brain tumors treated with cisplatin and carboplatin-based high-dose chemotherapy with autologous bone marrow rescue. *Med Pediatr Oncol* 1996; **26**: 95–100.

4. Neuwelt EA, *et al.* First evidence of otoprotection against carboplatin-induced hearing loss with a two-compartment system in patients with central nervous system malignancy using sodium thiosulfate. *J Pharmacol Exp Ther* 1998; **286**: 77–84.
5. Doolittle ND, *et al.* Delayed sodium thiosulfate as an otoprotectant against carboplatin-induced hearing loss in patients with malignant brain tumors. *Clin Cancer Res* 2001; **7**: 493–500.

Effects on the eyes. Cortical blindness developed in 2 patients with impaired renal function receiving high-dose carboplatin;[1] although 10 cases of visual disturbances in patients receiving carboplatin had been reported to the manufacturers, none of these had sudden blindness and it was thought that the effect represented CNS toxicity in the presence of poor renal excretion. It was concluded that it was unwise to give high-dose carboplatin to patients whose glomerular filtration rate is less than 50 mL/minute.

Severe ocular and orbital toxicity has been reported after intracarotid injection of carboplatin for the treatment of recurrent glioblastomas.[2]

1. O'Brien MER, *et al.* Blindness associated with high-dose carboplatin. *Lancet* 1992; **339**: 558.
2. Watanabe W, *et al.* Severe ocular and orbital toxicity after intracarotid injection of carboplatin for recurrent glioblastomas. *Graefes Arch Clin Exp Ophthalmol* 2002; **240**: 1033–5.

Effects on the heart. Atrial flutter has been reported following the first dose of a second course of carboplatin.[1] The patient spontaneously reverted to sinus rhythm after 24 hours.

1. Zakaria S, *et al.* Atrial flutter associated with carboplatin administration. *Ann Pharmacother* 2011; **45**: e59.

Effects on the kidneys. Although carboplatin is reported to be much less nephrotoxic than cisplatin it is not devoid of adverse effects on the kidney.[1-8] Salt wasting nephropathy (similar to that seen with cisplatin),[1] and decreased creatinine clearance[2] and glomerular filtration rate[3] have occurred, as has acute renal failure, including in 2 patients given intraperitoneal carboplatin[4] (although these patients had been heavily pretreated with cisplatin). It has been suggested that renal toxicity may be more likely at cumulative carboplatin doses of about 750 mg/m² or more,[3] and there is some evidence to suggest that intensive hydration may ameliorate nephrotoxic effects.[2]

Hypersensitivity. In one series, 12% of 205 patients treated with carboplatin developed a hypersensitivity reaction after a median of 8 courses of platinum therapy.[1] Symptoms were at least moderately severe in half of the patients. Reactions to cisplatin might be anticipated in patients who have been previously sensitised to carboplatin although they do not necessarily occur (see p. 768.1). In another study,[2] patients receiving more than 7 courses of carboplatin therapy were given a skin test before each course in an attempt to identify patients at risk for hypersensitivity reactions. The test consisted of 0.02 mL of an undiluted aliquot of their planned infusion, injected intradermally 1 hour before the dose. A negative skin test accurately predicted the absence of a hypersensitivity reaction. In a further extended report[3] by the same group, the skin test had been given about 30 minutes before carboplatin doses in 126 women who had already received at least 6 courses of a platinum-based regimen for a gynaecological cancer. Of 668 negative skin tests, a hypersensitivity reaction developed on 10 occasions (in 7 patients), giving a false-negative rate of 1.5%. None of the reactions were severe. Of the 39 patients who had a positive skin test, 7 elected to receive the dose of carboplatin; 6 of these developed a hypersensitivity reaction but none were severe.

The use of a desensitisation regimen has been successful in a small number of patients,[4,5] although others have not found it useful.[6]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies carboplatin as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/08/11)

Pregnancy. For a report of the successful use of carboplatin-based chemotherapy during pregnancy, with no adverse effects on the infant, see Pregnancy, under Cisplatin, p. 768.2.

Interactions

As for Cisplatin, p. 768.2. When used with docetaxel, clearance of carboplatin has been reported to be about 50% higher than values reported for carboplatin monotherapy.

Pharmacokinetics

Intravenous carboplatin exhibits a biphasic elimination and is excreted mainly in the urine, about 70% of a dose being excreted within 24 hours, the majority in the first 6 hours. About a third of a dose is excreted unchanged. The terminal *half-life* (as free platinum) is reported to be about 6 hours. (For the effect of docetaxel on carboplatin clearance, see Interactions, above.) Platinum from carboplatin slowly becomes protein bound, and is subsequently excreted with a *half-life* of 5 days or more.

Carfilzomib *(USAN, rINN)*

Carfilzomibum; PR-171; Карфилзомиб.

(2*S*)-*N*-[(1*S*)-1-Benzyl-2-[[(1*S*)-3-methyl-1-[[(2*R*)-2-methyloxiran-2-yl]carbonyl]butyl]amino]-2-oxoethyl]-4-methyl-2-[[(2*S*)-2-[(morpholin-4-ylacetyl)amino]-4-phenylbutanoyl]amino]pentanamide.

$C_{40}H_{57}N_5O_7$=719.9

CAS — 868540-17-4.

UNII — 72X6E3J5AR.

Uses and Administration

Carfilzomib is an irreversible inhibitor of the 20S proteasome, a core unit within the 26S proteasome (see also Bortezomib, p. 752.1), that disrupts tumour cell turnover and induces apoptosis. It is used for the treatment of multiple myeloma (p. 699.2) in patients who have received at least 2 prior therapies including bortezomib and an immune modulator, and whose disease has progressed on or within 60 days of completing the last therapy. Carfilzomib is given intravenously over 2 to 10 minutes on 2 consecutive days each week for 3 weeks (days 1, 2, 8, 9, 15, and 16), followed by a 12-day rest to give a 28-day treatment cycle. In cycle 1, a dose of carfilzomib 20 mg/m² is given. If tolerated, the dose is increased in subsequent cycles to 27 mg/m². Treatment may be continued until disease progression or unacceptable toxicity occurs.

The dose of carfilzomib should be calculated using the patient's actual body-surface at baseline up to a maximum of 2.2 m². Dose adjustments only need to be made when the patient's weight shows greater than 20% change from the previous measurement.

To reduce the incidence and severity of infusion reactions premedication with dexamethasone 4 mg orally or intravenously should be given before each dose of carfilzomib in cycle 1, and before each dose during the first cycle of dose escalation. Premedication with dexamethasone should also be used if infusion reactions develop or reappear in subsequent cycles.

Doses should be modified if toxicity occurs, see Administration in Subsequent Cycles, below.

2. Khan RZ, Badros A. Role of carfilzomib in the treatment of multiple myeloma. *Expert Rev Hematol* 2012; **5**: 361–72.

Administration in subsequent cycles. Intravenous doses of carfilzomib should be modified if marked toxicity occurs. Doses can be decreased from 27 mg/m² to 20 mg/m² (one dose level), or from 20 mg/m² to 15 mg/m² (one dose level). For specific toxicities, the following adjustments are recommended:

For *haematological toxicity* (grade 3 or 4 neutropenia and grade 4 thrombocytopenia), carfilzomib should be withheld. If there is full recovery before the next scheduled dose carfilzomib may be continued at the same dose. If there is recovery to grade 2 neutropenia or grade 3 thrombocytopenia, carfilzomib should be reduced by one dose level. If tolerated, the reduced dose may be increased to the previous level.

For *cardiotoxicity* (grade 3 or 4, new-onset or worsening of heart failure, decreased left ventricular function, or myocardial ischaemia), *pulmonary complications* (grade 3 or 4), *pulmonary hypertension*, *hepatotoxicity* (grade 3 or 4, increases in liver transaminases, bilirubin, or other liver abnormality), or peripheral neuropathy (grade 3 or 4), carfilzomib should be withheld until toxicity has resolved or organ function has returned to baseline. A reduction of carfilzomib by one dose level should be considered when restarting treatment. If tolerated, the reduced dose may be increased to the previous level.

For *renal toxicity* (serum creatinine ≥twice baseline), carfilzomib should be withheld until renal function has returned to grade 1 or baseline. If toxicity is due to carfilzomib, treatment should be reduced by one dose level when restarting. However, if toxicity is not due to carfilzomib, treatment may be restarted at the previous dose. If tolerated, the reduced dose may be increased to the previous level.

Adverse Effects and Precautions

For a general outline see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The most common adverse effects of carfilzomib include fatigue, fever, gastrointestinal disturbances, and dyspnoea; treatment should be withheld if dyspnoea occurs. Anaemia

and thrombocytopenia are also very common. The platelet count should be monitored frequently during treatment; the nadir of the count usually occurs around day 8. Other haematological toxicities such as neutropenia, lymphopenia, and leucopenia also occur commonly. Neutropenia and thrombocytopenia may be dose limiting.

Other common adverse reactions include peripheral neuropathy, headache, cough, peripheral oedema, pain, insomnia, muscle spasms, asthenia, electrolyte disturbances, respiratory-tract infections, dizziness, hypoaesthesia, anorexia, hyperglycaemia, and increases in blood creatinine. Acute renal failure has been reported.

Cardiovascular adverse effects include hypertension, myocardial ischaemia, and myocardial infarction. Pulmonary hypertension and new onset or worsening of pre-existing heart failure have been reported. Carfilzomib should be withheld or stopped if serious cardiac events occur.

Infusion reactions can occur immediately following, or up to 24 hours after, carfilzomib administration. Reactions include fever, chills, arthralgia, myalgia, facial flushing, facial oedema, vomiting, weakness, dyspnoea, hypotension, syncope, chest tightness, or angina. Dexamethasone should be given before carfilzomib infusions, see Uses and Administration, p. 760.3.

Tumour lysis syndrome has been reported with carfilzomib; patients with multiple myeloma and a high tumour burden may be at increased risk. If tumour lysis syndrome occurs, treatment should be interrupted until symptoms have resolved.

Hepatotoxicity may occur with increases in liver enzyme values and bilirubin. Hepatic failure has been reported. Liver enzymes should be monitored frequently and treatment withheld for severe increases in transaminases, bilirubin, or other liver abnormalities.

Reactivation of herpes zoster has occurred and antiviral prophylaxis should be considered for patients with a history of herpes zoster infection.

Pharmacokinetics

Carfilzomib was about 97% bound to plasma proteins when tested *in vitro*. It is rapidly and extensively metabolised. The main metabolic pathways are peptidase cleavage and epoxide hydrolysis to inactive metabolites. Cytochrome P450 isoenzymes play only a minor role in the overall metabolism. Carfilzomib is rapidly cleared with a half-life of 1 hour or less on day 1 of cycle 1.

Pharmacopoeias. In *Chin.* and *Jpn.*

Profile

Carmofur is an orally active derivative of fluorouracil (p. 795.2) and has similar actions. It is used in the adjuvant treatment of colorectal and breast cancer, and has also been used in ovarian cancer. Carmofur has been associated with the development of neurological disorders including leukoencephalopathy. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

1,3-Bis(2-chloroethyl)-1-nitrosourea.

$C_5H_9Cl_2N_3O_2$=214.0

CAS — 154-93-8.

ATC — L01AD01.

ATC Vet — QL01AD01.

UNII — U68WG3173Y.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Ph. Eur. 8: (Carmustine). A yellowish, granular powder. Very slightly soluble in water; freely soluble in dehydrated alcohol; very soluble in dichloromethane. It melts at about 31 degrees with decomposition. Store at a temperature of 2 degrees to 8 degrees in airtight containers. Protect from light.

USP 36: (Carmustine). Light yellow powder. Freely soluble in ether. Store in airtight containers at a temperature of 2 degrees to 8 degrees. Protect from light.

Stability. Licensed product information states that, when reconstituted, resulting carmustine solutions (undiluted or further diluted in sodium chloride 0.9% or glucose 5%) are stable for 8 hours at room temperature, or 24 hours at 2 degrees to 8 degrees, when protected from light. Carmustine is adsorbed onto PVC giving sets and containers, and polyethylene or glass should be used.

A study has indicated that diluted solutions of carmustine undergo increased degradation in the presence of sodium bicarbonate, with only 73% of the original concentration of carmustine remaining after 90 minutes, much of the loss being in the first 15 minutes.[1]

1. Colvin M, *et al.* Stability of carmustine in the presence of sodium bicarbonate. *Am J Hosp Pharm* 1980; 37: 677–8.

Uses and Administration

Carmustine is a cell-cycle phase non-specific antineoplastic belonging to the nitrosourea group of compounds, which are considered to function as alkylating agents. It is believed to alkylate DNA and RNA, and may also inhibit enzymatic processes by carbamoylation of amino acids in proteins. Carmustine is used in the treatment of brain tumours, and in combination chemotherapy for multiple myeloma. It may be given as second-line therapy in Hodgkin's disease, non-Hodgkin's lymphoma, and some other malignancies (see below).

Carmustine is licensed for use as a single agent either as a single dose of 150 to 200 mg/m^2 or divided into doses of 75 to 100 mg/m^2 given on 2 successive days. Doses are given by intravenous infusion over 1 to 2 hours in sodium chloride 0.9% or glucose 5%. Lower doses are usually given in combination therapy. Doses may be repeated every 6 weeks provided that blood counts have returned to acceptable levels. Subsequent doses must be adjusted according to the haematological response (see also Bone-marrow Depression, p. 730.3).

Polymer implants containing carmustine have been developed for implantation into the brain in the localised treatment of high-grade malignant glioma or recurrent glioblastoma multiforme. Each implant contains 7.7 mg of carmustine: up to 8 such implants are inserted into the cavity left by surgical removal of the tumour.

Amyloidosis. For mention of chemotherapy with epirubicin, cyclophosphamide, and carmustine to suppress amyloidosis after cardiac transplantation, see p. 819.3.

Malignant neoplasms. Carmustine has been used in chemotherapeutic regimens for several malignancies. Because of its ability to pass the blood-brain barrier it has been extensively used in malignant neoplasms of the brain (p. 701.2). As an extension of such use, carmustine-releasing wafers have been implanted directly into the brain.[1-3] In a multicentre study[4] in patients with recurrent malignant glioma, biodegradable poly(carboxyphenoxypropane/sebacic acid)anhydride polymer wafers containing carmustine implanted into the brain after tumour resection produced a median survival of 31 weeks compared with 23 weeks for placebo. A subsequent small cohort study[5] failed to find a clear survival benefit associated with wafer implantation in recurrent glioma, and reported a higher rate of complications including seizures, cerebral oedema, CSF leaks, sepsis, and wound infections. The limitations of this small study were acknowledged by the authors, and a review[6] that included these studies concluded that despite limited data, carmustine wafers do provide some survival benefit. A randomised study in 240 patients found that treatment with carmustine wafers reduced the risk of death by 28% compared with placebo;[7] this survival advantage was maintained at 1, 2, and 3 years, with statistical significance at 3 years.[8] The adverse effect profile was similar for carmustine and placebo groups,[7] and retrospective reviews[2,9] found carmustine wafers to be well tolerated with a low incidence of surgical complications such as infection. However, it was noted that, in some patients, neurological symptoms developed during an attempted tapering of dexamethasone dosage after carmustine with radiotherapy and that close supervision of patients is warranted. Treatment effects or necrosis can radiographically mimic recurrent tumour in a proportion of patients;[9] implantation of wafers caused morphological changes of the brain immediately adjacent to the implants.[10] There is considerable interest in multimodal therapy, using adjuvant temozolomide and radiotherapy after surgery and implantation of carmustine wafers.[3]

Other conditions in which carmustine has been used include malignant melanoma (p. 714.3) and Hodgkin's disease (p. 696.1).

Adverse Effects and Treatment

For a general outline see Antineoplastics, p. 726.1 and p. 730.2. Delayed and cumulative bone-marrow depression is the most frequent and serious adverse effect of intravenous carmustine. Platelets and leucocytes are mainly affected, with platelet nadirs occurring at 4 to 5 weeks after a dose and leucocyte nadirs at 5 to 6 weeks; although thrombocytopenia is usually more severe, leucopenia may also be dose-limiting. Other adverse effects include pulmonary fibrosis (mainly but not exclusively at high cumulative doses—see also Effects on the Lungs, p. 729.1), renal and hepatic damage, and neuroretinitis. Nausea and vomiting, beginning up to 2 hours after a dose, is common but can be reduced by prophylactic antiemetic therapy. Venous irritation may follow intravenous injection and transient hyperpigmentation has been noted after contact of a solution with the skin. Flushing of the skin and suffusion of the conjunctiva may occur on rapid intravenous infusion. Hypotension, tachycardia, chest pain, headache, and hypersensitivity reactions have been reported.

Convulsions, cerebral oedema, and various neurological symptoms have been reported in patients given carmustine-containing polymer implants; abnormalities of wound

healing at the site of implantation, and an increased incidence of intracranial infection have also been reported.

As with other alkylating agents, carmustine is potentially carcinogenic, mutagenic, and teratogenic.

Effects on the eyes. Ocular toxicity has been reported in patients given carmustine,[1,2] and seems to be more likely when given into the carotid artery,[1,2] although it was also seen with high-dose intravenous therapy. There is some evidence that the alcohol diluent used to prepare carmustine solutions may contribute to the retinopathy.[2]

1. Shingleton BJ, *et al.* Ocular toxicity associated with high-dose carmustine. *Arch Ophthalmol* 1982; 100: 1766–72.
2. Greenberg HS, *et al.* Intra-arterial BCNU chemotherapy for treatment of malignant gliomas of the central nervous system. *J Neurosurg* 1984; 61: 423–9.

Effects on the lungs. Studies have found a high incidence of fatal pulmonary fibrosis (see also Effects on the Lungs, p. 729.1) in patients treated with carmustine for gliomas during childhood; patients who were treated before 5 or 6 years of age were more likely to die of pulmonary fibrosis than those treated at a later age.[1,2] However, there are reports of pulmonary toxicity and upper lobe pulmonary fibrosis occurring in adults given carmustine and high-dose chemotherapy.[3]

2. Lohani S, *et al.* 25-year study of lung fibrosis following carmustine therapy for brain tumor in childhood. *Chest* 2004; 126: 1007.
3. Parish JM, *et al.* Upper lobe pulmonary fibrosis associated with high-dose chemotherapy containing BCNU for bone marrow transplantation. *Mayo Clin Proc* 2003; 78: 630–4.

Extravasation. For mention of the use of sodium bicarbonate as a specific antidote after carmustine extravasation, see under Treatment of Adverse Effects of Antineoplastics, p. 731.3.

Precautions

For reference to the precautions necessary with antineoplastics, see p. 732.2. Carmustine should be used with extreme caution in children, who are at particular risk of severe delayed pulmonary toxicity. It should also be used with caution in patients with reduced lung function. Lung function should be monitored before and frequently during therapy. Blood counts should be monitored weekly during therapy, and for at least 6 weeks after the last dose. Renal and hepatic function should also be monitored periodically.

Patients undergoing craniotomy for malignant glioma and implantation of carmustine wafers should be monitored closely for complications, including seizures, intracranial infections, abnormal wound healing, and brain oedema. Brain oedema and compression (intracerebral mass effect) due to tumour recurrence, infection, or necrosis, may require further surgery or the removal of carmustine wafers.

Handling and disposal. Carmustine has been shown to permeate latex, PVC, and rubber gloves, the degree of permeation tending to increase with time,[1-3] up to an equilibrium value.[2] The permeation rate appears not to depend solely on glove thickness and material, and may be different for different gloves made from the same material.[2] The time for initial penetration was reported to vary between 4.7 and 66.0 minutes in one study,[2] and gloves could be chosen accordingly depending on the anticipated length of exposure. Double-gloving, particularly with thicker PVC[1] or ethylmethacrylate[3] gloves, may offer some additional protection.

3. Mellström GA, *et al.* Barrier effect of gloves against cytostatic drugs. *Curr Probl Dermatol* 1996; 25: 163–9.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Cimetidine. Reductions in white cell counts and platelet counts well below those normally attributed to treatment with carmustine alone were seen in 6 of 8 patients receiving their first course of carmustine and corticosteroids with cimetidine given prophylactically,[1] and in 9 patients in a further study.[2] Cimetidine was also reported to exacerbate the neutropenia and leucopenia in a patient receiving lomustine.[3]

1. Selker RG, *et al.* Bone-marrow depression with cimetidine plus carmustine. *N Engl J Med* 1978; 299: 834.
2. Volkin RL, *et al.* Potentiation of carmustine-cranial irradiation-induced myelosuppression by cimetidine. *Arch Intern Med* 1982; 142: 243–5.
3. Hess WA, Kornblith PL. Combination of lomustine and cimetidine in the treatment of a patient with malignant glioblastoma: a case report. *Cancer Treat Rep* 1985; 69: 733.

Pharmacokinetics

Intravenous carmustine is rapidly metabolised, and no intact drug is detectable after 15 minutes; metabolites have a much longer half-life and are presumed to be responsible for its activity. It is mainly excreted in the urine; some is also excreted as carbon dioxide, via the lungs. Carmustine readily crosses the blood-brain barrier, appearing in CSF in substantial concentrations almost immediately after intravenous injection. Carmustine diffuses from polymer implants into surrounding brain tissue; however, tissue and plasma concentrations after implantation have not been determined.

Catumaxomab *(rINN)*

Catumaxomabum; Катумаксомаб.

Immunoglobulin G2a, anti-(human antigen 17-1A) (mouse monoclonal Ho-3/TP-A-01/TPBs01 heavy chain), disulfide with mouse monoclonal Ho-3/TP-A-01/TPBs01 light chain, disulfide with immunoglobulin G2b anti-(human CD3 (antigen)) (rat monoclonal 26/II/6-1.2/TPBs01 heavy chain), bidisulfide with rat monoclonal 26/II/6-1.2/TPBs01 light chain.

CAS — 509077-98-9.
ATC — L01XC09.
ATC Vet — QL01XC09.

Uses and Administration

Catumaxomab is a rat-mouse hybrid monoclonal antibody that is specifically directed against the epithelial cell adhesion molecule EpCAM, which is overexpressed in most carcinomas, and the CD3 antigen; a third binding site enables interaction with accessory immune cells. These binding properties induce a reaction against tumour cells which includes T-cell activation, antibody-dependent cell mediated cytotoxicity, complement-dependent cytotoxicity, and phagocytosis.

Catumaxomab is used for the intraperitoneal treatment of malignant ascites in patients with EpCAM-positive carcinomas where standard therapy is not available or no longer feasible. Catumaxomab is diluted with sodium chloride 0.9% in polypropylene syringes before infusion via a constant infusion pump system. Four intraperitoneal infusions are given:

- first dose (day 0): 10 micrograms in 10 mL sodium chloride (total volume 10.1 mL)
- second dose (day 3): 20 micrograms in 20 mL sodium chloride (total volume 20.2 mL)
- third dose (day 7): 50 micrograms in 49.5 mL sodium chloride (total volume 50 mL)
- fourth dose (day 10): 150 micrograms in 48.5 mL sodium chloride (total volume 50 mL)

At least 2 days must elapse between infusions; this interval can be prolonged in the event of adverse reactions, but the overall treatment period should not exceed 20 days.

Catumaxomab is also under investigation for the treatment of gastric cancer.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Infusion-related reactions characteristic of a cytokine release syndrome (including fever, nausea, vomiting, chills, dyspnoea, and hypotension or hypertension) occur commonly with catumaxomab. A systemic inflammatory response syndrome (SIRS) may also occur; this generally develops within 24 hours of infusion, and manifests as fever, tachycardia, tachypnoea, and leucocytosis. Premedication with analgesics, antipyretics, or NSAIDs is recommended as prophylaxis for both syndromes.

Myelosuppression is common with catumaxomab. Other common adverse effects include tachycardia, vertigo, gastrointestinal disturbances, hyperbilirubinaemia, hepatitis, electrolyte imbalances (hyponatraemia, hypocalcaemia, hypokalaemia), hyperglycaemia, arthralgia, myalgia, headache, dizziness, anxiety, insomnia, and renal disorders such as proteinuria and haematuria. Ileus and abdominal pain may be serious. Skin and subcutaneous reactions are also common, and may be severe. Uncommon adverse effects which may be serious, include pulmonary embolism, pleural effusion, acute renal failure, convulsions, intestinal obstruction, gastric haemorrhage, and extravasation. Infections are common, and can be severe; use of catumaxomab is not recommended during acute infection.

CAS — 857036-77-2.
UNII — 68AYS9A614.

Profile

Cediranib is an inhibitor of tyrosine kinase associated with the vascular endothelial growth factor (VEGF) receptor. It is under investigation for the treatment of recurrent glioblastoma. It has been investigated for metastatic colorectal cancer and non-small cell lung cancer but results were disappointing. Adverse effects include hypertension and proteinuria.

Stability. Cetuximab 2 mg/mL was physically stable when stored for 14 days at 4 degrees in either PVC infusion bags or the opened original glass vial.[1]

1. Ikesue H, *et al.* Stability of cetuximab and panitumumab in glass vials and polyvinyl chloride bags. *Am J Health-Syst Pharm* 2010; 67: 223–6.

Uses and Administration

Cetuximab is a chimeric monoclonal antibody that binds to the epidermal growth factor receptor (EGFR). Signal transduction through the EGFR results in activation of the protein expressed by the wild-type *KRAS* gene (Kirsten rat sarcoma 2 viral oncogene homologue), which plays a role in cell growth regulation and angiogenesis. In patients with

KRAS gene mutations, activation of the *KRAS* protein is independent of EFGR regulation and cetuximab is ineffective. It is, however, used in the treatment of EGFR-expressing, *KRAS* wild-type, metastatic colorectal cancer (p. 706.3). Cetuximab may be used first-line with fluorouracil-based combinations such as the FOLFOX (infusional fluorouracil, folinic acid, and oxaliplatin) or FOLFIRI (fluorouracil, folinic acid, and irinotecan) regimens. It is also used with irinotecan in patients refractory to irinotecan-based chemotherapy, or as monotherapy in patients intolerant to irinotecan-based regimens or after failure of both oxaliplatin- and irinotecan-based regimens. Cetuximab with radiotherapy may be used for the treatment of locally advanced squamous cell cancer of the head and neck (p. 708.1). It is also used with platinum-based chemotherapy for the treatment of patients with recurrent or metastatic squamous cell carcinoma of the head and neck, and as monotherapy in those for whom prior platinum-based therapy has failed. It is under investigation for non-small cell lung cancer and other solid tumours.

For all indications, cetuximab 400 mg/m^2 is given as a loading dose by intravenous infusion over 2 hours. This is followed by once weekly maintenance doses of 250 mg/m^2 given over 1 hour. The maximum infusion rate is 10 mg/min. Premedication with a histamine H_1-antagonist and corticosteroids is recommended, and patients should be closely monitored for at least 1 hour after the end of the cetuximab infusion. A low-protein-binding 0.22-micrometre in-line filter should be used, and the infusion given via an infusion or syringe pump.

In combined therapy for colorectal cancer, chemotherapy should not be given for at least 1 hour after the end of cetuximab infusion. In head and neck carcinoma, cetuximab therapy is started one week before radiation therapy and continued until the end of the radiation therapy period. Cetuximab is usually given 1 hour before radiation therapy. When used as monotherapy, cetuximab is continued until disease progression or unacceptable toxicity occurs.

The infusion rate should be permanently reduced in patients who have had a mild to moderate infusion reaction, and cetuximab should be immediately and permanently stopped if a severe reaction has occurred (see Adverse Effects and Precautions, below). When a severe acneform rash has occurred, the next dose should be delayed by 1 to 2 weeks. After the first occurrence, the full maintenance dose may be given if there has been improvement in the rash; after a second occurrence the next dose should be delayed and reduced to 200 mg/m^2; after a third occurrence the next dose should be delayed and reduced to 150 mg/m^2. If there is no improvement in the rash when therapy has been delayed, or if the rash has occurred 4 times, cetuximab should be stopped.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Adverse effects associated with cetuximab include skin reactions, asthenia, and gastrointestinal disturbances. Skin reactions present mainly as an acneform rash, and, if severe, require dosage adjustment (see Uses and Administration, p. 762.3). Sun exposure should be limited. Infusion reactions suggestive of a cytokine release syndrome can occur, usually with the first dose. Mild reactions include chills, fever, and dyspnoea; severe reactions include bronchospasm, urticaria, hypotension or hypertension, and loss of consciousness, and fatalities have occurred. Premedication with a histamine H_1-antagonist and corticosteroids is recommended, and dose adjustment may be necessary (see Uses and Administration, p. 762.3). Cardiopulmonary arrest and/or sudden death has been reported in patients treated with cetuximab and radiation therapy, and cetuximab should be given with caution to head and neck cancer patients with coronary artery disease, congestive cardiac failure, or arrhythmias. Radiation dermatitis has also been reported with cetuximab. Cardiotoxicity may be increased when cetuximab is used with fluorouracil. When used with platinum compounds, the frequency of severe leucopenia or severe neutropenia may be increased, leading to infectious complications such as febrile neutropenia, pneumonia, and sepsis. Hypomagnesaemia can occur; patients should be monitored for this and accompanying hypocalcaemia and hypokalaemia before, during, and for up to 8 weeks after stopping therapy. Interstitial lung disease, pulmonary embolism, deep-vein thrombosis, and renal failure have been reported rarely. Common adverse effects include headache, increases in liver enzyme concentrations, and conjunctivitis.

Effects on the nervous system. A 54-year-old man had a generalised seizure within 15 minutes of starting his first infusion of cetuximab;[1] he had been pretreated with ondansetron, ranitidine, diphenhydramine, and dexamethasone. The authors considered the seizure to be an infusion reaction.

1. McClellan NH, Bell WA. Seizure activity during cetuximab infusion in a patient with metastatic colorectal cancer. *Am J Health-Syst Pharm* 2012; 69: 1881–4.

Effects on the skin, hair, and nails. Acneform follicular rashes have been reported with cetuximab therapy;[1,2] lesions were pustular and papular,[2-4] and commonly occurred on the face, scalp, chest, and upper back.[1-5] The relative risk of developing high-grade rash was estimated to be over 20 times greater in patients given cetuximab than in controls; the incidence was higher in patients with colorectal cancer (12.6%) than in those with other malignancies (6.6%).[6] It has been suggested that there is a relationship between rash and response to therapy or survival, i.e. that rash might be a surrogate marker of cetuximab activity;[7,8] doubling the cetuximab dose in patients without severe initial skin reactions is reported to increase their response rate to therapy.[9] A few cases of lengthening eyelash and eyebrow hair[10] and abnormal growth of chest hair[11] have been described. Paronychia has also been reported,[1,5,12] as have intraoral aphthous ulcers.[1]

Treatment with oral isotretinoin 500 micrograms/kg daily has been reported to successfully clear acneform skin lesions in 2 patients; topical therapy with metronidazole 0.75% gel or erythromycin 1% was also used.[13] Prophylactic oral minocycline 100 mg daily, started on the same day as cetuximab and given for 8 weeks, significantly reduced total facial lesion counts in the first 4 weeks when compared with placebo; this difference tapered by the end of 8 weeks of treatment. Topical tazarotene showed no clinical benefit and caused local irritation that forced tazarotene to be stopped in many patients.[14]

Some have suggested that the clinical findings of papulopustular rash, nail and periungual abnormalities, alterations in hair texture and growth, and dry skin and pruritus, constitute a syndrome unique to the epidermal growth factor receptor (EGFR) inhibitors, believed to be due to EGFR inhibition in the epidermis, hair follicle, and nail matrix.[15] A retrospective study[16] of patients treated with EGFR inhibitors (erlotinib, cetuximab, or panitumumab) for more than 6 months found that all patients had cutaneous adverse effects. However, the frequency of skin changes arising from long-term use was different to effects seen soon after treatment; the incidence of folliculitis diminished over time, whereas paronychia, skin dryness, and hair modifications became more predominant.

Erythema and focal epidermolysis, progressing to severe radiation dermatitis with necrosis, has been reported in patients given radiation therapy with cetuximab.[17]

Hypersensitivity. For limited data pointing to a lack of cross-sensitivity between cetuximab and panitumumab, see Hypersensitivity, under Panitumumab, p. 843.2.

For a report of a generalised seizure considered to be an infusion reaction, see Effects on the Nervous System, above.

Hypomagnesaemia. A patient given cetuximab developed profound hypomagnesaemia, requiring intravenous supplementation with up to 10 g magnesium sulfate daily, throughout the duration of cetuximab therapy. This case prompted a review of 154 patients treated with cetuximab, of whom 34 had their magnesium concentrations measured at least once. Among these 34 patients, 6 had grade 3 and 2 had grade 4 hypomagnesaemia; this equated to an incidence of 24% of grade 3/4 hypomagnesaemia. In each of these cases the need for supplementation subsided after stopping cetuximab, with resolution of the hypomagnesaemia within several weeks.[1] However, it was not clear whether all patients had a normal magnesium concentration before treatment, nor was there any indication of the median time to development of hypomagnesaemia.

Another retrospective review of 114 patients did address these issues.[2] It found 48 patients had normal baseline magnesium concentrations before starting cetuximab. Of these 48 evaluable patients, 13 developed grade 3 or grade 4 hypomagnesaemia (27%); median time to onset of grade 3/4 hypomagnesaemia was 5.5 months. There was a significant association between duration of cetuximab therapy and grade of hypomagnesaemia. Magnesium replacement therapy was given to those patients with grade 3/4 toxicity. Initial attempts at oral replacement with up to 1.6 g magnesium oxide three times daily were ineffective, and intravenous supplementation was needed. However, the effects of infusion did not extend beyond 48 to 72 hours, with some patients requiring daily magnesium sulfate infusions of up to 10 g daily. Furthermore, in some patients, magnesium supplementation became less effective with continued cetuximab treatment. Of 3 patients evaluable for recovery from hypomagnesaemia after stopping cetuximab, 2 were found to correct their magnesium concentrations without supplementation after 1 month. However, 1 patient required prolonged and ongoing supplementation for more than 5 months, at 4 g infused 3 times weekly (having received 8 g daily while on cetuximab).[2] A prospective study[3] found that a progressive decrease in serum magnesium concentrations was seen in 97% of patients after treatment with cetuximab, panitumumab, or matuzumab. The authors concluded that magnesium wasting was specifically due to inhibition of the epidermal growth factor receptor (EGFR), and suggested hypomagnesaemia might be a class effect of the monoclonal antibodies directed against EGFR. However, incidence and severity may vary between products. There was also high interindividual variability; increasing age was associated with more severe hypomagnesaemia.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies cetuximab as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pharmacokinetics

The pharmacokinetics of cetuximab have been reported to be non-linear and dose-dependent. Steady-state concentrations are reached after 3 weeks. Cetuximab has a long elimination half-life of about 70 to 100 hours.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, and *US*.

Ph. Eur. 8: (Chlorambucil). A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in alcohol and in acetone. Protect from light.

USP 36: (Chlorambucil). An off-white, slightly granular powder. M.p. 65 degrees to 69 degrees. Very slightly soluble in water; soluble 1 in 2 of acetone; soluble in dilute alkali. Store in airtight containers. Protect from light.

Storage. Licensed product information recommends that tablets of chlorambucil should be stored at 2 degrees to 8 degrees and kept dry.

Uses and Administration

Chlorambucil is an oral antineoplastic derived from chlormethine (p. 765.1) and has a similar mode of action. It acts on lymphocytes and to a lesser extent on neutrophils and platelets. Chlorambucil is most valuable in those conditions associated with the proliferation of white blood cells, especially lymphocytes, and is used in the treatment of chronic lymphocytic leukaemia and lymphomas, including Hodgkin's disease. It is also used in Waldenström's macroglobulinaemia and has been given in gestational trophoblastic tumours. Although formerly widely used in the management of polycythaemia vera it has largely been superseded.

Chlorambucil also has immunosuppressant properties and has been given in auto-immune disorders including amyloidosis, Behçet's syndrome, glomerular kidney disease, primary biliary cirrhosis, polymyositis, rheumatoid arthritis, and sarcoidosis.

The use of chlorambucil in these disorders is discussed under the individual headings below.

Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

Chlorambucil is better tolerated than chlormethine hydrochloride and serious bone-marrow toxicity is not usually a problem with normal doses. When used as a single-agent antineoplastic for chronic lymphocytic leukaemia and lymphomas, chlorambucil is licensed for oral use in usual initial doses of 100 to 200 micrograms/kg daily (usually 4 to 10 mg once daily), for 3 to 8 weeks. A dose of 100 micrograms/kg daily may be adequate for the treatment of non-Hodgkin's lymphoma; 150 micrograms/kg daily until the total leucocyte count falls below 10 000 cells/mm^3 may be used in chronic lymphocytic leukaemia; and in Hodgkin's disease, 200 micrograms/kg daily is usually required. Lower doses may be given as part of a combination regimen. If lymphocytic infiltration of the bone marrow is present or if the bone marrow is hypoplastic, the daily dose should not exceed 100 micrograms/kg. Alternatively, high-dose chlorambucil may be given intermittently. For example, in chronic lymphocytic leukaemia it may be given in an initial single dose of 400 micrograms/kg increased by 100 micrograms/kg at each 2- or 4-week dose interval until control of lymphocytosis is achieved or toxicity occurs.

Once a remission has been established the patient may receive continuous maintenance with 30 to 100 micrograms/kg daily. However, short intermittent courses appear to be safer and are generally preferred for maintenance.

In patients with Waldenström's macroglobulinaemia chlorambucil is licensed in an initial oral dose of 6 to 12 mg daily until leucopenia develops. Maintenance therapy with doses of 2 to 8 mg daily may then be given indefinitely.

Total and differential white cell counts and haemoglobin and platelet examinations are recommended each week during treatment with chlorambucil.

Amyloidosis. Chlorambucil may be of use in preserving kidney function and improving survival in patients with amyloidosis secondary to rheumatic disease,[1-4] the management of which is discussed in more detail on p. 819.3.

1. Berglund K, *et al.* Alkylating cytostatic treatment in renal amyloidosis secondary to rheumatic disease. *Ann Rheum Dis* 1987; 46: 757–62.
2. Berglund K, *et al.* Results, principles and pitfalls in the management of renal AA-amyloidosis: a 10-21 year followup of 16 patients with rheumatic disease treated with alkylating cytostatics. *J Rheumatol* 1993; 20: 2051–7.
3. David J, *et al.* Amyloidosis in juvenile chronic arthritis: a morbidity and mortality study. *Clin Exp Rheumatol* 1993; 11: 85–90.
4. Savolainen HA. Chlorambucil in severe juvenile chronic arthritis: longterm followup with special reference to amyloidosis. *J Rheumatol* 1999; 26: 898–903.

Blood disorders, non-malignant. Chlorambucil may produce a response in cold auto-immune haemolytic anaemia (p. 1122.2).

Connective tissue and muscular disorders. Chlorambucil has been used as a corticosteroid-sparing agent in patients with Behçet's syndrome (p. 1601.1). It has occasionally been tried in polymyositis (p. 1611.1). In both these conditions, the potential benefits must be weighed against the possibility of toxicity.

Kidney disorders, non-malignant. Chlorambucil has been used in some forms of glomerular kidney disease (p. 1604.3). Minimal change nephropathy occurs mainly in young children and is the most common cause of childhood nephrotic syndrome. Treatment with cytotoxics is reserved for the most severe cases because of fears about toxicity; cyclophosphamide is generally preferred to chlorambucil because it is perceived as entailing somewhat less risk although chlorambucil has been used successfully in cyclophosphamide-resistant disease.[1] Although not licensed for use in children with relapsing corticosteroid-sensitive nephrotic syndrome, the *BNFC* suggests that children from 3 months of age may be given an oral dose of 200 micrograms/kg once daily for 8 weeks. Chlorambucil has been used with corticosteroids in patients with membranous nephropathy,[2-4] but again cyclophosphamide may be better tolerated.

1. Ueda N, *et al.* Beneficial effect of chlorambucil in steroid-dependent and cyclophosphamide-resistant minimal change nephrotic syndrome. *J Nephrol* 2009; 22: 610–5.
2. Ponticelli C, *et al.* Methylprednisolone plus chlorambucil as compared with methylprednisolone alone for the treatment of idiopathic membranous nephropathy. *N Engl J Med* 1992; 327: 599–603.
3. Reichert LJM, *et al.* Preserving renal function in patients with membranous nephropathy: daily oral chlorambucil compared with intermittent monthly pulses of cyclophosphamide. *Ann Intern Med* 1994; 121: 328–33.
4. Ponticelli C, *et al.* A 10-year follow-up of a randomized study with methylprednisolone and chlorambucil in membranous nephropathy. *Kidney Int* 1995; 48: 1600–4.

Liver disorders, non-malignant. No treatment has proven unequivocally successful in the management of primary biliary cirrhosis (p. 2638.3). Chlorambucil is one of several drugs for which reports of benefit exist.[1]

1. Hoofnagle JH, *et al.* Randomized trial of chlorambucil for primary biliary cirrhosis. *Gastroenterology* 1986; 91: 1327–34.

Malignant neoplasms. Chlorambucil is used in the management of haematological malignancies such as chronic lymphocytic leukaemia (p. 693.3), Hodgkin's disease (p. 696.1), indolent low-grade non-Hodgkin's lymphomas (p. 696.3), and Waldenström's macroglobulinaemia (p. 699.1). It was formerly used in polycythaemia vera (p. 695.2) but is now largely superseded.

Ocular disorders, non-malignant. Chlorambucil is one of the immunosuppressants that may be considered for patients with uveitis (p. 1615.1) unresponsive to corticosteroids in tolerable doses.[1-3]

1. Mudun AB, *et al.* Short-term chlorambucil for refractory uveitis in Behcet's disease. *Ocul Immunol Inflamm* 2001; 9: 219–29.
2. Miserocchi E, *et al.* Efficacy and safety of chlorambucil in intractable noninfectious uveitis. *Ophthalmology* 2002; 109: 137–42.
3. Goldstein DA, *et al.* Long-term follow-up of patients treated with short-term high-dose chlorambucil for sight-threatening ocular inflammation. *Ophthalmology* 2002; 109: 370–7.

Pemphigus and pemphigoid. Chlorambucil with prednisone or prednisolone has been reported[1,2] to be effective in the treatment of pemphigus and pemphigoid (p. 1687.1).

1. Shah N, *et al.* The use of chlorambucil with prednisone in the treatment of pemphigus. *J Am Acad Dermatol* 2000; 42: 85–8.
2. Chave TA, *et al.* Chlorambucil as a steroid-sparing agent in bullous pemphigoid. *Br J Dermatol* 2004; 151: 1107–8.

Rheumatoid arthritis. Chlorambucil has been used for its immunosuppressant properties in a few patients with severe rheumatoid arthritis (p. 13.2), especially with vasculitis, who have failed to respond to other drugs. However, the use of cytotoxic immunosuppressants other than methotrexate is considered debatable.

Sarcoidosis. Where drug therapy is required for sarcoidosis (p. 1612.2), corticosteroids are the usual treatment. Chlorambucil is one of several cytotoxic immunosuppressants that have been tried, with variable results, as a second-line therapy.

Adverse Effects and Treatment

For a general outline see Antineoplastics, p. 726.1 and p. 730.2.

A reversible progressive lymphocytopenia tends to develop during treatment with chlorambucil. Neutropenia may continue to develop up to 10 days after the last dose. Irreversible bone-marrow depression can occur particularly when the total dosage for the course approaches 6.5 mg/kg.

Other reported adverse effects include gastrointestinal disturbances, hepatotoxicity, skin rashes (rarely Stevens-Johnson syndrome or toxic epidermal necrolysis), peripheral neuropathy, and central neurotoxicity, including seizures. Interstitial pneumonia and pulmonary fibrosis have occurred; the latter is usually reversible but fatalities have been recorded. Chlorambucil in high doses may produce azoospermia and amenorrhoea; sterility has developed particularly when chlorambucil has been given to boys at or before puberty.

Overdosage may result in pancytopenia and in neurotoxicity, including agitation, ataxia, and grand mal seizures.

Like other alkylating agents, chlorambucil is potentially mutagenic, teratogenic, and carcinogenic, and an increased incidence of acute leukaemias and other secondary malignancies has been reported in patients who have received the drug.

Effects on the bladder. Chlorambucil-induced cystitis was reported in a 73-year-old woman given 2 mg daily for over 2 years for the treatment of lymphocytic lymphoma.[1]

1. Daoud D, *et al.* Sterile cystitis associated with chlorambucil. *Drug Intell Clin Pharm* 1977; 11: 491.

Effects on the eyes. Visual impairment and optic atrophy in a patient who had been receiving chlorambucil for 5 years to control non-Hodgkin's lymphoma were thought to be due to the drug,[1] although ocular effects are extremely rare with chlorambucil.

1. Yiannakis PH, Larner AJ. Visual failure and optic atrophy associated with chlorambucil therapy. *BMJ* 1993; 306: 109.

Effects on the nervous system. There have been a few reports of seizures in patients given chlorambucil. A review[1] of these suggested that in adults, patients with a history of seizures, or those given high doses of chlorambucil may be at increased risk. The reports in children consisted mainly of patients being treated for nephrotic syndrome, possibly because the condition may alter the pharmacokinetics of chlorambucil.

1. Salloum E, *et al.* Chlorambucil-induced seizures. *Cancer* 1997; 79: 1109–13.

Hypersensitivity. Drug fever, characterised by high temperature, rigors, and malaise, may occur in patients within hours or days of starting chlorambucil, often after a drug-free interval. In 3 patients who developed symptoms of chlorambucil-induced drug fever, desensitisation, beginning with an oral dose of 500 micrograms daily, increased about every 5 days by 500 micrograms up to 2 mg was successful. In one patient the dose was successfully increased to 4 mg daily by continuing to increase by 500 micrograms every 7 days.[1]

1. Weber E, *et al.* Rapid desensitization for chlorambucil drug fever. *Haematologica* 2007; 92: e77.

Precautions

For reference to the precautions necessary with antineoplastics, see p. 732.2. Chlorambucil should be avoided, or given with great care and at reduced doses, for at least 4 weeks after treatment with radiotherapy or other antineoplastics (unless only low doses of radiation have been given to parts remote from the bone marrow and the neutrophil and platelet counts are not depressed). The dose should be reduced if there is lymphocytic involvement of the bone marrow or if it is hypoplastic. Chlorambucil should be given with care to patients with impaired renal function; consideration should also be given to dose reduction in patients with gross hepatic dysfunction. Children with nephrotic syndrome, patients receiving high-dose pulse therapy with chlorambucil, and those with a history of seizures, may be at increased risk of seizures. Regular blood counts are required during therapy.

Handling and disposal. Chlorambucil is irritant; avoid contact with skin and mucous membranes.

Urine produced for up to 48 hours after a dose of chlorambucil should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies chlorambucil as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Pregnancy. A patient with chronic lymphocytic leukaemia who was taking low-dose chlorambucil was found to be pregnant with a viable 20-week fetus during the third month of chlorambucil treatment. Treatment was stopped, and a healthy child without apparent congenital anomaly was delivered at 36 weeks by caesarean section. Development and growth had remained normal at 3 months of age.[1]

1. Ali R, *et al.* Pregnancy in chronic lymphocytic leukemia: experience with fetal exposure to chlorambucil. *Leuk Res* 2009; 33: 567–9.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Pharmacokinetics

Chlorambucil is rapidly and almost completely absorbed from the gastrointestinal tract after oral doses and is reported to have a terminal half-life in plasma of about 1.5 hours. It is extensively metabolised in the liver, mainly to active phenylacetic acid mustard, which has a slightly longer plasma half-life of about 1.8 to 2.5 hours, and which like chlorambucil also undergoes some spontaneous degradation to further derivatives. Chlorambucil and its metabolites are extensively protein bound. It is excreted in the urine almost entirely as metabolites with less than 1% unchanged.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Leukeran; *Austral.*: Leukeran; *Austria*: Leukeran; *Belg.*: Leukeran; *Braz.*: Leukeran; *Canad.*: Leukeran; *Chile*: Leukeran; *China*: Leukeran (留可然); *Cz.*: Leukeran; *Denm.*: Leukeran; *Fin.*: Leukeran; *Ger.*: Leukeran; *Gr.*: Leukeran; *Hong Kong*: Leukeran; *India*: Clokeran; Leukeran; *Irl.*: Leukeran; *Israel*: Leukeran; *Ital.*: Leukeran; *Malaysia*: Leukeran; *Mex.*: Leukeran; *Neth.*: Leukeran; *Norw.*: Leukeran; *NZ*: Leukeran; *Philipp.*: Leukeran; *Pol.*: Leukeran; *Port.*: Leukeran; *Rus.*: Leukeran (Лейкеран); *S. Pharmacopoeial Preparations
BP 2014: Chlorambucil Tablets;
USP 36: Chlorambucil Tablets.

Chlormethine Hydrochloride

(BANM, rINNM)

Chlorethazine Hydrochloride; Chlorméthine, Chlorhydrate de; Chlormethini Hydrochloridum; Clormetina, hidrocloruro de; Hidrocloruro de clormetina; HN2 (chlormethine); Klormetin Hidroklorür; Mechlorethamine Hydrochloride; Mecloretamina (chlormethine); Mustin Hidroklorür; Mustine Hydrochloride; Nitrogen Mustard (chlormethine); NSC-762; WR-147650; Хлорметина Гидрохлорид.

Bis(2-chloroethyl)methylamine hydrochloride; 2,2′-Dichloro-*N*-methyldiethylamine hydrochloride.

$C_5H_{11}Cl_2N,HCl=192.5$

CAS — 51-75-2 (chlormethine); 55-86-7 (chlormethine hydrochloride).

ATC — L01AA05.

ATC Vet — QL01AA05.

UNII — L0MR697HHL

Pharmacopoeias. In *Br.*, *Chin.*, *Int.*, and *US*.

BP 2014: (Chlormethine Hydrochloride). A white or almost white, hygroscopic, vesicant, crystalline powder or mass. Very soluble in water. Store at a temperature of 8 degrees to 15 degrees.

USP 36: (Mechlorethamine Hydrochloride). A white, hygroscopic, crystalline powder. A 0.2% solution in water has a pH of 3.0 to 5.0. Store in airtight containers. Protect from light.

Stability. Solutions of chlormethine hydrochloride lose their activity very rapidly, particularly at neutral or alkaline pH.

A study[1] using an assay specific for chlormethine found that a 0.1% solution in Water for Injections or sodium chloride 0.9% injection underwent a loss of about 10% when stored for 6 hours at room temperature, and of about 4 to 6% when stored for the same period at 4 degrees; similar results were obtained whether the solution was stored in glass vials or plastic syringes. Solutions in 500 mL of sodium chloride or glucose 5% injection and stored in PVC infusion bags were still less stable, with 15% and 10% degradation respectively after 6 hours at room temperature.

Chlormethine hydrochloride has been used in extemporaneous ointment preparations in the treatment of mycosis fungoides.[2] One formulation of chlormethine hydrochloride, dissolved in acetone and worked into white soft paraffin, was reported[3] to be stable for at least 84 days when stored at 4 degrees, and for at least 40 days at 37 degrees.

3. Cummings J, *et al.* The long term stability of mechlorethamine hydrochloride (nitrogen mustard) ointment measured by HPLC. *J Pharm Pharmacol* 1993; 45: 6–9.

Uses and Administration

Chlormethine belongs to the group of antineoplastic drugs described as alkylating agents. It also possesses weak immunosuppressant properties.

Chlormethine hydrochloride has been used in the treatment of advanced Hodgkin's disease (p. 696.1), historically with a vinca alkaloid, procarbazine, and prednisone or prednisolone (the MOPP regimen). Chlormethine has also been tried in non-Hodgkin's lymphomas, notably mycosis fungoides (p. 698.3), and some other malignancies including chronic leukaemias, tumours of the breast, ovary, and lung, and in polycythaemia vera. Chlormethine has been used in the management of malignant effusions but is not the agent of choice.

In the MOPP regimen chlormethine hydrochloride has been given in doses of 6 mg/m^2. However, when licensed for use as a single agent, the usual dose of chlormethine hydrochloride is 400 micrograms/kg, preferably as a single dose, although it may be divided into 2 or 4 equal doses on successive days. It is given by intravenous injection in a strength of 1 mg/mL in Water for Injections or sodium chloride 0.9%. Injection over 2 minutes into the tubing of a fast running intravenous infusion of sodium chloride 0.9% or glucose 5% may reduce the incidence of thrombophlebitis and the risk of extravasation.

The response should be assessed by the trend of the blood counts. Treatment with chlormethine may be repeated when the bone-marrow function has recovered.

Intracavitary injections of 200 to 400 micrograms/kg have been given in the treatment of malignant, especially pleural, effusions.

For topical treatment of mycosis fungoides, see below.

Histiocytic syndromes. Dilute solutions of chlormethine (200 micrograms/mL) have been applied topically for the cutaneous symptoms of Langerhans-cell histiocytosis (p. 692.1).[1,2] Such therapy was reported to effectively clear skin lesions in most patients, and be well tolerated. However, although no malignant skin disease developed during the follow-up of one group of children, the long-term effects of topical chlormethine are of concern in young patients.[2]

1. Sheehan MP, *et al.* Topical nitrogen mustard: an effective treatment for cutaneous Langerhans cell histiocytosis. *J Pediatr* 1991; 119: 317–21.
2. Roeger PH, *et al.* Long term follow up of topical mustine treatment for cutaneous Langerhans cell histiocytosis. *Arch Dis Child* 2000; 82: 483–7.

Mycosis fungoides. Chlormethine is used topically in the management of mycosis fungoides (p. 698.3). A retrospective cohort analysis[1] of 203 patients treated with chlormethine found a partial response rate of 33% and a complete response rate of 50%. The median time to achieve complete response was 12 months and the time to relapse was also 12 months. Mild disease of limited skin involvement responded better than generalised patch/plaque disease, and more patients with mild disease obtained long-term remission. Maintenance therapy was used in some patients, but on cessation the relapse rate was similar to patients who did not receive maintenance therapy. Although unlicensed in the UK, guidelines[2] suggest chlormethine as a treatment option for early-stage mycosis fungoides, applied in a concentration of 0.01% or 0.02%, either as an aqueous solution in sodium chloride 0.9% or in an ointment base such as emulsifying ointment.

Whittaker SJ, *et al.* Joint British Association of Dermatologists and UK Cutaneous Lymphoma Group guidelines for the management of primary cutaneous T-cell lymphomas. *Br J Dermatol* 2003; 149: 1095–1107. Also available at: http://www.bad.org.uk/Portals/_Bad/Guidelines/Clinical%20Guidelines/Cutaneous%20T%20Cell%20Lymphoma.pdf (accessed 22/04/10)

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Chlormethine hydrochloride is extremely toxic and its use is invariably accompanied by adverse effects. Severe nausea and vomiting may begin within an hour of injection of the drug and last for some hours; antiemetics should be given before treatment. It causes varying degrees of bone-marrow depression depending on the dose. In heavily pretreated patients, or when the total dose for a single course exceeds 400 micrograms/kg, there is a risk of severe and possibly fatal depression with anaemia, lymphocytopenia, granulocytopenia, and thrombocytopenia with consequent haemorrhage. Depression of lymphocytes may be apparent within 24 hours of a dose and maximum suppression of granulocytes and platelets occurs within 7 to 21 days; haematological recovery may be adequate after 4 weeks.

Tinnitus, vertigo, deafness, headache, drowsiness, and other neurological symptoms have been reported, as have episodes of jaundice. Skin reactions to chlormethine hydrochloride include maculopapular rashes. Hypersensitivity is frequent when topical preparations are used.

Chlormethine hydrochloride has a powerful vesicant action on the skin and mucous membranes and great care must be taken to avoid contact with the eyes. Thrombophlebitis is a potential hazard of chlormethine particularly if it is not sufficiently diluted. Extravasation of the injection causes severe irritation and even sloughing. If extravasation occurs during injection, it has been suggested that the involved area should be infiltrated with an isotonic 4% solution of sodium thiosulfate, followed by the application of an ice compress intermittently for 6 to 12 hours, although the role of specific antidotes in antineoplastic extravasation is somewhat contentious (see p. 731.3).

Chlormethine hydrochloride may produce temporary or permanent inhibition of fertility. There is some evidence of mutagenicity, teratogenicity, and carcinogenicity.

Effects on the nervous system. Severe immediate neurotoxicity developed[1] in 14 of 21 evaluable patients who underwent bone marrow transplantation after preparation with cytotoxic regimens including chlormethine 0.3 to 2 mg/kg. Symptoms developed a median of 4 days after treatment and included headache, hallucinations, confusion, convulsions, paraplegia, and tremor. Symptoms resolved in most, although in some they had not done so before their death. Six of the patients who recovered from acute toxicity developed a delayed neurotoxicity, beginning a median of 169 days after the first chlormethine injection and characterised by symptoms including confusion, somnolence, personality change, dementia, focal motor seizures, and hydrocephalus. Patients older than 21 years, those who had received CNS irradiation, and those treated concomitantly with other cytotoxic agents were at increased risk of neurotoxicity.

1. Sullivan KM, *et al.* Immediate and delayed neurotoxicity after mechlorethamine preparation for bone marrow transplantation. *Ann Intern Med* 1982; 97: 182–9.

Handling and disposal. Chlormethine hydrochloride is a strong vesicant; avoid contact with skin and mucous membranes.

The manufacturers state that *unused injection* solutions of chlormethine hydrochloride may be neutralised by mixing with an equal volume of a solution containing sodium thiosulfate 5% and sodium bicarbonate 5% and allowing to stand for 45 minutes. Equipment used in the preparation and administration of such solutions may be treated similarly. Alternatively a solution containing sodium carbonate 2.5% or sodium hydroxide in a mixture of industrial methylated spirit and water has been suggested for the decontamination of equipment.

Urine produced for up to 48 hours after a dose of chlormethine should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies chlormethine as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Pharmacokinetics

On intravenous injection, chlormethine is rapidly converted to a reactive ethyleneimmonium ion. It usually disappears from the blood in a few minutes. A very small proportion is excreted unchanged in the urine.

Preparations

Proprietary Preparations (details are given in Volume B)

ATC Vet — QL01XA01.
UNII — Q20Q21Q62J.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Cisplatin). A yellow powder or yellow or orange-yellow crystals. Slightly soluble in water; practically insoluble in alcohol; sparingly soluble in dimethylformamide. A 0.1% solution in sodium chloride 0.9% has a pH of 4.5 to 6.0 immediately after preparation. Store in airtight containers. Protect from light.

USP 36: (Cisplatin). Store in airtight containers. Protect from light.

Incompatibility. Cisplatin is rapidly degraded in the presence of bisulfite or metabisulfite,[1,2] and admixture with preparations containing these as preservatives may result in loss of activity.[2] Sodium bicarbonate may also increase the loss of cisplatin from solution, and in some cases may cause precipitation.[3] The stability of cisplatin when mixed with fluorouracil is reported to be limited, with 10% loss of cisplatin in 1.2 to 1.5 hours.[4] Mixtures with etoposide[5] in sodium chloride 0.9% injection formed a precipitate if mannitol and potassium chloride were present as additives, but not when the diluent was glucose 5% with sodium chloride 0.45%. Turbidity has been reported[6] within 4 hours of mixing 0.1% solutions of cisplatin and thiotepa in glucose 5%. Cisplatin exhibits variable incompatibility with paclitaxel, depending on the paclitaxel concentration and the temperature.[7]

Cisplatin reacts with aluminium causing loss of potency and precipitate formation. Needles, syringes, catheters or giving sets that contain aluminium should not be used for preparing or giving cisplatin.

7. Zhang Y, *et al.* Compatibility and stability of paclitaxel combined with cisplatin and with carboplatin in infusion solutions. *Ann Pharmacother* 1997; 31: 1465–70.

Stability. Decomposition of cisplatin in aqueous solutions is mainly due to reversible substitution of water for chloride, and its stability is enhanced in sodium chloride solutions because of the excess of chloride ions available.[1,2] A solution in sodium chloride 0.9% injection has been reported to lose 3% of the drug in less than one hour and to remain stable at this equilibrium value for 24 hours at room temperature.[1] Stability is decreased if exposed to intense light, but the effect of normal lighting conditions is apparently smaller.[1,2] It has been recommended that admixtures of cisplatin with mannitol and magnesium sulfate (in glucose 5% with sodium chloride 0.45%) stored at room temperature in PVC bags should be used within 48 hours, but may be stored for 4 days at 4 degrees or frozen and stored at -15 degrees for up to 30 days.[3] However, solutions containing 600 micrograms/mL or more of cisplatin precipitate out when refrigerated and are slow to redissolve.[1]

3. LaFollette JM, *et al.* Stability of cisplatin admixtures in polyvinyl chloride bags. *Am J Hosp Pharm* 1985; 42: 2652.

Uses and Administration

The antineoplastic cisplatin is a platinum-containing complex that may act similarly to the alkylating agents. Its antineoplastic actions are cell-cycle non-specific and are dependent upon its *cis* configuration; they appear to be related to its hydrolysis in the body to form reactive aquated species. Although it causes immunosuppression, stimulation of the host immune response against the tumour has been suggested as contributing to cisplatin's antineoplastic action.

Cisplatin is of value in the treatment of tumours of the testis, usually as a major component of combination chemotherapy regimens, and particularly with bleomycin and etoposide (BEP), or with bleomycin and a vinca alkaloid. It is also used in metastatic ovarian tumours, cervical tumours, lung cancer, advanced bladder cancer, and squamous cell carcinoma of the head and neck. It has been reported to be active against many other solid tumours, as indicated by the cross references given under Malignant Neoplasms, p. 767.1.

Cisplatin is given by intravenous infusion in sodium chloride 0.9% or in a mixture of sodium chloride and glucose. In monotherapy, it is usually given as a single dose of 50 to 120 mg/m² every 3 to 4 weeks. Alternatively, 15 to 20 mg/m² is given daily for 5 days, every 3 to 4 weeks. Lower doses are generally used for combination chemotherapy regimens than for single agent therapy; 20 mg/m² or more is given once every 3 to 4 weeks. A dose of 20 mg/m² daily for 5 days every 3 to 4 weeks has been used in combination chemotherapy of testicular tumours.

Licensed product information recommends that cisplatin is given in 2 litres of chloride-containing infusion fluid. In practice, volumes of less than 2 litres have been used in expert centres. The infusion may be given over 1 to 2 hours, although licensed product information generally recommends a longer infusion time of 6 to 8 hours in order to reduce renal and gastrointestinal toxicities.

To aid diuresis and protect the kidneys, 37.5 g of mannitol (e.g. 375 mL of mannitol 10%) is usually added to the infusion or is infused separately immediately before cisplatin. In order to begin diuresis the patient is usually hydrated by the infusion of 1 to 2 litres of a suitable fluid over several hours before giving cisplatin. Adequate hydration must also be maintained for up to 24 hours after a dose. Renal, haematological, auditory, and neurological function should be monitored during therapy, and dosage adjusted accordingly.

Cisplatin has also been given by the intra-arterial and intraperitoneal routes, and by instillation into the bladder. It is being investigated as a liposomal formulation, and as a collagen-based injectable gel containing cisplatin and adrenaline (MPI-5010) to localise the effect. An oral formulation of cisplatin is also under investigation.

Various analogues of cisplatin have been developed or investigated including those with fewer adverse effects e.g. carboplatin, p. 759.1; nedaplatin, p. 834.3), an altered spectrum of activity (oxaliplatin, p. 838.1), or activity on oral dosage (satraplatin, p. 856.3).

Administration. Adjustments to the way in which cisplatin is given have been suggested in an attempt to improve efficacy while reducing toxicity.

Hydration before and after a dose of cisplatin, together with the use of mannitol to promote diuresis, is now standard (see Uses and Administration, above). Higher doses of cisplatin (up to 200 mg/m² per treatment cycle) have been successfully given by infusion in hypertonic sodium chloride, accompanied by intensive hydration.[1,2] Sodium chloride 3% infusion solution has been used.[3] However, while such a regimen may limit nephrotoxicity, other toxic effects, such as peripheral neuropathy, are not prevented;[1,2,4,5] myelosuppression may be less if the total dose is given in 2 divided doses rather than divided over 5 days.[2] High-dose cisplatin has been given once weekly; haematological toxicity may be dose-limiting with this regimen.[3]

Toxicity has been reported to be reduced when cisplatin was given by continuous intra-arterial[6] or intravenous[7] infusion. It has also been suggested that giving cisplatin in the evening rather than the morning results in less damage to renal function, apparently because of circadian variations in urine production.[8] However, another study[9] found that morning, rather than evening, doses of cisplatin resulted in less renal damage. Noting the inconsistency with previous reports, the authors concluded that use of a prolonged hydration protocol and concomitant furosemide might have been responsible for these results (see also under Interactions, Cardiovascular Drugs, p. 768.3). It was also found that morning dosage of cisplatin may be more emetogenic than evening dosage, although the use of prophylactic ondansetron before cisplatin reduced this apparent circadian effect on vomiting.

A suggested alternative way to increase the platinum dose without producing incapacitating toxicity has been the combination of cisplatin and carboplatin.[10] Formulation as liposomal cisplatin is also under investigation.[11]

Various drugs have been investigated to reduce toxicity, including amifostine, glutathione, and thiosulfate, as discussed under Effects on the Ears, p. 767.2 Effects on the Kidneys, p. 767.2 and Effects on the Nervous System, p. 767.3.

A retrospective study of patients with bladder cancer found that calculation of creatinine clearance (CC) by mathematical formulas was inadequate in determining renal eligibility for treatment with cisplatin, especially in patients over 65 years of age; up to 44% of patients who were treated with cisplatin based on measured CC would have been deemed ineligible using mathematical calculations.[12] The value of therapeutic drug monitoring has been reviewed.[13]

Administration in the elderly. Despite receiving less chemotherapy than their younger counterparts, selected

elderly patients have been shown to benefit from adjuvant cisplatin-based chemotherapy and studies have concluded that chemotherapy should not be withheld from patients on the basis of age.[1,2] A review[3] considered cisplatin to be a viable treatment option in selected elderly patients; renal function and the high incidence of age-related hearing loss should, however, be taken into consideration. The authors recommended that cisplatin be used at the lower range of dosage, and preferably at a reduced infusion rate (for example, over 24 hours) to avoid excessive toxicity in the elderly; hydration should be monitored to prevent fluid overload and concomitant use of nephrotoxic drugs should be avoided.

Use of mathematical formulas to determine renal eligibility for cisplatin treatment has been deemed to be inadequate, especially in patients over 65 years of age, see Administration, p. 766.3.

Administration in renal impairment. Licensed product information generally contra-indicates the use of cisplatin in patients with renal impairment. However, there are reports of the use of cisplatin with peritoneal dialysis[1] or haemodialysis[2,3] in a few patients.

Malignant neoplasms. Cisplatin is used in the management of many solid malignancies, notably those of the bladder, cervix, lung, ovary, and testis, as discussed on p. 700.2, p. 704.2, p. 710.2, p. 711.2, and p. 715.1 respectively. Other malignancies where cisplatin may be employed, as discussed in the introduction to this chapter, include non-Hodgkin's lymphomas (p. 696.3), tumours of brain (p. 701.2), endometrium (p. 704.3), oesophagus, stomach, and anus (p. 705.3, p. 706.1, and p. 708.1), head and neck (p. 708.1), and thymus (p. 715.3), neuroblastoma (p. 716.2), and sarcoma of bone and soft tissue (p. 717.3 and p. 718.2).

Adverse Effects and Treatment

For a general outline see Antineoplastics, p. 726.1 and p. 730.2.

Severe nausea and vomiting occur in most patients during treatment with cisplatin; nausea may persist for up to a week.

Serious toxic effects on the kidneys, bone marrow, and ears have been reported in up to about one third of patients given a single dose of cisplatin; the effects are generally dose-related and cumulative.

Damage to the renal tubules may be evident during the second week after a dose of cisplatin and renal function must return to normal before further cisplatin is given. Adequate hydration, and use of osmotic diuretics such as mannitol to increase urine volume and thus decrease the urinary concentration of platinum, can reduce the incidence of nephrotoxicity. Electrolyte disturbances, particularly hypomagnesaemia and hypocalcaemia, may occur, possibly as a result of renal tubular damage. Hyperuricaemia is also seen.

Bone-marrow depression may be severe with higher doses of cisplatin. Nadirs in platelet and leucocyte counts occur between days 18 and 23 and most patients recover by day 39; anaemia is common and may be partly related to decreased production of erythropoietin after renal damage.

Ototoxicity may be more severe in children. It can manifest as tinnitus, loss of hearing in the high frequency range, and occasionally deafness or vestibular toxicity. Other neurological effects reported include peripheral neuropathies, loss of taste, seizures, and encephalopathy including reversible posterior leukoencephalopathy. Ocular toxicities include optic neuritis, papilloedema, and cerebral blindness.

Anaphylactoid reactions and cardiac abnormalities have occurred. Injection site reactions, including localised oedema, pain, erythema, skin ulceration and phlebitis may occur. Extravasation may lead to tissue cellulitis, fibrosis, and necrosis. Intra-arterial use of cisplatin has been associated with hepatobiliary disorders, including cholecystitis, biloma, and liver abscesses.

Platinum derivatives are potentially mutagenic and teratogenic, and there is some evidence they may be associated with the development of secondary leukaemias—see Carcinogenicity, p. 726.2.

Effects on the blood. Cisplatin-induced anaemia appears to be disproportionate to the effects on other blood cells, and to correlate with renal tubular dysfunction.[1] It may therefore be due to an erythropoietin deficiency state resulting from cisplatin-induced renal tubular damage. Haemolysis has also been reported.[2]

THROMBOEMBOLISM. For discussion of thromboembolic events possibly associated with cisplatin-containing chemotherapy regimens see Effects on the Cardiovascular System, p. 727.2.

Effects on the ears. Ototoxicity is a well-established adverse effect of cisplatin.[1] It appears to be due to generation of reactive oxygen species that cause apoptosis of hair cells in the cochlea,[1] and results in hearing loss, particularly at high frequencies.[1,2] Risk factors include younger age,[1] larger cumulative doses[1] (one study[2] identified doses above 60 mg/m^2 as risk factors), pre-existing hearing loss or renal disease,[1] and irradiation of the brain or base of the skull.[1,3] Various substances including thiols, amifostine, ebselen, allopurinol, and salicylates have been investigated in *animals* for their protective effect against cisplatin-induced neurotoxicity[1] but although some promising results have been seen, benefit is yet to be shown in large clinical studies, and there is some concern about the risk of reducing the antineoplastic effect of cisplatin as well. However, a small study comparing cisplatin chemoradiation with or without sodium thiosulfate tentatively concluded that thiosulfate did seem to offer some protection against hearing loss.[4] Another study[5] in young patients with average-risk medulloblastoma found that amifostine, given before and during cisplatin infusion, significantly reduced the risk of severe ototoxicity. It was noted[6] that the cisplatin dose and schedule used for this study were different to those commonly used in other paediatric malignancies, and that amifostine might not necessarily be protective in other settings.

Effects on electrolytes. Renal-magnesium wasting and, less commonly, symptomatic hypomagnesaemia occurs with cisplatin therapy.[1,2] Adding magnesium to the pre- and posthydration fluids has been suggested.[2] When hypocalcaemia is also present, tetany may result,[1,3] although this has responded to electrolyte infusion without the need to interrupt chemotherapy.[1] Cisplatin therapy may also be associated with significant hypokalaemia,[1] and salt-wasting,[4] and hyponatraemia.[5,6]

Effects on the heart. Cases of cardiac arrhythmias (including atrial fibrillation, supraventricular tachycardia, sinus tachycardia, sinus bradycardia, and third-degree heart block) have been reported following the use of cisplatin and other platinum-based antineoplastic drugs.[1,2] It was proposed that this may be due to either direct arrhythmogenicity, hypersensitivity, or electrolyte imbalances (see also Effects on Electrolytes, above).

2. Zakaria S, *et al.* Atrial flutter associated with carboplatin administration. *Ann Pharmacother* 2011; **45**: e59.

Effects on the kidneys. Nephrotoxicity is a well-established adverse effect of cisplatin, may be dose-limiting, and can manifest as acute or chronic renal failure, polyuria, or chronic hypomagnesaemia.[1] The mechanism appears to involve mainly damage to the proximal renal tubule; selective magnesium loss may be due to a specific membrane or transport system abnormality. Sulfhydryl metabolism and oxidative stress play a role in toxicity, and measures that reduce glutathione depletion and scavenge intracellular free oxygen radicals have been tried in an attempt to modulate nephrotoxicity.[1-3] However, the primary measures for reducing renal damage have been aggressive hydration with chloride-containing solutions, and the use of mannitol (see also Prophylaxis, below). It has been suggested that cisplatin may mobilise lead accumulated in bone and cause temporary accumulation in the kidney, with concomitant toxicity,[4] but this has been vigorously disputed.[5-7]

PROPHYLAXIS. Hydration with 1 to 2 litres of fluid before treatment, and infusion of cisplatin in a further 2 litres of infusion fluid containing an osmotic diuretic such as mannitol reduces the nephrotoxicity of cisplatin, but does not abolish it. Maintaining adequate hydration and urinary output post-treatment is also important. It has been recommended[1] that urinary output be maintained at 3 to 4 litres daily for 2 to 3 days after a dose of cisplatin. Giving cisplatin over 6 to 8 hours rather than 1 to 2 hours may also decrease renal toxicity.

Sulfur-containing nucleophiles can inactivate cisplatin, and have therefore been investigated for their chemoprotective potential. Amifostine is a prodrug that is selectively activated by normal tissue, and has been shown to protect normal tissue (principally the kidney) against the cytotoxicity of cisplatin without affecting antitumour activity (for references, see Cytoprotection, p. 1539.3). Glutathione (p. 1555.2) is a similar agent, which may be selectively taken up by kidney and neural tissue. Sodium thiosulfate (p. 1576.1) does not show selective activation or uptake, and its use is therefore limited to situations where cisplatin is given locally (e.g. intraperitoneal[2,3]) or directly (e.g. intra-arterial[4]).

Effects on the nervous system. The features of cisplatin-induced peripheral neuropathy are consistent with damage mainly to sensory fibres, with numbness, tingling, and decreased vibratory sensation and deep tendon reflexes, progressing in severe cases to disabling sensory ataxia.[1] The toxicity is dose-dependent, with symptoms usually appearing in patients who have received cumulative doses of 300 to 600 mg/m^2, although individuals vary in susceptibility. Neuropathy is reversible but recovery may take a year or more. The pathophysiology is unknown. Peripheral neuropathy can be a dose-limiting toxicity for cisplatin and agents such as Org-2766 (a corticotropin analogue) and amifostine (p. 1539.2) have been investigated for their potential in protecting peripheral nerves.[1-3] Vitamin E has been reported to be effective in reducing cisplatin-induced peripheral neuropathy.[4,5] Glutathione is also under investigation for the prevention of neurotoxicity (see p. 1555.2). Other drugs that have been tried include oxcarbazepine and ditiocarb sodium.[6] However, a systematic review considered that the evidence for most of the interventions intended to reduce cisplatin neurotoxicity was insufficient to show benefit.[6] Autonomic neuropathy, with, in some cases, consequent orthostatic hypotension, has also been described after treatment with cisplatin-containing regimens.[7] Apart from ototoxicity (see above), cisplatin has also been associated with central neurotoxicity, including leukoencephalopathy or focal encephalopathy, seizures, aphasia, confusion, agitation, and cortical blindness.[8-12] It has been suggested that the mechanism of focal encephalopathy may be vascular,[8] although this is uncertain.

Extravasation. For discussion of the management of extravasation, including methods to manage cisplatin extravasation, see under Treatment of the Adverse Effects of Antineoplastics, p. 731.3.

Hypersensitivity. Anaphylactoid reactions to intravenous cisplatin generally appear within a few minutes of dosage and have manifested as facial oedema, wheezing, tachycardia, and hypotension.[1] A high incidence of anaphylactoid reaction has also been seen after intravesical instillation in patients with bladder cancer,[2] but intraperitoneal or intrapleural use does not seem to be associated with an enhanced risk of hypersensitivity,[3] although anaphylactoid reactions have occurred when cisplatin is given intraperitoneally.[4] Anaphylactoid symptoms and ischaemia of the hands accompanied severe exfoliative dermatitis in one patient on the second cycle of cisplatin-based chemotherapy;[5] she had earlier had exfoliative dermatitis associated with carboplatin. However, it is unclear to what extent cross-sensitivity exists between platinum compounds; cisplatin has been successfully used after a hypersensitivity reaction to oxaliplatin.[6] Palmar-plantar erythrodysesthesia (p. 730.1) has also occurred with cisplatin.[7]

Nausea and vomiting. For discussion of the management of chemotherapy-induced nausea and vomiting, see under Nausea and Vomiting, p. 1814.3.

Overdosage. Fatalities have occurred with a total intravenous cisplatin dose of 640 mg given over 4 days and 750 mg given over 1 day; overdoses ranging from 180 to 480 mg/m^2 have been reported without fatalities, although significant toxicities are expected to occur. Immediate effects, in the first hours or days include nausea and vomiting, and rarely, diarrhoea. These may be followed by acute renal failure, electrolyte disturbances, hepatotoxicity, and rarely, pancreatitis, respiratory failure, and seizures. Later adverse effects that occur after days or weeks include chronic renal failure, myelosuppression, ototoxicity, peripheral neuropathy, and retinopathy. Key management strategies for a cisplatin overdose involve renal protection and enhancing drug elimination. Aggressive intravenous hydration with at least 3 to 6 litres daily is essential for reducing nephrotoxicity (for prophylaxis of nephrotoxicity with therapeutic doses, see p. 767.3). The osmotic diuretic mannitol (25 to 50 g intravenously, diluted in 250 to 500 mL of a suitable infusion fluid and given over 60 minutes) may be used to achieve a urine output of 1 to 3 mL/kg per hour for 6 to 24 hours. Sodium thiosulfate may be considered, particularly within the first 2 hours, although the optimum dose regimen has not been established. It is thought to bind free platinum thereby limiting renal tubular necrosis, and may protect against renal magnesium wasting. Plasmapheresis has been used successfully in some cases; haemodialysis, although useful for acute renal failure, is not effective at removing cisplatin from the circulation. Investigational therapies include amifostine, ditiocarb sodium, acetylcysteine, fosfomycin, and colestipol.[1]

Precautions

For reference to the precautions necessary with antineoplastics, see p. 732.2. Cisplatin is generally contra-indicated in patients with renal or hearing impairment, or bone-marrow depression. Renal and neurological function and hearing should be monitored during treatment, and regular blood counts performed. Electrolytes should be measured before starting therapy, and before each subsequent course. Adequate hydration and urinary output must be maintained before, and for 24 hours after, a dose.

Patients are recommended to use appropriate contraceptive measures during treatment and for 6 months after stopping treatment.

Breast feeding. Platinum concentrations in a patient receiving cisplatin were 900 nanograms/mL in breast milk and 800 nanograms/mL in plasma.[1] Although most of the platinum in breast milk is probably protein-bound the authors considered that a mother should not breast feed while receiving cisplatin. However, in another report,[2] cisplatin was undetectable in breast milk and the American Academy of Pediatrics[3] considers its use to be compatible with breast feeding.

Handling and disposal. Methods for the destruction of *cisplatin wastes* by reduction with zinc powder under acidic conditions or by reaction with ditiocarb sodium have been described.[1] Residue produced by the degradation of cisplatin by either method showed no mutagenicity *in vitro*.

Urine produced for up to 7 days after a dose of cisplatin should be handled wearing protective clothing.[2]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies cisplatin as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/08/11)

Pregnancy. Cisplatin was given with etoposide and bleomycin to a pregnant woman at 26 weeks of gestation for carcinoma of uncertain primary origin. At 27 weeks of gestation, she developed profound neutropenia followed by septicaemia and went into premature labour. The infant had profound leucopenia and neutropenia by day 3, which was attributed to chemotherapy given 6 days before delivery; prophylactic antibacterials including gentamicin were given. Hair loss at the age of 10 days was attributed to etoposide. At 1 year of age, the child had moderate bilateral sensorineural hearing loss; this was considered to be either due to cisplatin exposure *in utero* or to gentamicin use.[1] However, there are other reports of cisplatin use during the second or third trimester of pregnancy with no subsequent apparent adverse effects on the infant.[2-5] In most cases, cisplatin had been given with cyclophosphamide,[2-4] although in one instance it was given with paclitaxel.[5] In one report, cisplatin-induced maternal ototoxicity led to it being replaced after 2 courses by carboplatin.[4]

1. Raffles A, *et al.* Transplacental effects of maternal cancer chemotherapy: case report. *Br J Obstet Gynaecol* 1989; 96: 1099–1100.

3. King LA, *et al.* Treatment of advanced epithelial ovarian carcinoma in pregnancy with cisplatin-based chemotherapy. *Gynecol Oncol* 1991; 41: 78–80.
4. Henderson CE, *et al.* Platinum chemotherapy during pregnancy for serous cystadenocarcinoma of the ovary. *Gynecol Oncol* 1993; 49: 92–4.
5. Sood AK, *et al.* Paclitaxel and platinum chemotherapy for ovarian carcinoma during pregnancy. *Gynecol Oncol* 2001; 83: 599–600.

Radiotherapy. Enhanced ototoxicity has been reported in patients given cisplatin with cranial irradiation.[1,2]

1. Granowetter L, *et al.* Enhanced cis-platinum neurotoxicity in pediatric patients with brain tumors. *J Neurooncol* 1983; 1: 293–7.
2. Mahoney DH, *et al.* Ototoxicity with cisplatin therapy. *J Pediatr* 1983; 103: 1006.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Use with other myelosuppressive, nephrotoxic or ototoxic drugs may exacerbate the adverse effects of cisplatin. The effects of cisplatin on renal function may also affect the pharmacokinetics of other drugs excreted by the renal route.

Antibacterials. Although the use of cisplatin with other nephrotoxic or ototoxic drugs requires great caution, there is some evidence that *aminoglycosides* can be used in patients who have recently received cisplatin if appropriate supportive care is available.[1]

1. Cooper BW, *et al.* Renal dysfunction during high-dose cisplatin therapy and autologous hematopoietic stem cell transplantation: effect of aminoglycoside therapy. *Am J Med* 1993; 94: 497–504.

Antineoplastics. The ototoxicity of cisplatin was reportedly enhanced by *ifosfamide*,[1] a drug that is not ototoxic when given alone, although it does have nephrotoxic potential, making reports of increased nephrotoxicity in patients who have received both unsurprising.[2,3]

For a report of increased toxicity with *etoposide*, see p. 792.1. Cisplatin may reduce the clearance of *paclitaxel*, see p. 842.2.

2. Rossi R, Ehrich JHH. Partial and complete de Toni-Debré-Fanconi syndrome after ifosfamide chemotherapy of childhood malignancy. *Eur J Clin Pharmacol* 1993; 44 (suppl 1): S43–S45.
3. Martinez F, *et al.* Ifosfamide nephrotoxicity: deleterious effect of previous cisplatin administration. *Lancet* 1996; 348: 1100–1.

Cardiovascular drugs. A patient whose renal function was unaffected by cisplatin alone developed nephrotoxicity when given cisplatin and antihypertensive therapy with *furosemide, hydralazine, diazoxide,* and *propranolol*.[1] Previous results in *animals* suggest that furosemide may aggravate cisplatin nephrotoxicity, while the other antihypertensives might have contributed to a transient fall in renal-blood flow with resultant increased renal-tubular cisplatin concentration.

1. Markman M, Trump DL. Nephrotoxicity with cisplatin and antihypertensive medications. *Ann Intern Med* 1982; 96: 257.

Gastrointestinal drugs. For mention of 2 retrospective studies, one showing a decreased area under the plasma-concentration time curve of high-dose cisplatin with *ondansetron* and the other an increase, see p. 773.3.

Pharmacokinetics

After intravenous doses cisplatin disappears from the plasma in a biphasic manner and half-lives of 25 to 49 minutes and 3 to 4 days have been reported for total platinum. More than 90% of the platinum from a dose is protein bound within 2 to 4 hours; only the unbound fraction has significant antineoplastic activity. Cisplatin is concentrated in the liver, kidneys, and large and small intestines. Penetration into the CNS appears to be poor. Excretion is mainly in the urine but is incomplete and prolonged: up to about 50% of a dose has been reported to be excreted in urine over 5 days, and platinum may be detected in tissue for several months afterwards. The unbound fraction, which is more rapidly cleared, may be actively secreted by the renal tubules. Cisplatin is well-absorbed on intraperitoneal use. Cisplatin may be distributed into breast milk (see Breast Feeding, above).

Cladribine *(BAN, USAN, rINN)*

2-Chlorodeoxyadenosine; Cladribin; Cladribina; Cladribinum; Kladribiini; Kladribin; Kladrybina; RWJ-26251-000; RWJ-26251; Кладрибин.
2-Chloro-2′-deoxyadenosine.
$C_{10}H_{12}ClN_5O_3$=285.7
CAS — 4291-63-8.
ATC — L01BB04.
ATC Vet — QL01BB04.
UNII — 47M74X9YT5.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Cladribine). A white or almost white crystalline powder. It exhibits polymorphism. Slightly soluble in water and in methyl alcohol; soluble in dimethyl sulfoxide; practically insoluble in acetonitrile. Store at a temperature of 2 degrees to 8 degrees. Protect from light.

USP 36: (Cladribine). Store at a temperature of 2 degrees to 8 degrees. Protect from light.

Stability. Cladribine shows increased degradation in glucose 5%, therefore this diluent should not be used. Cladribine in sodium chloride 0.9% is stable for at least 24 hours at room temperature and ambient lighting in PVC infusion containers.

Licensed product information states that cladribine should be stored at 2 degrees to 8 degrees and protected from light.

Uses and Administration

Cladribine is a chlorinated purine nucleoside analogue that inhibits DNA synthesis and repair, particularly in lymphocytes and monocytes. It is used as an antimetabolite antineoplastic for the treatment of lymphoid malignancies including hairy-cell leukaemia (p. 694.3) and chronic lymphocytic leukaemia (p. 693.3). It has also been used in histiocytic syndromes (p. 692.1) and in Waldenström's macroglobulinaemia (p. 699.1).

The recommended intravenous dose of cladribine in **hairy-cell leukaemia** is a single course of 90 micrograms/kg (3.6 mg/m²) daily for 7 days by continuous infusion. If the patient does not respond to the initial course, they are unlikely to respond to further doses. Cladribine is also given subcutaneously in a dose of 140 micrograms/kg (5.6 mg/m²) daily for 5 consecutive days.

For the treatment of **chronic lymphocytic leukaemia** the recommended intravenous dose is 120 micrograms/kg (4.8 mg/m²) daily for 5 consecutive days of a 28-day cycle; the infusion is given over 2 hours. Response should be determined every 2 cycles, and once maximum response has occurred a further 2 cycles of treatment are recommended, up to a maximum of 6 cycles. Patients who do not respond with a lymphocyte reduction of 50% or more after 2 cycles should not receive further therapy. Cladribine is also given subcutaneously in a dose of 100 micrograms/kg (4 mg/m²) daily for 5 consecutive days. This dose of subcutaneous cladribine is also licensed in some countries for the treatment of indolent **non-Hodgkin's lymphoma** and **Waldenström's macroglobulinaemia**.

Multiple sclerosis. Cladribine has been investigated for the treatment of multiple sclerosis (p. 996.3).

Adverse Effects and Treatment

For a general outline see Antineoplastics, p. 726.1 and p. 730.2.

Cladribine produces severe myelosuppression, including neutropenia, anaemia, and thrombocytopenia, especially at high doses. Transfusion of blood products may be required. Prolonged CD4 lymphopenia with a nadir at 4 to 6 months also develops. Prolonged bone-marrow hypocellularity may also occur, although it is not clear if this is due to the drug or underlying disease. Haemolytic anaemia has also been reported. Severe infections can occur, and may be fatal. Myelodysplastic syndrome has been reported rarely.

Other adverse effects include fever, chills, diaphoresis, fatigue, malaise, mild nausea and gastrointestinal disturbances, rashes, pruritus, purpura, headache, anxiety, dizziness, abnormal breath and/or chest sounds, cough, dyspnoea, oedema, tachycardia, hypotension, arthralgia, and myalgia. Reversible, mild increases in bilirubin and hepatic transaminases are common. Rare adverse events include hepatic, renal, or cardiac failure, atrial fibrillation, and hypereosinophilia; tumour lysis syndrome can occur, and may be fatal.

Very high doses of cladribine have been associated with severe renal and nervous system toxicity as well as myelosuppression. Severe neurotoxicity is rare at currently recommended doses, but confusion, neuropathy, ataxia, insomnia, and somnolence have occurred.

Carcinogenicity. As with some other antimetabolites (see p. 726.2), Epstein-Barr virus-related lymphoma has been reported after cladribine therapy.[1] A study found that in patients with chronic lymphocytic leukaemia, treatment with cladribine did not increase the risk of secondary malignancies when compared with treatment with alkylating agents and combination therapy. However, lung cancers occurred more frequently with cladribine treatment.[2]

1. Niesvizky R, *et al.* Epstein-Barr virus-associated lymphoma after treatment of macroglobulinemia with cladribine. *N Engl J Med* 1999; **341**: 55.
2. Robak T, *et al.* Second malignancies and Richter's syndrome in patients with chronic lymphocytic leukaemia treated with cladribine. *Eur J Cancer* 2004; **40**: 383–9.

Precautions

For the precautions necessary with antineoplastics, see p. 732.2. Careful haematological monitoring is recommended, especially during the first 4 to 8 weeks of therapy. Renal and hepatic function should also be monitored periodically.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies cladribine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

Lamivudine. A patient with chronic lymphocytic leukaemia had no decrease in lymphocyte count when cladribine was given with lamivudine, the latter being to prevent reactivation of hepatitis B. Lamivudine was stopped and, after another course of cladribine, the lymphocyte count responded. Study *in-vitro* found that lamivudine inhibited the phosphorylation of cladribine, rendering it inactive.[1]

1. Chtioui H, *et al.* Concomitant treatment with lamivudine renders cladribine inactive by inhibition of its phosphorylation. *Br J Haematol* 2009; **144**: 136–7.

Pharmacokinetics

Plasma-cladribine concentrations after intravenous infusion show either a biphasic or triphasic decline, with terminal half-lives ranging from 3 to 22 hours. A bi-exponential decline has been reported after subcutaneous injection, with an initial and terminal half-life of about 2 and 11 hours, respectively. Cladribine is extensively distributed and penetrates into the CNS. It is about 20% bound to plasma proteins. Cladribine is phosphorylated within cells by deoxycytidine kinase to form 2-chlorodeoxyadenosine-5′-monophosphate which is further phosphorylated to the diphosphate by nucleoside monophosphate kinase and to the active metabolite 2-chlorodeoxyadenosine-5′-triphosphate (CdATP) by nucleoside diphosphate kinase.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Hemobine; Intocel; Leustat; *Austral.*: Leustatin; Litak; *Austria*: Leustatin; Litak; *Belg.*: Leustatin; *Braz.*: Leustatin; *Canad.*: Leustatin; *China*: Ai Bo Ding (艾博定); *Cz.*: Leustatin†; Litak; *Denm.*: Litak; *Fin.*: Leustatin; Litak; *Fr.*: Leustatine; Litak; *Ger.*: Leustatin; Litak; *Gr.*: Leustatin; Litak; *Hong Kong*: Leustatin; *Irl.*: Litak; *Israel*: Leustatin†; Litak; *Ital.*: Leustatin; *Neth.*: Leustatin; Litak; *Norw.*: Leustatin; Litak; *NZ*: Leustatin; *Philipp.*: Leustatin†; *Pol.*: Biodribin; Litak; *Port.*: Leustatin; Litak; *Rus.*: Leicladin (Лейкладин); Movectro (Мовектро); *S.Afr.*: Leustatin; Litak; *Singapore*: Leustatin†; *Spain*: Leustatin; Litak; *Swed.*: Leustatin; Litak; *Switz.*: Leustatin; Litak; *UK*: Leustat; Litak; *USA*: Leustatin; *Venez.*: Leustatin.

Clofarabine *(BAN, USAN, rINN)*

Cl-F-Ara-A; Clofarabina; Clofarabinum; Клюфарабин.
2-Chloro-9-(2-deoxy-2-fluoro-β-D-arabinofuranosyl)-9*H*-purin-6-amine.
$C_{10}H_{11}ClFN_5O_3$=303.7
CAS — 123318-82-1.
ATC — L01BB06.
ATC Vet — QL01BB06.
UNII — 762RDY0Y2H.

Uses and Administration

Clofarabine, a purine nucleoside analogue, is used as an antimetabolite antineoplastic in the treatment of relapsed or refractory acute lymphoblastic leukaemia (p. 692.3) in patients aged 1 to 21 years. A dose of 52 mg/m² is given daily for 5 days, by intravenous infusion (see Administration, below) over 2 hours. A longer infusion time should be considered in children weighing less than 20 kg to reduce anxiety and irritability, and to avoid high clofarabine concentrations. The course may be repeated every 2 to 6 weeks, depending on the patient's recovery from bone-marrow depression and other adverse effects (see Administration in Subsequent Cycles, p. 770.1). Treatment is usually assessed after 2 treatment cycles.

For doses in hepatic and renal impairment, see below and p. 770.1, respectively.

Clofarabine is also under investigation for the treatment of acute myeloid leukaemia. An oral formulation is under investigation for the treatment of patients with myelodysplastic syndromes.

Administration. Instructions for dilution of clofarabine for intravenous use may vary according to country. US licensed product information recommends to filter clofarabine through a 0.2 micrometre syringe filter and then dilute with either glucose 5% or sodium chloride 0.9%, to obtain a final concentration between 150 and 400 micrograms/mL. However, UK licensed product information states that, after filtration (as above), clofarabine should be diluted with sodium chloride 0.9%; total volumes are based on body-surface area as follows:
- ⩽1.44 m²: 100 mL
- 1.45 to 2.4 m²: 150 mL
- 2.41 to 2.5 m²: 200 mL

UK licensed product information also states that if the use of a 0.2 micrometre syringe filter is unfeasible, then the concentrate may be filtered with a 5 micrometre filter, diluted as above, and then given through a 0.22 micrometre in-line filter.

Administration in children. Clofarabine is licensed for use in patients aged 1 to 21 years, see Uses and Administration, above.

Administration in hepatic impairment. Clofarabine should be used with caution in hepatic impairment, because data are limited, and there is a potential for hepatotoxicity (see Adverse Effects, p. 770.1). UK licensed product information states that use in severe hepatic impairment is therefore contra-indicated. US licensed product information states that if grade 3 (or higher) increases in bilirubin are seen, clofarabine dosage should be withheld; it may be restarted at a dose reduced by 25% once organ function has recovered (see also Administration in Subsequent Cycles, p. 770.1).

Administration in renal impairment. Clofarabine should be used with caution in renal impairment, because data are limited, and there is a potential for accumulation in patients with decreased creatinine clearance. In patients with moderate impairment (creatinine clearance 30 to 60 mL/min), a dose reduction of 50% is recommended. No dosage recommendations are made for patients with severe impairment and UK licensed product information contra-indicates its use in such patients.

If grade 3 (or higher) increases in creatinine are seen, clofarabine dosage should be withheld; it may be restarted at a dose reduced by 25% once organ function has recovered (see also Administration in Subsequent Cycles, below).

Administration in subsequent cycles. Dosage of clofarabine is determined by body-surface (see Uses and Administration, p. 769.3), based on the actual height and weight before the start of each cycle.

- Treatment cycles are repeated after recovery or return to baseline organ function, about every 2 to 6 weeks.
- Subsequent cycles should not be given sooner than 14 days from the starting day of the previous cycle.
  The absolute **neutrophil** count (ANC) should be ≥ 750 cells/mm^3 before a dose is given.
  If the ANC has not recovered after 6 weeks from the start of a cycle, a bone marrow aspirate should be performed to determine possible refractory disease; if this is not evident, and once the ANC has recovered to the above concentration, the dose for the next cycle should be reduced by 25% (of the previous dose given).
  If a patient has severe neutropenia, defined as ANC < 500 cells/mm^3, that lasts ≥ 4 weeks, the dose for the next cycle should be reduced by 25%.
- Clofarabine should be withheld in the event of a clinically significant **infection**; once controlled, treatment may be restarted at the full dose. However, if a second significant infection occurs, treatment may be restarted at a dose reduced by 25% once the infection is controlled.
- If **other** severe toxicities occur (grade 3 toxicities excluding nausea and vomiting), then clofarabine should be withheld until recovery, and restarted at a dose reduced by 25%. If the same toxicity recurs on a second occasion, treatment is withheld until recovery and a *further* 25% dose reduction is recommended.

If a severe toxicity recurs on a third occasion, or does not resolve within 14 days, or is life-threatening or disabling, then clofarabine treatment should be stopped.

Adverse Effects, Treatment, and Precautions

As for Fludarabine Phosphate, p. 794.3, although neurotoxicity is less severe. Febrile neutropenia is very common with clofarabine, as are anxiety, headache, flushing, mucosal inflammation, pruritus, and palmar-plantar erythrodysesthesia syndrome. Other common adverse effects include pain, myalgia, arthralgia, hypersensitivity reactions, haematuria, skin exfoliation, alopecia, erythema (which can be generalised), petechiae, dry skin, hyperhidrosis, dizziness, tremor, hearing loss, and epistaxis. Hypertension has also been reported. Hepatotoxicity is also common and can include hyperbilirubinaemia, jaundice, and veno-occlusive disease; patients who have received a haematopoietic stem cell transplant may be at higher risk for hepatotoxicity.

Patients should be monitored for signs and symptoms of cytokine release (including tachypnoea, tachycardia, hypotension, and pulmonary oedema) that could develop into systemic inflammatory response syndrome (SIRS) or capillary leak syndrome, which can be fatal. Symptoms of the latter include respiratory distress, hypotension, pleural and pericardial effusions, and multi-organ failure. Prophylactic corticosteroids may be useful, but clofarabine must be stopped immediately if signs or symptoms of SIRS, capillary leak syndrome, or hypotension develop; further treatment, at a lower dose (see Uses and Administration, p. 769.3), can be considered once patients are stabilised and organ function has returned to baseline. Patients with cardiac disease should be closely monitored. Enterocolitis, including neutropenic enterocolitis and *Clostridium difficile* colitis have been reported, usually within a month of treatment with clofarabine, and usually when given with other chemotherapy.

Renal and hepatic function, and complete blood counts, should be monitored during clofarabine therapy. Hydration should be maintained during treatment to minimise the risk of tumour lysis syndrome and other adverse effects.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies clofarabine as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

Patients taking drugs that affect blood pressure or cardiac function should be closely monitored during clofarabine therapy. Drugs that are eliminated by renal tubular secretion might interfere with the excretion of clofarabine and should be avoided.

Pharmacokinetics

Clofarabine is about 47% bound to plasma proteins, mainly to albumin. About 50 to 60% of a dose is excreted unchanged in the urine and it has a terminal half-life of about 5 hours.

Corynebacterium parvum

C. parvum; NSC-220537; *Propionibacterium acnes*.
UNII — TRZ1AA965O.

Profile

Inactivated *Corynebacterium parvum* has been used in the treatment of malignant effusions, and has been tried as an adjuvant to cancer chemotherapy for its immunostimulant properties. It has also been used in the treatment of musculoskeletal and joint disorders.

Fever and pain have occurred after intracavitary injection. There have been reports of nephrotoxicity after intravenous use.

Crizotinib *(USAN rINN)*

Crizotinibum; PF-02341066; Кризотиниб.
3-[(1*R*)-1-(2,6-Dichloro-3-fluorophenyl)ethoxy]-5-[1-(piperidin-4-yl)-1*H*-pyrazol-4-yl]pyridine-2-amine.
$C_{21}H_{22}Cl_2FN_5O$=450.3
CAS — 877399-52-5.
UNII — 53AH36668S.

Uses and Administration

Crizotinib is an inhibitor of receptor tyrosine kinases, including ALK (anaplastic lymphoma kinase) and hepatocyte growth factor receptor (HGFR; c-Met). Crizotinib is used for the treatment of patients with locally advanced, metastatic, or advanced and refractory non-small cell lung cancer (p. 711.1) that is ALK-positive. The recommended dose is 250 mg orally twice daily; capsules should be swallowed whole. Treatment is continued until patients no longer benefit, or unacceptable toxicity occurs. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* If a daily dose of crizotinib is missed, no catch-up dose is recommended if it is less than 6 hours before the next dose. Doses may need to be reduced or treatment interrupted for toxicity (see Administration in Subsequent Cycles, below).

Crizotinib is also under investigation for the treatment of other solid tumours and non-Hodgkin's lymphoma.

References.

3. Gadgeel SM, Bepler G. Crizotinib: an anaplastic lymphoma kinase inhibitor. *Future Oncol* 2011; 7: 947–53.

Administration in subsequent cycles. The oral dose of crizotinib may need to be reduced or therapy withheld if toxicities occur. Licensed product information gives the following guidelines:

for haematological toxicities

- grade 3: withhold until recovery $\leq$ grade 2, then resume at the same dose schedule
- grade 4: withhold until recovery $\leq$ grade 2, then resume at 200 mg twice daily; in the case of recurrence, withhold again until recovery $\leq$ grade 2, then resume at 250 mg once daily. For further grade 4 recurrence, permanently stop crizotinib

for non-haematological toxicities

- any grade pneumonitis (that is not due to disease progression, other pulmonary disease, infection, or effects of radiation): permanently stop crizotinib
- grade 3 or 4 alanine aminotransferase (ALT) or aspartate aminotransferase (AST) elevation with total bilirubin $\leq$ grade 1: withhold until recovery to $\leq$ grade 1 or baseline, then resume at 200 mg twice daily; in the case of recurrence, withhold again until recovery $\leq$ grade 1, then resume at 250 mg once daily. For further grade 3 or 4 recurrence, permanently stop crizotinib
- grade 2, 3, or 4 ALT or AST elevation with concurrent grade 2, 3, or 4 total bilirubin elevation (without evidence of cholestasis or haemolysis): permanently stop crizotinib
- grade 3 QTc prolongation: withhold until recovery to $\leq$ grade 1, then resume at 200 mg twice daily; in the case of recurrence, withhold again until recovery $\leq$ grade 1, then resume at 250 mg once daily. For further grade 3 recurrence, permanently stop crizotinib
- grade 4 QTc prolongation: permanently stop crizotinib

Adverse Effects, Treatment, and Precautions

Crizotinib has been associated with severe pneumonitis and fatalities have been reported. Patients should be monitored for pulmonary symptoms and crizotinib should be permanently stopped in those diagnosed with treatment-related pneumonitis. Other respiratory adverse effects associated with fatalities have included hypoxia, acute respiratory distress syndrome, dyspnoea, empyema, and pulmonary haemorrhage. Pulmonary embolism can occur. Increases in liver transaminases have been seen, and liver function tests should be monitored monthly, or more frequently if needed. While most patients were asymptomatic, some may require dose interruption or for therapy to be permanently stopped. QTc prolongation can occur and crizotinib should be avoided in patients with congenital long QT syndrome. Monitoring (using ECGs and electrolyte concentrations) should be considered in those with congestive heart failure, bradyarrhythmias, electrolyte abnormalities, or who are taking drugs known to prolong the QT interval. Bradycardia can occur with crizotinib therapy. Severe neutropenia, thrombocytopenia, and lymphopenia have been reported and dose modifications may be needed. For details of dose delay, dose reductions, or stoppage of therapy for adverse effects, see Administration in Subsequent Cycles, above.

The most common adverse effects associated with crizotinib are visual disorders, gastrointestinal disturbances and oedema. Visual disorders include visual impairment, blurred vision, diplopia, photopsia, photophobia, and vitreous floaters; events have generally been reported within 2 weeks of starting crizotinib. Gastrointestinal disturbances include nausea, diarrhoea, vomiting, constipation, oesophageal disorders, abdominal pain, and stomatitis. Other common adverse effects include fatigue, decreased appetite, hypophosphataemia, dizziness, headache, dysgeusia, insomnia, upper respiratory-tract infection, dyspnoea, cough, arthralgia, and rash. Neuropathy is also common and can include burning sensations, dysaesthesia, hypoaesthesia or hyperaesthesia, neuralgia, and paraesthesia; peripheral neuropathy can be sensory or motor. Pain (in the chest or back) and fever can occur. Renal cysts without evidence of abnormal urinalysis or renal impairment, have been reported.

Interactions

Crizotinib is metabolised by cytochrome P450 isoenzyme CYP3A4/5. Strong CYP3A inhibitors (such as atazanavir, clarithromycin, indinavir, itraconazole, ketoconazole, nefazodone, nelfinavir, ritonavir, saquinavir, telithromycin, troleandomycin, and voriconazole) can increase crizotinib plasma concentrations and concomitant use should be avoided; grapefruit juice should also be avoided. Caution is advised with concomitant use of moderate CYP3A inhibitors. Strong CYP3A inducers (such as carbamazepine, phenobarbital, phenytoin, rifabutin, rifampicin, and St John's Wort) can decrease crizotinib plasma concentration and concomitant use should be avoided. Crizotinib also inhibits CYP3A and dose reduction may be needed for drugs that are mainly metabolised by CYP3A. Use of crizotinib with CYP3A substrates with narrow therapeutic indices (such as alfentanil, ciclosporin, dihydroergotamine, ergotamine, fentanyl, pimozide, quinidine, sirolimus, and tacrolimus) should be avoided.

Pharmacokinetics

Peak plasma concentrations occur between 4 to 6 hours after a single oral dose of crizotinib. Mean bioavailability is about 43%. Exposure is reduced by a high-fat meal; however, crizotinib can be given with or without food. Steady-state concentrations are reached within 15 days. Plasma protein binding is about 90%. *In-vitro* data suggest that crizotinib is a substrate for P-glycoprotein, tha

metabolism is mainly via the cytochrome P450 isoenzymes CYP3A4 and CYP3A5. The main metabolic pathways are oxidation (to crizotinib lactam) and *O*-dealkylation. The mean apparent plasma terminal half-life has been reported to be about 42 hours after a single dose of crizotinib. About 63% and 22% of a single dose is recovered in faeces and urine, respectively (of which unchanged drug is about 53% and 2.3%, respectively).

Cyclophosphamide *(BAN, rINN)*

B-518; Ciclofosfamida; Ciklofosfamidas; Ciklofoszfamid; Cyclophosphamid; Cyclophosphamidum; Cyclophosphamidum Monohydricum; Cyclophosphanum; Cyklofosfamid; Cyklofosfamid monohydrát; NSC-26271; Siklofosfamid; Syklofosfamidi; WR-138719; Циклофосфамид.

2-[Bis(2-chloroethyl)amino]perhydro-1,3,2-oxazaphosphorinan 2-oxide monohydrate.

$C_7H_{15}Cl_2N_2O_2P,H_2O$=279.1

CAS — 6055-19-2 (cyclophosphamide monohydrate); 50-18-0 (anhydrous cyclophosphamide).

ATC — L01AA01.

ATC Vet — QL01AA01.

UNII — 8N3DW7272P (cyclophosphamide); 6UXW23996M (anhydrous cyclophosphamide).

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Cyclophosphamide). A white or almost white, crystalline powder. Soluble in water; freely soluble in alcohol. A freshly prepared 2% solution in water has a pH of 4.0 to 6.0.

USP 36: (Cyclophosphamide). A white, crystalline powder. It liquefies upon loss of its water of crystallisation. Soluble in water and in alcohol. A 1% solution in water has a pH of 3.9 to 7.1 when determined 30 minutes after preparation. Store in airtight containers at 2 degrees to 30 degrees.

Uses and Administration

Cyclophosphamide is an antineoplastic that is converted in the body to active alkylating metabolites with properties similar to those of chlormethine (p. 765.2). It also possesses marked immunosuppressant properties.

Cyclophosphamide is widely used, often with other agents, in the treatment of malignant diseases. It is given for Burkitt's and other non-Hodgkin's lymphomas, multiple myeloma, and mycosis fungoides. It is also used in gestational trophoblastic tumours and malignancies of the brain, breast, endometrium, lung, and ovary; in childhood malignancies such as neuroblastoma, retinoblastoma, Wilms' tumour; and in sarcomas and some leukaemias.

The immunosuppressant properties of cyclophosphamide have been used in organ and tissue transplantation. It has also been used in the management of disorders thought to have an auto-immune component including amyloidosis, Behçet's syndrome, glomerular kidney disease, immune thrombocytopenia, aplastic anaemia, idiopathic pulmonary fibrosis, polymyositis, scleroderma, SLE, and vasculitic syndromes including the Churg-Strauss syndrome, polyarteritis nodosa, and Wegener's granulomatosis.

The use of cyclphosphamide is these disorders is further discussed under the headings below.

Cyclophosphamide is usually given orally or by intravenous injection.

In the BP 2014 the content of Cyclophosphamide Injection is expressed in terms of the equivalent amount of anhydrous cyclophosphamide whereas the content of Cyclophosphamide Tablets is given in terms of the monohydrate; the USP 36 expresses content in terms of anhydrous cyclophosphamide for both injection and tablets. Confusion has arisen when patients were changed from a preparation in which the content was expressed as the monohydrate to one in which it was expressed as the anhydrous substance (see Effects on the Bladder, p. 772.3). 53.45 mg of cyclophosphamide monohydrate is equivalent to 50 mg of anhydrous cyclophosphamide. *Doses below are given in terms of anhydrous cyclophosphamide.*

The dosage of cyclophosphamide given may vary considerably depending on the disease being treated, the condition of the patient including the state of the bone marrow, and use with radiotherapy or other chemotherapy. The white cell count is usually used to guide the dose. Every effort should be made to establish that the dose is appropriate according to the above factors. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

In the UK, examples of regimens given, generally without specific indications, in licensed product information are:

- *low-dose*: cyclophosphamide 2 to 6 mg/kg weekly as a single intravenous dose or in divided oral doses
- *moderate-dose*: 10 to 15 mg/kg weekly as a single intravenous dose.
- *high-dose*: 20 to 40 mg/kg as a single intravenous dose every 10 to 20 days, although higher doses have been used

Alternative regimens include:

- 100 to 300 mg daily in divided oral doses
- 50 to 250 mg/m² daily orally
- 80 to 300 mg/m² daily as a single intravenous dose, or daily in divided oral doses
- 300 to 600 mg/m² weekly as a single intravenous dose
- 600 to 1500 mg/m² as a single intravenous dose or short infusion at 10- to 20-day intervals

Alternative regimens used in some other European countries include:

- 3 to 6 mg/kg (about 120 to 240 mg/m²) daily intravenously
- 10 to 15 mg/kg (about 400 to 600 mg/m²) every 2 to 5 days intravenously

In the UK, the use of mesna is generally recommended with single doses of cyclophosphamide over 2 g, but it is used with cyclophosphamide doses as low as 10 mg/kg in some countries.

In the USA, an initial dose of 40 to 50 mg/kg has been licensed for single agent therapy of malignancy, given intravenously in divided doses over 2 to 5 days although in practice treatment of malignancy will generally be with combination regimens. Other licensed regimens include:

- 3 to 5 mg/kg twice weekly intravenously
- 10 to 15 mg/kg every 7 to 10 days intravenously
- 1 to 5 mg/kg daily orally

In patients who are to undergo haematopoietic stem cell transplantation, intravenous doses of 20 to 40 mg/kg (about 800 to 1600 mg/m²) and higher are given, at intervals of 21 to 28 days. Alternatively, very high doses of cyclophosphamide such as 60 mg/kg daily for 2 days may be given as part of the conditioning regimen.

Cyclophosphamide has also been given intramuscularly, intraperitoneally, and intrapleurally, as well as intra-arterially, and by local perfusion (but passage through the liver is required for its activation—see Pharmacokinetics, p. 774.1). A liquid preparation of cyclophosphamide for oral use may be prepared using the powder for injection.

Regular blood counts are essential during therapy with cyclophosphamide and treatment should be withdrawn or delayed if leucopenia or thrombocytopenia becomes severe (see also Bone-marrow Depression, p. 730.3). Patients should be adequately hydrated and urine output maintained.

Administration in the elderly. Despite some suggestion that cyclophosphamide metabolism may be slower in the elderly, there appear to be no pharmacokinetic differences based on age alone. A review concluded that healthy older patients should not be denied adjuvant chemotherapy on an age basis, and that there is no solid evidence for dose reduction of cyclophosphamide based on age alone.[1]

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; **25**: 1832–43.

Amyloidosis. Although there is no unequivocally effective treatment for amyloidosis (p. 819.3), cyclophosphamide may reduce the decline in renal function and prolong survival;[1-3] it has also been used with epirubicin and carmustine to suppress the disease in a patient who had undergone heart transplantation for cardiac amyloid.[4] Good responses have also been reported to cyclophosphamide given in a regimen with thalidomide and dexamethasone.[5]

Blood disorders, non-malignant. Cyclophosphamide has been used in patients with immune thrombocytopenia (p. 1606.1), but cytotoxic immunosuppressants tend to be a second-line treatment option. Responses generally occur within 8 weeks.[1] In patients with refractory life-threatening disease, high-dose cyclophosphamide[1] may be tried. Combination chemotherapy including cyclophosphamide has also produced responses in a few patients.[2]

In the management of warm auto-immune haemolytic anaemia (p. 1122.2) low-dose cyclophosphamide may be used in patients refractory to corticosteroids and splenectomy. A small number of patients with severe refractory disease have been treated with high-dose cyclophosphamide with some success.[3]

Cyclophosphamide is often used in preparation for bone marrow transplantation in patients with aplastic anaemia (p. 1121.3), and complete remission has also been reported with high-dose cyclophosphamide alone.[4,5] However, a randomised study[6] of high-dose cyclophosphamide plus ciclosporin compared with conventional immunosuppression was stopped early when a higher mortality was seen in those given cyclophosphamide. Further follow-up[7] also found that relapse rates were no different.

Cyclophosphamide with a corticosteroid has been tried in the rare condition of acquired haemophilia (p. 1126.3).

Cogan's syndrome. For reference to the use of cyclophosphamide with corticosteroids for Cogan's syndrome, see p. 1603.2.

Connective tissue and muscular disorders. Cyclophosphamide is one of several immunosuppressants that have been tried for disease control in Behçet's syndrome (p. 1601.1); such drugs may permit a reduction in the use of corticosteroids, although they carry their own risks of toxicity. In polymyositis (p. 1611.1) cyclophosphamide may have a role where there is lung disease; the role of immunosuppressants other than azathioprine or methotrexate is poorly defined. In patients with SLE (p. 1613.3), cyclophosphamide has been used with some success for severe disease or disease refractory to corticosteroids alone, and appears to be more effective than corticosteroids for lupus nephritis; the evidence for its use has been critically assessed.[1,2]

1. Houssiau F. Thirty years of cyclophosphamide: assessing the evidence. *Lupus* 2007; **16**: 212–16.
2. Bargman JM. How did cyclophosphamide become the drug of choice for lupus nephritis? *Nephrol Dial Transplant* 2009; **24**: 381–4.

Kidney disorders, non-malignant. Cyclophosphamide is used with corticosteroids in the treatment of some forms of glomerular kidney disease (p. 1604.3). In children with nephrotic syndrome, oral cyclophosphamide 2 to 3 mg/kg daily for 8 weeks may be added to a course of corticosteroid therapy in relapsing disease; intravenous cyclophosphamide 500 mg/m² monthly for 6 months also substantially reduces the risk of relapse.[1] Addition of cyclophosphamide to corticosteroid therapy also improves the prospect of remission in focal glomerulosclerosis. Oral cyclophosphamide helps to stabilise progressive disease in patients with membranous nephropathy[2] although intermittent intravenous pulses are reported to be ineffective.[3] Such treatment is usually reserved for those whose disease is severe and progressive enough to justify it, but is probably better tolerated than other alkylating agents such as chlorambucil.[4] Cyclophosphamide has been given with methylprednisolone for rapidly progressive glomerulonephritis,[5] and has been used as part of the aggressive management of renal lesions in Goodpasture's syndrome. A systematic review[6] concluded that pulse cyclophosphamide, which allows for a reduced dose, results in good remission rates in rapidly progressive glomerulonephritis, but has an increased risk of relapse when compared with continuous use.

6. Walters G, *et al.* Interventions for renal vasculitis in adults. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2008 (accessed 22/07/09).

Liver disorders, non-malignant. For mention of the use of cyclophosphamide in auto-immune hepatitis inadequately

controlled by corticosteroids and azathioprine see Chronic Active Hepatitis, p. 1602.3.

Lung disorders, non-malignant. Cyclophosphamide has been used with corticosteroids in patients with idiopathic pulmonary fibrosis as mentioned under Interstitial Lung Disease, p. 1607.1.

Malignant neoplasms. Cyclophosphamide is one of the most widely used drugs for the chemotherapy of malignancy, and mention of its role may be found in the discussions of the management of gestational trophoblastic tumours (p. 691.2); the non-Hodgkin's lymphomas, including AIDS-related lymphoma, Burkitt's lymphoma, and mycosis fungoides (p. 696.3, p. 697.2, p. 697.3, p. 698.3); malignancies of the brain (p. 701.2), breast (p. 702.1), lung (p. 710.2), ovary (p. 711.2) and thymus (p. 715.3); multiple myeloma (p. 699.2); Wilms' tumour, neuroblastoma, and retinoblastoma (p. 709.1, p. 716.2, and p. 717.2 respectively); and sarcomas of bone (p. 717.3) and rhabdomyosarcoma (see Soft-tissue Sarcoma, p. 718.2). Cyclophosphamide is also used in the management of acute lymphoblastic leukaemia (p. 692.3) and chronic lymphocytic leukaemia (p. 693.3).

Neuromuscular disorders. Cyclophosphamide has been tried in myasthenia gravis (p. 684.1) in patients who require immunosuppressants but are intolerant of or unresponsive to corticosteroids and azathioprine. Cyclophosphamide has also been tried in regimens for the management of multiple sclerosis (p. 996.3), but the reported benefits have generally been slight and outweighed by toxicity, such that it is usually reserved for patients with severe disease resistant to standard therapies.

Ocular disorders, non-malignant. Immunosuppressive agents, including cyclophosphamide, have been used in scleritis and uveitis (see p. 1612.3 and p. 1615.1) unresponsive to corticosteroids in tolerable doses.

Organ and tissue transplantation. Cyclophosphamide is used in high doses, usually with busulfan or irradiation, in conditioning regimens for bone marrow transplantation (see Haematopoietic Stem Cell Transplantation, p. 1937.1). It has been tried as part of immunosuppressant regimens after transplantation of heart grafts (p. 1938.2).

Paraquat poisoning. For reference to the use of cyclophosphamide in paraquat poisoning, see p. 2159.2.

Pemphigus and pemphigoid. Corticosteroids are the main treatment for blistering in pemphigus and pemphigoid (p. 1687.1). Immunosuppressive therapy, including cyclophosphamide,[1,2] has been used with corticosteroids to permit a reduction in corticosteroid dosage. Cyclophosphamide with a corticosteroid is also reported to be of value in ocular mucous membrane pemphigoid,[3] although treatment may not completely prevent cicatrisation.[4] Oral cyclophosphamide is considered an alternative to azathioprine in pemphigus vulgaris and pulsed intravenous doses might be considered in severe or recalcitrant cases.[5] There is less support for cyclophosphamide in bullous pemphigoid and it should only be considered if other treatments have failed or are contra-indicated.[6] However, oral or intravenous cyclophosphamide with corticosteroids may be considered for first-line treatment of severe or rapidly progressive mucous membrane pemphigoid.[7]

Retroperitoneal fibrosis. There are reports[1,2] of success with cyclophosphamide, with or without corticosteroids, in the treatment of retroperitoneal fibrosis (p. 1612.1). In one study,[2] severe or refractory disease was treated with monthly intravenous pulses of cyclophosphamide 15 mg/kg, for 6 months, followed by azathioprine; all patients went into remission.

1. Fukuda W, *et al.* Multifocal fibrosclerosis: retroperitoneal fibrosis associated with a suprasellar tumor and pachymeningitis. *Intern Med* 2003; 42: 1006–10.
2. Warnatz K, *et al.* Immunosuppressive treatment of chronic periaortitis: a retrospective study of 20 patients with chronic periaortitis and a review of the literature. *Ann Rheum Dis* 2005; 64: 828–33.

Rheumatoid arthritis. Cyclophosphamide has been used as a disease-modifying antirheumatic drug in rheumatoid arthritis (p. 13.2), usually in patients with severe disease unresponsive to other drugs; its severe toxicity limits its usefulness.[1] It is of most value in controlling antibody-mediated systemic complications of the disease such as vasculitis[2] through inhibition of B-cell function.

1. Suarez-Almazor ME, *et al.* Cyclophosphamide for treating rheumatoid arthritis. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2000 (accessed 12/05/05).
2. Choy E, Kingsley G. How do second-line agents work? *Br Med Bull* 1995; 51: 472–92.

Sarcoidosis. Where drug therapy is required for sarcoidosis (p. 1612.2), corticosteroids are the usual treatment. Cyclophosphamide is one of several cytotoxic immunosuppressants that have been tried, with variable results, as a second-line therapy; its use has been limited by toxicity.

Scleroderma. As discussed on p. 1942.3 the role of drug treatment for scleroderma is not well determined, and it is unclear whether cyclophosphamide (with or without a corticosteroid) is useful for patients with lung involvement.

Vasculitic syndromes. Treatment of the systemic vasculitides has revolved around the use of corticosteroids and cyclophosphamide. The benefits are uncertain in polyarteritis nodosa (p. 1610.2) and Takayasu's arteritis (p. 1614.3), but the benefits of combined therapy are generally accepted in Churg-Strauss syndrome (p. 1603.1) and microscopic polyangiitis (p. 1610.2), and cyclophosphamide is the mainstay of effective treatment of Wegener's granulomatosis (p. 1615.2). Several cyclophosphamide regimens are used, with no major differences reported in outcome.[1] A pulsed regimen (intermittent high-dose intravenous therapy) was found to be as effective in antineutrophil cytoplasmic antibody-associated vasculitis as an oral daily regimen; pulsed therapy allowed for a reduced cumulative cyclophosphamide dose and caused fewer adverse effects.[2]

1. Richmond R, *et al.* Optimisation of cyclophosphamide therapy in systemic vasculitis. *Clin Pharmacokinet* 1998; 34: 79–90.
2. de Groot K, *et al.* EUVAS (European Vasculitis Study Group). Pulse versus daily oral cyclophosphamide for induction of remission in antineutrophil cytoplasmic antibody-associated vasculitis: a randomized trial. *Ann Intern Med* 2009; 150: 670–80.

Adverse Effects and Treatment

For a general outline see Antineoplastics, p. 726.1 and p. 730.2. The major dose-limiting effect is myelosuppression. After single doses the nadir of the white cell count may occur in around 1 to 2 weeks with full recovery usually in 3 to 4 weeks. Thrombocytopenia and anaemia may occur but tend to be less common and less severe.

Haemorrhagic cystitis may develop after high or prolonged dosage, and can be life-threatening. Adequate hydration to maintain urine output at 100 mL/hour and use of mesna (see p. 1557.2) are generally recommended in an attempt to reduce urotoxicity. If mesna is used, frequent emptying of the bladder should be avoided. Doses of cyclophosphamide should be given early in the day.

Alopecia occurs in about 20% of patients given low doses and in practically all patients given high doses. Hair loss starts after 3 weeks of treatment but regrowth is usually evident after 3 months, even with continued treatment. Hyperpigmentation of skin, especially that of the palms and soles, and of the nails, has been reported.

Nausea and vomiting commonly occur, and may be reduced by prophylactic antiemetics. Mucositis may also occur.

Other adverse effects include a syndrome resembling inappropriate secretion of antidiuretic hormone (which may require diuretic therapy), disturbances of carbohydrate metabolism, gonadal suppression (common and occasionally resulting in sterility), interstitial pulmonary fibrosis, and, especially at high doses, cardiotoxicity.

Cyclophosphamide, in common with other alkylating agents, has carcinogenic, mutagenic, and teratogenic potential and secondary malignancies have occurred in patients given previous antineoplastic therapy including cyclophosphamide—see p. 726.2.

Effects on the bladder. *Sterile haemorrhagic cystitis* (p. 2347.3) can occur after high-dose infusions of cyclophosphamide or after prolonged low-dose oral use.[1-4] It is believed to be secondary to renal excretion of alkylating metabolites, particularly the acrolein metabolite, that cause sloughing, thinning, and inflammation of the bladder wall. Damage ranges from minor bleeding to diffuse necrotic ulceration, and can lead to anaemia, constriction of the bladder, bladder perforation, and death.[2] Symptoms may be delayed, and have been reported to occur up to 6 months after stopping the drug.[3] An increased incidence of cystitis when patients on a high-dose cyclophosphamide regimen were transferred from one brand to another has been reported,[4] apparently because one was labelled in terms of the anhydrous substance and one as the monohydrate, resulting in a 6.4% difference in the content of active substance.[7]

Measures used to prevent haemorrhagic cystitis include intravenous hydration with diuresis, frequent voiding, or bladder catheterisation with irrigation, to increase urine output and dilute the excreted metabolites. Mesna may be used as a uroprotectant to reduce exposure to the metabolites.[2-4] If bleeding occurs, various drugs have been instilled intravesically, including sodium chloride 0.9%, alum, or prostaglandins.[2,3,8-11] Silver nitrate, formaldehyde, or phenol instillations have been used but are painful and patients require anaesthesia.[2] There is limited information to suggest that conjugated oestrogens given orally or intravenously may be effective;[2,12] oral pentosan polysulfate sodium may also be of benefit.[3] Nonpharmacological techniques are reserved for refractory cases and include arterial embolisation or surgery.[2]

In addition to the shorter term effects, cyclophosphamide has been reported to be associated with the development of *bladder carcinoma*.[1,4,13-16] A history of cyclophosphamide-induced cystitis may be associated with an increased risk of bladder carcinoma[1,4,13] but some studies have not found a link,[15] and bladder malignancies can develop in patients who have not experienced cystitis while receiving cyclophosphamide.[14] For a discussion of the carcinogenic effects of antineoplastics, including cyclophosphamide, see p. 726.2.

Effects on the blood. Amifostine has been reported to protect against the myelosuppressive effects of cyclophosphamide, and may be used to reduce neutropenia-related infection associated with the combination of cyclophosphamide and cisplatin (see p. 1539.2).

Effects on carbohydrate metabolism. Acute onset type 1 diabetes occurred in a patient treated with cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP), and was thought to be due to the cyclophosphamide.[1]

1. Atlan-Gepner C, *et al.* A cyclophosphamide-induced autoimmune diabetes. *Lancet* 1998; 352: 373–4.

Effects on electrolytes. Water intoxication has been reported with cyclophosphamide,[1-4] usually in high doses (30 to 50 mg/kg or more) although symptoms have been reported after a dose of 20 mg/kg in a patient with renal disease,[5] and in another patient with SLE but apparently

normal renal function who received 10 mg/kg.[4] One case of severe hyponatraemia leading to convulsions and death has been reported.[5] Symptoms resemble the syndrome of inappropriate antidiuretic hormone secretion[5] but plasma concentrations of antidiuretic hormone do not appear to be raised in these patients.[3]

5. Harlow PJ, *et al.* A fatal case of inappropriate ADH secretion induced by cyclophosphamide therapy. *Cancer* 1979; 44: 896–8.

Effects on the eyes. Recurrent transient myopia, apparently due to increased hydration of the lens of the eye, was induced by an intravenous bolus of cyclophosphamide in an adolescent with SLE.[1]

CMV retinitis has occurred in patients during or after cyclophosphamide therapy; presenting symptoms included floaters and blurred or decreased vision.[2]

1. Arranz JA, *et al.* Cyclophosphamide-induced myopia. *Ann Intern Med* 1992; 116: 92–3.
2. Agrawal A, *et al.* Visual symptoms in patients on cyclophosphamide may herald sight threatening disease. *Br J Ophthalmol* 2003; 87: 122–3.

Effects on reproductive potential. Severe gonadal failure with transient or permanent azoospermia is common in men treated with cyclophosphamide. Suppression of germ-cell function with intramuscular testosterone in 5 men during cyclophosphamide therapy for nephrotic syndrome was associated with a more rapid return of spermatogenesis compared with 10 patients not given the androgen.[1] Others have also suggested that gonadal suppression using testosterone in men, and triptorelin in women, has some benefit in protecting against cyclophosphamide-induced damage.[2]

1. Masala A, *et al.* Use of testosterone to prevent cyclophosphamide-induced azoospermia. *Ann Intern Med* 1997; 126: 292–5.

Effects on the skin. An erythematous pruritic rash, similar to the palmar-plantar erythrodysesthesia syndrome (p. 730.1) but occurring on the dorsal surfaces of the hands and feet, occurred 6 days after the first high dose of cyclophosphamide in a patient being prepared for bone marrow transplantation.[1] Previous cyclophosphamide-containing chemotherapy did not produce this reaction. The symptoms improved somewhat on treatment with triamcinolone ointment, and subsequently desquamation of the hands occurred with decreased purplish discoloration and oedema of the feet. There has also been a report of 2 patients who developed Stevens-Johnson syndrome, with some features suggestive of overlapping toxic epidermal necrolysis.[2]

For reports of subacute cutaneous lupus erythematosus after treatment with cyclophosphamide plus doxorubicin, see Effects on the Skin and Nails, under Doxorubicin, p. 784.3.

Hypersensitivity. Occasional anaphylaxis has been reported with cyclophosphamide;[1] analysis of data by the Boston Collaborative Drug Surveillance Program detected only one allergic skin reaction among 210 patients given cyclophosphamide, resulting in a calculated incidence of 4.8 reactions per 1000 recipients.[2]

Precautions

For reference to the precautions necessary with antineoplastics, see p. 732.2.

Cyclophosphamide should not be given to patients with bone-marrow aplasia, acute infection, or drug- or radiation-induced urothelial toxicity. It should be given with care to those with diabetes mellitus. Care is also needed in elderly or debilitated patients, or those with renal or hepatic impairment or who have undergone adrenalectomy. Liberal fluid intake and frequent micturition are advised to reduce the risk of cystitis but care must be taken to avoid water retention and intoxication. Urine should be examined regularly for red cells, which may precede haemorrhagic cystitis. The haematological profile should be monitored regularly.

The use of cyclophosphamide in pregnancy should be avoided where possible.

Breast feeding. Cyclophosphamide has been detected in breast milk,[1] and there are reports of neutropenia,[2] and leucopenia and thrombocytopenia,[3] in infants who have been breast fed by women receiving cyclophosphamide. The American Academy of Pediatrics considers[4] that cyclophosphamide may interfere with cellular metabolism, causing neutropenia and possibly immune suppression in the infant, and has unknown effects on growth, and an association with carcinogenesis.

Handling and disposal. *Residues* of cyclophosphamide or ifosfamide destroyed using alkaline hydrolysis in the presence of dimethylformamide showed no mutagenicity *in vitro*.[1] An alternative method, involving refluxing of cyclophosphamide with hydrochloric acid, neutralising, and then reacting with sodium thiosulfate, was effective for the degradation of cyclophosphamide, but residues from ifosfamide were still highly mutagenic *in vitro* and this second method should therefore not be used to degrade ifosfamide.

Urine and faeces produced for up to 72 hours and 5 days respectively after an oral dose of cyclophosphamide should be handled wearing protective clothing.[2] As cyclophosphamide was present in sweat and saliva, protective clothing was advised for 72 hours after a dose when bathing the patient or carrying out oral procedures.

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies cyclophosphamide as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Pregnancy. For a report of a healthy infant born to a woman treated with a cyclophosphamide-containing regimen, see Pregnancy, under Teniposide, p. 867.2.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Since cyclophosphamide must undergo hepatic metabolism before it is active, interactions are possible with drugs that inhibit or stimulate the mixed function oxidase enzymes responsible. There may be an increased risk of cardiotoxicity in patients who have also received doxorubicin or other cardiotoxic drugs.

Allopurinol. Although the Boston Collaborative Drug Surveillance Program reported an increased incidence of bone-marrow depression in patients given allopurinol with cyclophosphamide than in those given cyclophosphamide without allopurinol (15 of 26 compared with only 6 of 32),[1] a subsequent study in patients given combination chemotherapy, including cyclophosphamide, for lymphomas failed to find any difference in the nadirs of the platelet and white blood cell counts in cycles in which allopurinol was given.[2] Although allopurinol pretreatment in 4 patients resulted in a longer cyclophosphamide half-life in a study in 26 patients given cyclophosphamide, urinary excretion of cyclophosphamide was unchanged.[3] A longer cyclophosphamide half-life was also seen in a study in children given allopurinol.[4]

2. Stolbach L, *et al.* Evaluation of bone marrow toxic reaction in patients treated with allopurinol. *JAMA* 1982; 247: 334–6.
3. Bagley CM, *et al.* Clinical pharmacology of cyclophosphamide. *Cancer Res* 1973; 33: 226–33.
4. Yule SM, *et al.* Cyclophosphamide pharmacokinetics in children. *Br J Clin Pharmacol* 1996; 41: 13–19.

Antibacterials. *Chloramphenicol* given before cyclophosphamide prolonged the mean cyclophosphamide serum half-life from 7.5 to 11.5 hours and reduced the peak activity in all of 5 subjects.[1] Giving *sulfaphenazole* before cyclophosphamide significantly inhibited the rate of biotransformation of cyclophosphamide in 2 of 7 subjects and enhanced it in 2; it remained unchanged in 3. A study in patients with non-Hodgkin's lymphoma found that giving *ciprofloxacin* before cyclophosphamide affected pharmacokinetic parameters of cyclophosphamide. The area under the concentration-time curve (AUC) of cyclophosphamide was increased and clearance was lower; AUC of the active metabolite of cyclophosphamide, 4-hydroxycyclophosphamide, was decreased and clearance increased.[2]

1. Faber OK, *et al.* The effect of chloramphenicol and sulphaphenazole on the biotransformation of cyclophosphamide in man. *Br J Clin Pharmacol* 1975; 2: 281–5.
2. Afsharian P, *et al.* The effect of ciprofloxacin on cyclophosphamide pharmacokinetics in patients with non-Hodgkin lymphoma. *Eur J Haematol* 2005; 75: 206–11.

Anticoagulants. For reference to the interaction of cyclophosphamide with *warfarin*, see p. 1532.2.

Antifungals. Analysis of cyclophosphamide metabolism in patients enrolled in a study comparing itraconazole with fluconazole found that those given itraconazole had higher exposure to toxic metabolites of cyclophosphamide. Both the antifungals appeared to alter cyclophosphamide metabolism and the authors cautioned against use of azole antifungals with antineoplastics that are metabolised via cytochrome P450 isoenzymes.[1]

1. Marr KA, *et al.* Cyclophosphamide metabolism is affected by azole antifungals. *Blood* 2004; 103: 1557–9.

Barbiturates. Although patients receiving cyclophosphamide developed higher peak plasma concentrations of active cyclophosphamide metabolites when given enzyme-inducing agents such as barbiturates, the active metabolites also disappeared rapidly.[1]

1. Bagley CM, *et al.* Clinical pharmacology of cyclophosphamide. *Cancer Res* 1973; 33: 226–33.

Chlorpromazine. The half-life of cyclophosphamide was about 200% greater in 2 children also taking chlorpromazine than in children not given the phenothiazine.[1]

1. Yule SM, *et al.* Cyclophosphamide pharmacokinetics in children. *Br J Clin Pharmacol* 1996; 41: 13–19.

Ciclosporin. For reference to the effect of cyclophosphamide on ciclosporin concentrations, see Interactions, Antineoplastics, p. 1957.2.

Colony-stimulating factors. Fatal respiratory insufficiency associated with alveolar fibrosis developed in an infant given cyclophosphamide and doxorubicin followed by *filgrastim*.[1] Since pulmonary toxicity with cyclophosphamide is normally associated with high cumulative doses it was suggested that in this case the effects might have been exacerbated by the granulocyte colony-stimulating factor. (The pulmonary toxicity of bleomycin has also been suggested to be exacerbated by colony-stimulating factors, as discussed on p. 751.3).

1. van Woensel JBM, *et al.* Acute respiratory insufficiency during doxorubicin, cyclophosphamide, and G-CSF therapy. *Lancet* 1994; 344: 759–60.

Corticosteroids. Single doses of *prednisone* have been found to inhibit the activation of cyclophosphamide but after longer-term treatment the rate of activation has increased.[1] A study in children found that pretreatment with *dexamethasone* was associated with increased clearance of cyclophosphamide and a decrease in its half-life relative to children not given the corticosteroid.[2]

1. Faber OK, Mouridsen HT. Cyclophosphamide activation and corticosteroids. *N Engl J Med* 1974; 291: 211.
2. Yule SM, *et al.* Cyclophosphamide pharmacokinetics in children. *Br J Clin Pharmacol* 1996; 41: 13–19.

Gastrointestinal drugs. In a retrospective study in patients receiving high-dose cyclophosphamide, cisplatin, and carmustine,[1] the area under the plasma-concentration time curve (AUC) for cyclophosphamide (measured as the parent compound) was 17% lower when *ondansetron* rather than prochlorperazine was added to the antiemetic regimen. In addition, the AUC for cisplatin was 10% higher with the ondansetron regimen. In a similar study,[2] the AUCs for both cyclophosphamide and cisplatin were lower in patients receiving an antiemetic regimen including ondansetron rather than prochlorperazine. The authors of both studies noted that the relevance of these findings to toxicity and antitumour effect of the antineoplastics remained to be determined.

2. Cagnoni PJ, *et al.* Modification of the pharmacokinetics of high-dose cyclophosphamide and cisplatin by antiemetics. *Bone Marrow Transplant* 1999; 24: 1–4.

NSAIDs. Acute life-threatening water intoxication was reported in a patient given low-dose cyclophosphamide with *indometacin*.[1] The patient had previously received

treatment with cyclophosphamide (for multiple myeloma) without significant adverse effect.

1. Webberley MJ, Murray JA. Life-threatening acute hyponatraemia induced by low dose cyclophosphamide and indomethacin. *Postgrad Med J* 1989; 65: 950–2.

Suxamethonium. For reference to a possible interaction between cyclophosphamide and suxamethonium, see under Suxamethonium Chloride, p. 2039.3.

Pharmacokinetics

After oral doses, cyclophosphamide is well absorbed from the gastrointestinal tract with a bioavailability greater than 75%. It is widely distributed in the tissues and crosses the blood-brain barrier. It undergoes activation by various cytochrome P450 isoenzymes (notably CYP2B6) in the liver. The initial metabolites are 4-hydroxycyclophosphamide and its acyclic tautomer, aldophosphamide, which both undergo further metabolism; aldophosphamide may undergo non-enzymatic conversion to active phosphoramide mustard. Acrolein is also produced and may be responsible for bladder toxicity. Cyclophosphamide is excreted principally in urine, as metabolites and some unchanged drug. It crosses the placenta, and is found in breast milk.

Reviews.

2. de Jonge ME, *et al.* Clinical pharmacokinetics of cyclophosphamide. *Clin Pharmacokinet* 2005; 44: 1135–64.

Absorption. Cyclophosphamide was detected in the urine of 5 patients after application to intact skin, showing that cyclophosphamide can be absorbed via this route.[1] Absorption continued after the site of application had been cleaned, suggesting that cyclophosphamide had penetrated subcutaneous lipid and was slowly released to the circulation from this depot. Cyclophosphamide was also identified in the urine of 2 oncology nurses but appeared more quickly than in patients, suggesting a faster route of absorption, perhaps by inhalation of aerosols generated during dissolution of the drug.

Pharmacopoeial Preparations

BP 2014: Cyclophosphamide Injection; Cyclophosphamide Oral Solution; Cyclophosphamide Tablets;
USP 36: Cyclophosphamide for Injection; Cyclophosphamide Tablets.

Cytarabine *(BAN, USAN, rINN)*

Ara-C; Arabinosylcytosine; Citarabin; Citarabina; Citarabinas; Citosina arabinósido; Cytarabin; Cytarabina; Cytarabine Liposome; Cytarabinum; Cytosine Arabinoside; Liposomal Cytarabine; NSC-63878 (cytarabine hydrochloride); Sitarabin; Sytarabiini; U-19920; U-19920A (cytarabine hydrochloride); WR-28453; Цитарабин.

1-β-D-Arabinofuranosylcytosine; 4-Amino-1-β-D-arabinofuranosylpyrimidin-2(1*H*)-one.

$C_9H_{13}N_3O_5$=243.2.

CAS — 147-94-4 (cytarabine); 69-74-9 (cytarabine hydrochloride).

ATC — L01BC01.

ATC Vet — QL01BC01.

UNII — 04079A1RDZ.

Pharmacopoeias. In *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Chin. includes the hydrochloride.

Ph. Eur. 8: (Cytarabine). A white or almost white, crystalline powder. Freely soluble in water; very slightly soluble in alcohol and in dichloromethane. Store in airtight containers. Protect from light.

USP 36: (Cytarabine). An odourless, white to off-white, crystalline powder. Freely soluble in water; slightly soluble in alcohol and in chloroform. Protect from light.

Incompatibility. Although cytarabine has been stated in the literature to be incompatible with solutions of fluorouracil[1,2] and methotrexate[2] some studies have reported it to be stable for some hours when mixed with the latter.[3]

Uses and Administration

Cytarabine, a pyrimidine nucleoside analogue, is an antimetabolite antineoplastic that inhibits DNA synthesis. Its actions are specific for the S phase of the cell cycle. It also has antiviral and immunosuppressant properties. Cytarabine is one of the mainstays of the treatment of acute myeloid leukaemia (p. 693.1), and is used in regimens for consolidation in patients with acute lymphoblastic leukaemia (p. 692.3). It has also been used for chronic myeloid leukaemia (p. 694.2) and the myelodysplasias (p. 694.3) (see also Low-dose Therapy, under Administration, below). It may be used in salvage regimens for Hodgkin's disease (p. 696.1), as part of the complex regimens sometimes employed in aggressive intermediate- and high-grade non-Hodgkin's lymphomas (p. 696.3 *et seq.*), and for meningeal leukaemia or lymphoma.

Cytarabine is usually given intravenously; it is also used subcutaneously. Higher doses can be tolerated when given by rapid intravenous injection rather than slow infusion, because of the rapid clearance of cytarabine, but there is little evidence of clinical advantage either way. Cytarabine (in a suitable formulation) may be given intrathecally for leukaemic or lymphomatous meningitis.

For the induction of remission in **acute leukaemias** many dosage regimens have been used: 100 mg/m² twice daily by rapid intravenous injection, or 100 mg/m² daily by continuous intravenous infusion, both for 7 days, are used in combination regimens for acute myeloid leukaemia. Cytarabine 200 mg/m² by continuous intravenous infusion for 5 days, at intervals of about 2 weeks, has also been used as monotherapy. Other recommended regimens include a continuous dosing regimen in which cytarabine 2 mg/kg daily is given by rapid intravenous injection for 10 days; thereafter, the dose may be increased if necessary to 4 mg/kg until a therapeutic response or toxicity is evident. Alternatively, 0.5 to 1 mg/kg may be infused daily (over 1 to 24 hours) for 10 days, increased thereafter to 2 mg/kg daily until toxicity or remission occurs. Intermittent regimens include intravenous cytarabine 3 to 5 mg/kg daily for 5 consecutive days, repeated after an interval of 2 to 9 days, until therapeutic response or toxicity occurs.

For maintenance 1 to 1.5 mg/kg once or twice weekly may be given intravenously or subcutaneously.

In the treatment of refractory non-Hodgkin's **lymphomas**, high-dose regimens have been used, with cytarabine given in doses of 3 g/m² every 12 hours for up to 12 doses. These doses should be given by intravenous infusion over 1 to 3 hours.

In the management of meningeal leukaemia and other **meningeal neoplasms**, cytarabine has been given by intrathecal injection in doses of 5 to 75 mg/m², or 30 to 100 mg, once every 2 to 7 days to once daily for 4 or 5 days. The dosage schedule is usually determined by the type and severity of CNS manifestations and the patient's response to prior therapy. A commonly used intrathecal cytarabine regimen is 10 to 30 mg/m² 3 times weekly, or 30 mg/m² once every 4 days, until CSF findings are normal; the latter regimen is followed by one additional dose. If systemic toxicity occurs with intrathecal cytarabine, modification of other therapy may be necessary. A liposomal formulation is available in some countries for intrathecal use, and permits less frequent dosing because of its longer duration of action: the recommended dose for lymphomatous meningitis is 50 mg intrathecally every 2 weeks for 5 doses then every 4 weeks for 5 doses. Oral or intravenous dexamethasone 4 mg twice daily for 5 days should be given, starting on the day of the liposomal cytarabine intrathecal injection. If neurotoxicity develops, the dose may be reduced to 25 mg; if this persists, liposomal cytarabine therapy should be stopped. For discussion of use of this formulation in children, see Administration in Children, below.

White cell and platelet counts should be determined regularly during treatment with cytarabine and therapy should be stopped or modified if platelets fall below 50 000 cells/mm³ or the polymorphonuclear granulocyte count falls below 1000 cells/mm³.

Cytarabine ocfosfate is an orally active prodrug o cytarabine under investigation for acute and chroni myeloid leukaemia.

Administration. *INTRATHECAL.* Intrathecal cytarabine ha been associated with neurotoxicity (see also Effects on the Nervous System, p. 775.2), some of which has been var iously attributed to preservatives, volume, osmolality, anc pH of the preparation;[1] common practice is to prepare intrathecal chemotherapy with preservative-free diluen and limit the volume of the final solution, usually to 5 mL A study[1] evaluated pH and osmolality for cytarabine intrathecal solutions (in various diluents) at concentrations of 2, 5, 10, and 25 mg/mL. Osmolality increased with increased concentrations but was within 10% of the physiological range of the CSF. However, the pH o cytarabine at 10 and 25 mg/mL was more than 10% high er than the upper limit of the physiological pH of CSF.

Intrathecal doses of the liposomal formulation o cytarabine result in prolonged drug exposure when compared with intrathecal doses of the conventiona formulation (see Pharmacokinetics, p. 775.3). In a randomised study,[2] the liposomal formulation given once every 2 weeks produced a higher response rate anc improved Karnofsky score compared with the conventiona formulation given twice a week in patients with lymphomatous meningitis secondary to lymphoma. The use of liposomal formulations intrathecally to trea leukaemic or lymphomatous meningitis has been reviewed.[3,4] For discussion of use of this formulation in children, see Administration in Children, below.

LOW-DOSE THERAPY. Because of initial suggestions that low doses of cytarabine might induce differentiation and maturation of leukaemic cells, low-dose therapy has been tried in patients with myelodysplastic syndrome and acute myeloid leukaemia. Although complete remission may occur in about 20% of patients with myelodysplastic syndromes a similar proportion succumb to treatment-related mortality, and remissions do not appear to be particularly long-lasting. Bone-marrow suppression may be marked even at these doses.[1] Low-dose subcutaneous cytarabine (20 mg twice daily for 10 days, at intervals of 4 to 6 weeks) was found to be superior to hydroxycarbamide (with or without all-trans retinoic acid) in elderly patients with acute myeloid leukaemia. Although the authors considered the prognosis for these patients to still be unsatisfactory, they suggested that therapy with low-dose cytarabine could represent a baseline against which other promising treatments might be compared.[2]

A comparison of low-dose cytarabine and hydroxyurea with or without all-trans retinoic acid for acute myeloid leukemia and high-risk myelodysplastic syndrome in patients not considered fit for intensive treatment. *Cancer* 2007; 109: 1114–24.

Administration in children. UK licensed product information for conventional formulations of cytarabine indicates that children appear to tolerate proportionally higher doses by weight or surface area than adults, and that where a range of doses is given, children should be treated at the higher dose (see Uses and Administration, above).

UK and US licensed product information for liposomal formulations of cytarabine state that safety and efficacy in children have not been established. A dose of intrathecal liposomal cytarabine 35 mg (given with oral or intravenous dexamethasone 150 micrograms/kg twice daily for 5 days) has been recommended in patients between the ages of 3 and 21 years.[1] A pilot study to determine the feasibility, safety, and pharmacokinetics of this formulation in 6 patients aged less than 3 years found that it was safe and well tolerated when given with dexamethasone; drug exposure after a dose of 25 mg intrathecally was comparable to that after 50 mg in adults and 35 mg in older children.[2]

Administration in hepatic or renal impairment. For conventional formulations, UK licensed product information states that cytarabine should be used with caution in hepatic impairment, and suggests a reduced dose in patients whose liver function is poor; however, no specific

dose recommendations are given and no definition of the degree of hepatic impairment. Dosage reduction is not considered necessary in patients with renal impairment.

US licensed product information states that patients with renal or hepatic impairment may be more likely to have CNS toxicity after high-dose cytarabine, which should be used with caution and possibly at a reduced dose in these patients; no specific dose recommendations are given.

Leukoencephalopathy. There are anecdotal reports[1-3] of marked improvement in patients with progressive multifocal leukoencephalopathy secondary to AIDS or chemotherapy-induced immunosuppression who were given intravenous or intrathecal cytarabine. However, a randomised multicentre study[4] indicated that cytarabine was ineffective and had no role in this condition (see also Infections in Immunocompromised Patients, p. 960.2). Others[5] have suggested that even intrathecal dosage may not provide adequate delivery of cytarabine to target cells, and that delivering the drug directly into the brain under pressure might be an alternative. Cytarabine has also been used with cidofovir.[6]

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The major dose-limiting adverse effect of cytarabine is bone-marrow depression, manifest as leucopenia (particularly granulocytopenia), thrombocytopenia, and anaemia, sometimes with striking megaloblastic changes. Myelosuppression appears to be more evident after continuous infusions. Leucopenia is biphasic, with a nadir at 7 to 9 days after a dose and another, more severe, at 15 to 24 days. The nadir of the platelet count occurs at about 12 to 15 days. Recovery generally occurs in a further 10 days.

Gastrointestinal disturbances may occur: nausea and vomiting may be more severe when doses are given rapidly (but other adverse effects are reported to be worse when the drug is given by infusion). Other adverse effects reported include hepatic dysfunction, renal dysfunction, neurotoxicity, bleeding complications, rashes, oral and anal ulceration, gastrointestinal haemorrhage, oesophagitis, and conjunctivitis. A syndrome of bone and muscle pain, fever, malaise, conjunctivitis, and rash, sometimes described as flu-like, has been reported 6 to 12 hours after cytarabine doses, and may be treated or prevented with corticosteroids. Anaphylactoid reactions and pancreatitis have occurred rarely. There may be local pain, cellulitis, and thrombophlebitis at the site of injection.

Intrathecal use of the liposomal cytarabine formulation commonly causes chemical arachnoiditis manifesting as neck stiffness or pain, nausea, vomiting, headache, and fever. Dexamethasone should be used prophylactically to reduce the incidence and severity of this complication. Other rare adverse effects include encephalopathy, and focal seizures. Intrathecal use of conventional cytarabine formulations has rarely been associated with severe spinal cord toxicity, necrotising encephalopathy, blindness, and other neurotoxicities. If given intrathecally, preservative-free diluents must be used.

High-dose therapy has been associated with particularly severe gastrointestinal and CNS effects, including severe ulceration of the gastrointestinal tract, pneumatosis cystoides leading to peritonitis, necrotising colitis and bowel necrosis, peripheral neuropathy, and cerebral and cerebellar dysfunction, with personality changes, somnolence, and coma. There may also be corneal toxicity leading to punctate keratitis and haemorrhagic conjunctivitis, sepsis, liver abscess, severe skin rash leading to desquamation, alopecia, and cardiac disorders including pericarditis and fatal cardiomyopathy. Pulmonary toxicity sometimes fatal, has occurred.

Cytarabine is teratogenic in *animals* (but see Pregnancy, below).

In addition to frequent white blood cell and platelet counts, blood-uric acid should be monitored because of the risk of hyperuricaemia secondary to lysis of neoplastic cells, and renal and hepatic function should be periodically assessed. Cytarabine should be given with care to patients with impaired liver function; dosage reduction may be necessary.

The toxicity of cytarabine has been reviewed.[1] The principal toxicity of standard dosage regimens is myelosuppression but bleeding complications and gastrointestinal toxicity are also major problems at standard doses. With the high-dose regimens neurological toxicity may be dose-limiting: severe and sometimes irreversible symptoms have been seen in some 6 to 10% of patients receiving a cumulative dose of 36 g/m^2. Ocular toxicity may occur in up to 80% of patients at the highest doses. Since cytarabine toxicity is largely dose-related, low-dose cytarabine is generally well tolerated, even in elderly patients (who are more susceptible): its only significant toxicity is myelosuppression.

1. Stentoft J. The toxicity of cytarabine. *Drug Safety* 1990; **5:** 7–27.

Effects on the nervous system. Although paraplegia has been reported with intrathecal cytarabine[1] (see also under Benzyl Alcohol, p. 1740.3) and peripheral neuropathy has occurred in a patient who had received only conventional intravenous doses,[2] the majority of cases of neurotoxicity associated with cytarabine appear to be in patients given high-dose regimens.[3-7] Although some cases have manifested as demyelinating peripheral neuropathy,[3,4] including a syndrome of painful legs and involuntary movements in the toes which showed some response to carbamazepine,[3] most studies have reported in particular a syndrome of cerebellar toxicity,[5-8] with symptoms such as dysarthria, nystagmus, and ataxia. Toxicity appears to be dose-related: in one series[5] CNS toxicity occurred in none of 12 patients given total doses of up to 24 g/m^2 of cytarabine, 3 of 19 patients receiving 36 g/m^2, and 1 of 12 patients given 48 g/m^2, none of which were life-threatening or irreversible, whereas 4 of 6 patients given 54 g/m^2 (as 4.5 g/m^2 every 12 hours for 12 doses) developed neurotoxicity, which was fatal in one and irreversible in another. However, persistent, severe cerebellar toxicity has also been reported in a patient who had received a total dose of only 36 g/m^2 (as 3 g/m^2 every 12 hours).[8] There is some evidence[6] that patients aged over 50, and those who have recently received conventional-dose cytarabine[7] may be at increased risk. Intracranial hypertension (pseudotumor cerebri) has occurred rarely.[9] Neurological effects possibly related to cytarabine were seen in 2 out of 5 heavily pre-treated children given intrathecal liposomal cytarabine;[10] in 1 case, acute encephalopathy was probably caused by high-dose methotrexate but aggravated by cytarabine, and in the other case, persistent generalised seizures developed after the sixth intrathecal injection of cytarabine.

Effects on the skin. A syndrome of pain and erythema of the palms and soles, progressing to bullae and desquamation, has been seen in patients receiving intermediate- or high-dose cytarabine.[1-3] The syndrome is similar to the palmar-plantar erythrodysesthesia syndrome (p. 730.1) reported in patients receiving chemotherapy not including cytarabine,[4] although some considered the two forms of toxicity distinct.[5] Cutaneous small vessel necrotising vasculitis[6] and Henoch-Schönlein purpura[7] have been reported after therapy with cytarabine.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies cytarabine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pregnancy. Although there has been a report of limb and ear deformities in the infant of a woman given cytarabine at the estimated time of conception and 4 to 8 weeks later,[1] no congenital abnormalities were noted in 17 infants, 5 therapeutic abortions, and one still-birth (after pre-eclamptic toxaemia) resulting from over 20 known cases in which cytarabine was given during pregnancy.[2]

For a report of a fetal sinusoidal heart rate pattern and neonatal pancytopenia after a woman was given combination chemotherapy including cytarabine, see Pregnancy, under Etoposide, p. 791.3.

2. Morgenstern G. Cytarabine in pregnancy. *Lancet* 1980; **ii:** 259.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Antifungals. Cytarabine may inhibit the action of *flucytosine*—see p. 581.3.

Antineoplastics. Acute pancreatitis has been reported in patients given cytarabine who had previously received *asparaginase* therapy.[1] Subclinical damage to the pancreas by asparaginase may have rendered it susceptible to cytarabine.

For a report of hepatic dysfunction in patients who had received cytarabine and *daunorubicin* see under Daunorubicin Hydrochloride, p. 779.3.

Giving cytarabine after *fludarabine* is reported to result in a fivefold increase in intracellular cytarabine concentrations in leukaemic cells,[2] producing improved clinical response rates.

Pharmacokinetics

Cytarabine is not effective orally due to rapid deamination in the gastrointestinal tract; less than 20% of an oral dose is absorbed. After intravenous injection it disappears rapidly from the plasma with an initial half-life of about 10 minutes; the terminal elimination half-life ranges from 1 to 3 hours. It is converted by phosphorylation to an active form, which is rapidly deaminated, mainly in the liver and the kidneys, to inactive 1-β-D-arabinofuranosyluracil (uracil arabinoside, ara-U). The majority of an intravenous dose is excreted in the urine within 24 hours, mostly as the inactive metabolite with about 10% as unchanged cytarabine.

There is only moderate diffusion of cytarabine across the blood-brain barrier after intravenous injection, but, because of low deaminase activity in the CSF, concentrations achieved after continuous intravenous infusion or intrathecal injection are maintained for longer in the CSF than are those in plasma, with a terminal elimination half-life of 3.5 hours. After intrathecal doses of the liposomal formulation, a terminal elimination half-life of 100 to 263 hours was seen. Cytarabine also crosses the placenta.

UNII — B6DC89I63E.

Profile

Dabrafenib is an inhibitor of BRAF kinases that is used in the treatment of unresectable or metastatic melanoma (p. 714.3) with BRAF V600E mutations; it should not be used in patients with wild-type BRAF melanoma. It is given as the mesilate salt but doses are expressed as the base; 50 mg of dabrafenib is equivalent to about 59.25 mg dabrafenib mesilate. The usual oral dose is equivalent to 150 mg twice daily, taken 12 hours apart; capsules should be swallowed whole and taken on an empty stomach. A missed dose should not be taken within 6 hours of the next dose. Doses may need to be withheld or reduced if toxicity occurs. Where dose adjustment is required, the first dose reduction is to 100 mg twice daily, the second reduction to 75 mg twice daily, and the third reduction to 50 mg twice daily; dabrafenib should be stopped if the patient is unable to tolerate 50 mg twice daily. Treatment is continued until disease progression or unacceptable toxicity occurs. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Commonly reported adverse effects with dabrafenib include skin reactions, headache, fever, arthralgia, cough, and nasopharyngitis. New primary cutaneous malignancies such as squamous cell carcinoma, keratoacanthoma, and melanoma have occurred during treatment. Other effects include hyperglycaemia, uveitis, and iritis. Dabrafenib should be avoided during pregnancy and women of childbearing potential should use contraception during and for 4 weeks after treatment.

CAS — 4342-03-4 (dacarbazine); 64038-56-8 (dacarbazine citrate).
ATC — L01AX04.
ATC Vet — QL01AX04.
UNII — 7GR28W0FJI.

Pharmacopoeias. In *Eur.* (see p. vii), *Int.*, and *US*.

Ph. Eur. 8: (Dacarbazine). A white or slightly yellowish, crystalline powder. Slightly soluble in water and in anhydrous alcohol; practically insoluble in dichloromethane. Store at 2 degrees to 8 degrees. Protect from light.

USP 36: (Dacarbazine). Store in airtight containers at 2 degrees to 8 degrees. Protect from light.

Incompatibility. Dacarbazine has been reported to be incompatible with hydrocortisone sodium succinate but not with the sodium phosphate.[1] It has been reported to be incompatible with heparin,[2] although only with concentrated dacarbazine solutions (25 mg/mL).

Uses and Administration

Dacarbazine is a cell-cycle non-specific antineoplastic that is thought to function as an alkylating agent after it has been activated in the liver. Dacarbazine is used mainly in the treatment of metastatic malignant melanoma (p. 714.3). It is also given to patients with Hodgkin's disease (p. 696.1), notably with doxorubicin, bleomycin, and vinblastine (ABVD). Dacarbazine is used with other drugs in the treatment of soft-tissue sarcoma (p. 718.2), except mesothelioma and Kaposi's sarcoma, and may be given in neuroblastoma (p. 716.2), and other tumours.

Dacarbazine is given by the intravenous route. Injections may be given over 1 minute. The reconstituted solution can be further diluted with up to 300 mL of glucose 5% or sodium chloride 0.9% and given by infusion over 15 to 30 minutes; doses of 200 mg/m² and over are usually infused.

Dacarbazine is licensed for use as a single agent for **metastatic melanoma** in doses of 2 to 4.5 mg/kg daily for 10 days, repeated at intervals of 4 weeks, or 200 to 250 mg/m² daily for 5 days, repeated at intervals of 3 weeks. It can also be given in a dose of 850 mg/m² by intravenous infusion at 3-week intervals. In the treatment of **Hodgkin's disease** doses of 150 mg/m² daily for 5 days repeated every 4 weeks, or 375 mg/m² every 15 days have been given with other agents. In the treatment of **soft-tissue sarcoma**, dacarbazine 250 mg/m² is given daily for 5 days repeated every 3 weeks; it is usually given with doxorubicin.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Leucopenia and thrombocytopenia with dacarbazine, although usually moderate, may be severe. The nadir of the white cell count usually occurs 21 to 25 days after a dose. Anorexia, nausea, and vomiting occur in more than 90% of patients initially but tolerance may develop after repeated doses. Less frequent adverse effects include diarrhoea, skin reactions, alopecia, a flu-like syndrome, facial flushing and paraesthesia, headache, blurred vision, seizures, and rare but potentially fatal hepatotoxicity. There may be local pain at the injection site; extravasation produces pain and tissue damage. Anaphylaxis has occurred occasionally.

Dacarbazine should be used with caution in hepatic and renal impairment, and consideration given to reducing the dose. Haematological monitoring is required during therapy. Dacarbazine is potentially carcinogenic, mutagenic, and teratogenic.

Effects on the bladder. A report[1] of haemorrhagic cystitis associated with dacarbazine treatment for melanoma. The patient developed gross haematuria with inflammation and oedema of the bladder wall 2 weeks after completing 3 cycles of monotherapy with dacarbazine; the condition responded to symptomatic management with saline lavage and oral and intravenous hydration. Two subsequent transient episodes of haematuria resolved spontaneously.

Effects on the liver. Dacarbazine has been associated with fatal hepatic vascular toxicity, caused by thrombosis of the hepatic veins, necrosis, and extensive haemorrhage.[1] As the reaction usually occurs during the second course of dacarbazine it is thought to be immune mediated, and early corticosteroid treatment has been tried with a few reported cases of patient survival.[2] Other adverse hepatic effects have included[3] necrosis without inflammation, granulomatous hepatitis, and acute toxic hepatitis during the first course of dacarbazine. Morphological studies have suggested that dacarbazine may exert a toxic effect on the microfilamentous cytoskeleton of the hepatocytes.[3]

3. Dancygier H, *et al.* Dacarbazine (DTIC)-induced human liver injury. *Int* 1982; 23: A447.

Handling. Dacarbazine is irritant; avoid contact with skin and mucous membranes.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies dacarbazine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Levodopa. For a report of dacarbazine reducing the effects of levodopa, see Antineoplastics, p. 907.2.

Pharmacokinetics

Dacarbazine is poorly absorbed from the gastrointestinal tract. On intravenous injection it is rapidly distributed with an initial plasma half-life of about 20 minutes; the terminal half-life is reported to be about 5 hours. The volume of distribution is larger than body water content, suggesting localisation in some body tissues, probably mainly the liver. Only about 5% is bound to plasma protein. It crosses the blood-brain barrier to a limited extent; concentrations in CSF are about 14% of those in plasma. Dacarbazine is extensively metabolised in the liver by the cytochrome P450 isoenzymes CYP1A2 and CYP2E1 (and possibly in the tissues by CYP1A1) to its active metabolite 5-(3-methyltriazeno-1-yl)-imidazole-4-carboxamide (MTIC), which spontaneously decomposes to the major metabolite 5-amino-imidazole-4-carboxamide (AIC). About half of a dose is excreted unchanged in the urine by tubular secretion.

Dactinomycin *(BAN, USAN, rINN)*

Actinomicina D; Actinomycin C_1; Actinomycin D; Dactinomicina; Dactinomycine; Dactinomycinum; Daktinomis 1; Daktinomycin; Daktinomysiini; Daktynomycyna; Meractinomycin; NSC-3053; Дактиномицин.
$N^{2,1},N^{2',1'}$-(2-Amino-4,6-dimethyl-3-oxo-3*H*-phenoxazine-1,9-diyldicarbonyl)bis[threonyl-D-valylprolyl(*N*-methylglycyl)(*N*-methylvaline) 1,5→3,1-lactone].
$C_{62}H_{86}N_{12}O_{16}$=1255.4
CAS — 50-76-0.
ATC — L01DA01.
ATC Vet — QL01DA01.
UNII — 1CC1JFE158.

Description. Dactinomycin is an antineoplastic antibiotic produced by *Streptomyces parvulus* and other species of *Streptomyces*.

Cactinomycin (actinomycin C; HBF-386; NSC-18268 is a mixture of dactinomycin (actinomycin D) (10%), actinomycin C_2 (45%), and actinomycin C_3 (45%) produced by *Streptomyces chrysomallus*.

Pharmacopoeias. In *Chin.*, *Int.*, *Jpn*, *Pol.*, and *US*.

USP 36: (Dactinomycin). A bright red, somewhat hygroscopic, crystalline powder, affected by light and heat. It has a potency of not less than 950 and not more than 1030 micrograms/mg, calculated on the dried basis. Soluble in water at 10 degrees and slightly soluble in water at 37 degrees; freely soluble in alcohol; very slightly soluble in

ether. Store at a temperature not exceeding 40 degrees in airtight containers. Protect from light.

Adsorption. Dactinomycin binds to cellulose ester filters,[1] and such filtration should be avoided.[2] Although it has been suggested that significant amounts of drug may be adsorbed to glass or plastic,[3] dactinomycin is reportedly compatible with glass and PVC infusion containers,[4] and giving into the tubing of a fast-running intravenous infusion is recommended—see Uses and Administration, below.

Uses and Administration

Dactinomycin is a highly toxic antibiotic with antineoplastic properties. It inhibits the proliferation of cells in a cell-cycle non-specific way by forming a stable complex with DNA and interfering with DNA-dependent RNA synthesis. It may enhance the cytotoxic effects of radiotherapy (see also Adverse Effects, below). Dactinomycin also has immunosuppressant properties.

It has been used, usually with other drugs or radiotherapy, in the treatment of Wilms' tumour (p. 709.1), gestational trophoblastic tumours (p. 691.2), nonseminomatous testicular cancer (p. 715.1), and sarcomas such as rhabdomyosarcoma (see Soft-tissue Sarcoma, p. 718.2) and Ewing's sarcoma (see Bone Sarcoma, p. 717.3).

In the treatment of Wilms' tumour, childhood rhabdomyosarcoma, or Ewing's sarcoma, an intravenous dose of 15 micrograms/kg daily for 5 days has been used in combination regimens. In adults, gestational trophoblastic tumours have been treated with 12 micrograms/kg daily for 5 days as a single agent, or 500 micrograms on days 1 and 2 of combination regimens. Metastatic nonseminomatous testicular cancer has been treated with 1 mg/m^2 on day 1 of combination regimens. The dose intensity for adults or children should not exceed 15 micrograms/kg or 400 to 600 micrograms/m^2 daily for 5 days per 2-week cycle, and lower doses may need to be used in some chemotherapy combinations or with radiotherapy. Using a regional perfusion technique to localise the drug has permitted the use of higher doses, 50 micrograms/kg being suggested for an isolated lower extremity or pelvis and 35 micrograms/kg for an upper extremity.

Great care must be taken to avoid extravasation and it should be given, for preference, into the tubing of a fast-running intravenous infusion. Platelet and white cell counts should be performed frequently to detect bone-marrow depression; if either count shows a marked decrease the drug should be withheld until recovery occurs, which may take up to 3 weeks (see also Bone-marrow Depression, p. 730.3).

Administration in children. Dactinomycin is used in children in the treatment of malignant diseases as outlined in Uses and Administration, above. For a discussion of dactinomycin pharmacokinetics in children, see under Pharmacokinetics, below.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Apart from nausea and vomiting adverse effects are often delayed, beginning 2 to 4 days after the completion of a course of treatment and reaching a maximum after 1 to 2 weeks. Fatalities have occurred. Haematological and gastrointestinal effects (particularly stomatitis and diarrhoea) may prove dose-limiting. Myelosuppression is apparent 1 to 7 days after therapy and may be manifest first as thrombocytopenia; the nadir of the platelet and white cell counts usually occurs within 14 to 21 days, with recovery in 21 to 25 days. Other adverse effects include oral and gastrointestinal effects such as cheilitis, oesophagitis, gastrointestinal ulceration, and proctitis; fever, malaise, hypocalcaemia, myalgia, alopecia, pneumonitis, and kidney and liver abnormalities. Skin reactions include eruptions, acne, toxic epidermal necrolysis, Stevens-Johnson syndrome, and erythema multiforme. Hepatotoxicity, including fatal hepatic failure, has been reported; veno-occlusive disease (mainly hepatic) may be fatal, especially in children younger than 2 years. Anaphylactoid reactions have occurred. Dactinomycin is very irritant and extravasation results in severe tissue damage. Regional perfusion therapy has also resulted in damage to soft tissues and oedema.

The effects of radiotherapy are enhanced by dactinomycin and severe reactions may follow the use of high doses. Erythema and pigmentation of the skin may occur in areas previously irradiated. An increased incidence of second primary tumours has been seen in patients treated with radiation and dactinomycin.

Dactinomycin should not be given to patients with varicella or herpes zoster, as severe and even fatal systemic disease may occur. Its use is best avoided in infants under about 1 year of age as they are reported to be highly susceptible to the toxicity of dactinomycin. Blood counts and renal and hepatic function should be monitored frequently.

Effects on the liver. Although pulsed doses (given every 3 or 6 weeks) less than about 50 micrograms/kg or 1.5 mg/m^2 do not seem to be associated with an unacceptable degree of hepatotoxicity,[1] giving dactinomycin as a single dose of 60 micrograms/kg (about 1.8 mg/m^2) every 3 weeks to children with Wilms' tumour was associated with a high incidence of severe hepatotoxicity;[2] reduction of the dose to 45 micrograms/kg every 3 weeks reduced this incidence to levels comparable with a standard regimen of 15 micrograms/kg daily for 5 successive days.[3] Others have not seen such a high incidence of hepatotoxicity with doses of 60 micrograms/kg (despite some raised liver enzyme values), but in this case the high dose was given only every 6 weeks.[4] In general, dactinomycin should be given with caution to children with a history of antecedent liver damage, including abdominal irradiation or recent halothane anaesthesia.[1]

Reversible veno-occlusive disease has been seen particularly in children with Wilms' tumour given dactinomycin and vincristine. A literature review[5] noted a significant predominance in right-sided Wilms' tumour, possibly because the tumour mass could interfere with blood flow in the hepatic veins, which might make the liver more susceptible to the effects of dactinomycin. One study[6] found age of less than 1 year to be a risk factor and a study in children with rhabdomyosarcoma given dactinomycin, vincristine, and cyclophosphamide also found that young age (under 3 years) was associated with a greater risk of severe hepatotoxicity.[7] US licensed product information states that veno-occlusive disease (primarily hepatic) may be fatal, especially in children younger than 2 years of age.

Handling. Dactinomycin is irritant; avoid contact with skin and mucous membranes.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies dactinomycin as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3.

Pharmacokinetics

Intravenous doses of dactinomycin are rapidly distributed with high concentrations in bone marrow and nucleated cells. It undergoes only minimal metabolism and is slowly excreted in urine and bile. The terminal plasma half-life is reported to be about 36 hours. It does not cross the blood-brain barrier but is thought to cross the placenta.

In children. A study[1] involving 31 patients aged between 1 and 20 years given dactinomycin in intravenous doses of 0.7 to 1.5 mg/m^2 found that the pharmacokinetics of the drug were variable, but could be described by a 3-compartment model. Peak plasma concentrations varied from 3.2 to 99.2 nanograms/mL, and both peak plasma concentration and exposure were inversely related to bodyweight. Since there was evidence that exposure was also related to more severe toxicity, younger patients might be at greater risk with a regimen based on surface area; conversely the practice of capping the dose at 2 mg in older patients might result in underdosage.

For evidence that younger patients do have more liver toxicity with dactinomycin, see Effects on the Liver, above.

Dasatinib *(BAN, USAN, rINN)*

BMS-354825; Dasatinibum; Дазатиниб.

N-(2-Chloro-6-methylphenyl)-2-{[6-[4-(2-hydroxyethyl)-1-piperazinyl]-2-methyl-4-pyrimidinyl]amino}-5-thiazolecarboxamide.

$C_{22}H_{26}ClN_7O_2S$=488.0

CAS — 302962-49-8.

ATC — L01XE06.

ATC Vet — QL01XE06.

UNII — RBZ1571X5H (dasatinib); X78UG0A0RN (anhydrous dasatinib).

Uses and Administration

Dasatinib is an oral inhibitor of several tyrosine kinases including BCR-ABL (Philadelphia chromosome) and SRC family tyrosine kinases. It is used for the treatment of adults with all phases of chronic myeloid leukaemia (CML; p. 694.2) who have resistance or intolerance to previous therapy, including imatinib, and as first-line treatment in those with Philadelphia chromosome-positive chronic phase CML. It is also used for the treatment of adults with Philadelphia chromosome-positive acute lymphoblastic leukaemia (ALL; p. 692.3) who are resistant to or intolerant of prior therapy.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

The recommended oral starting dose of dasatinib in chronic phase CML is 100 mg once daily; tablets, which should be swallowed whole, not crushed or chewed, should be taken consistently either in the morning or the evening. The recommended starting dose for accelerated, myeloid, or lymphoid blast phase CML or Philadelphia chromosome-positive ALL is 140 mg once daily. Dosage may be adjusted according to response and tolerability; doses of up to 140 mg once daily have been used in patients with chronic phase CML, and up to 180 mg once daily in those with advanced phase, or with ALL. Treatment is continued until disease progression or unacceptable toxicity occurs. For dose adjustments in toxicity, see Administration in Subsequent Cycles, p. 778.1.

If concurrent use of potent inhibitors or inducers of cytochrome P450 isoenzyme CYP3A4 cannot be avoided, dose adjustments are considered necessary.

- An *increased* dose of dasatinib should be considered in those patients given strong CYP3A4 inducers, and the patient should be monitored for toxicity.
- For those given a strong CYP3A4 inhibitor, the dose of dasatinib should be *reduced* to 20 mg daily in those patients taking 100 mg daily, and to 40 mg daily in those taking 140 mg daily. If this is not tolerated, then either drug should be stopped; if the inhibitor is stopped, a washout period of about 1 week should be allowed before the dose of dasatinib is increased.

Administration in subsequent cycles. Licensed product information for dasatinib recommends adjustment of the oral dose in patients who develop marked haematological or other toxicity.

For patients with chronic phase chronic myeloid leukaemia (CML) started on a dose of 100 mg daily in whom neutrophil counts are below 500 cells/mm^3, the drug should be stopped until neutrophil counts recover to at least 1000 cells/mm^3; similarly if platelet counts are less than 50 000 cells/mm^3 the drug should be stopped until they exceed this value. If this recovery in blood counts occurs in 7 days or less, treatment should be resumed at the previous dose. If the fall in neutrophil counts recurs for more than 7 days, or the fall in platelet counts is extreme (below 25 000 cells/mm^3) treatment should again be stopped and only be resumed at a lower dose of 80 mg daily. If a second recurrence is seen, treatment should be resumed at a dose of 50 mg daily in those given dasatinib as first-line treatment; treatment should be stopped in those that are resistant to or intolerant of prior therapy.

Similarly, in patients with accelerated phase CML, blast phase CML, or Philadelphia chromosome-positive acute lymphoblastic leukaemia started on 140 mg daily, in whom neutrophil counts are below 500 cells/mm^3 or platelets below 10 000 cells/mm^3 (and in whom the cytopenia is not related to the disease), treatment should be stopped, and only restarted once cell counts are at least twice these values. Treatment is resumed at the original dose on the first occasion, but if cytopenia recurs, it should be resumed at 100 mg daily on the second occasion, and 80 mg daily on the third.

If severe non-haematological toxicity occurs, treatment should again be stopped, and only resumed, at a lower dose if appropriate, once toxicity has resolved.

Adverse Effects, Treatment, and Precautions

The most common adverse effects of dasatinib include fluid retention, gastrointestinal disturbances, and bleeding. Fluid retention may be severe, and can result in pleural and pericardial effusion, pulmonary oedema, and ascites. Myelosuppression, manifest as neutropenia, thrombocytopenia, or anaemia, occurs more frequently in patients with advanced chronic myeloid leukaemia (CML) or acute lymphoblastic leukaemia than in patients in chronic phase CML. Recovery generally occurs after dose interruption and/or reduction, although treatment may need to be stopped. Febrile neutropenia and, rarely, red cell aplasia have been reported. Full blood counts should be measured weekly for the first 2 months and then monthly thereafter. Severe bleeding events, including fatal CNS and gastrointestinal haemorrhages, have been reported, mostly in conjunction with thrombocytopenia although dasatinib also causes reversible platelet dysfunction *in vivo*. Treatment interruption and blood transfusion may be required for gastrointestinal haemorrhages. Caution is required when giving dasatinib with other drugs that affect platelet function or with anticoagulants (see Interactions, below). Embolic events including pulmonary embolism and deep-vein thrombosis have also been reported.

Cardiac failure, arrhythmias, and hypertension are common; hypotension, angina, myocardial infarction (including fatalities), pericarditis, myocarditis, acute coronary syndrome, and cor pulmonale occur more rarely. Dasatinib has the potential to prolong the QT interval, and should be given with caution to patients at risk of this, such as those with hypokalaemia or hypomagnesaemia, those on antiarrhythmic therapy or other drugs that prolong the QT interval, or those receiving cumulative high doses of anthracyclines.

Other common adverse effects include headache, pyrexia, chills, musculoskeletal pain, arthralgia, myalgia, asthenia, fatigue, chest pain, electrolyte disturbances, appetite and weight disturbances, mucositis, colitis, flushing, and skin disorders such as rash, alopecia, dermatitis, pruritus, acne, dry skin, and hyperhidrosis.

Respiratory adverse effects include dyspnoea, cough, pulmonary hypertension, pneumonitis, bronchospasm, respiratory distress syndrome, and interstitial lung disease. Infections, including pneumonia, are common; sepsis, although uncommon, may be fatal. Renal failure, urinary frequency, proteinuria, and liver disorders such as hepatitis, cholecystitis, and cholestasis have been reported. CNS adverse effects include depression, insomnia, dizziness, dysgeusia, somnolence, and neuropathy, and less commonly, anxiety, confusion, decreased libido, syncope, tremor, and amnesia. Stroke, transient ischaemic attacks, convulsions, and optic neuritis have been reported rarely. Visual disturbances, dry eye, tinnitus, conjunctivitis, and vertigo have occurred.

Uncommon adverse effects include tumour lysis syndrome, hyperuricaemia, hypoalbuminaemia, pancreatitis, gynaecomastia, irregular menstruation, rhabdomyolysis, hypersensitivity including erythema nodosum, and other skin disorders such as acute febrile neutrophilic dermatosis, photosensitivity, pigmentation disorders, panniculitis, skin ulcers, bullous conditions, nail disorders, and palmar-plantar erythrodysesthesia syndrome. Rare adverse effects include livedo reticularis (a mottled blue discoloration of the skin associated with poor venous return) and protein-losing gastroenteropathy.

Caution is advised when using dasatinib in patients with hepatic impairment.

Effects on the skin. Panniculitis has been reported with the use of dasatinib, which resolved upon stopping therapy. In one case, dasatinib was restarted with prednisone, and no recurrence of panniculitis was noted. In another patient, however, a rash recurred on restarting therapy that was not sensitive to corticosteroid treatment.[1]

1. Assouline S, *et al.* Panniculitis during dasatinib therapy for imatinib-resistant chronic myelogenous leukemia. *N Engl J Med* 2006; 354: 2623–4.

Lupus. A patient developed arthralgia and fatigue 3 months after starting dasatinib for chronic myeloid leukaemia. Symptoms worsened, drug-induced lupus was suspected, and dasatinib was stopped 9 months after starting therapy. Fever, arthralgia, fatigue, hepatosplenomegaly and pleuro-pericardial effusions all resolved fully within 1 month. It was suggested that the risk of developing dasatinib-associated autoimmunity be assessed prospectively by screening for autoantibodies before starting treatment *with dasatinib*.[1]

1. Rea D, *et al.* Dasatinib-induced lupus. *Lancet* 2008; 372: 713–14.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies dasatinib as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/09/11)

Interactions

Dasatinib is metabolised by the cytochrome P450 isoenzyme CYP3A4, and drugs that inhibit this enzyme, such as azole antifungals, macrolide antibacterials, HIV-protease inhibitors, and nefazodone may increase blood concentrations of dasatinib. Equally, inducers of CYP3A4 (such as carbamazepine, dexamethasone, phenobarbital, phenytoin, and rifampicin) may reduce blood concentrations of dasatinib. When use with such drugs cannot be avoided, dose adjustment of dasatinib may be necessary (see Uses and Administration, p. 777.3). Since St John's wort may decrease dasatinib concentrations unpredictably, these drugs should not be given together.

Dasatinib is a substrate of the cytochrome P450 isoenzyme CYP3A4, and may alter blood concentrations of other drugs that are substrates of this enzyme.

Since the solubility of dasatinib is dependent on pH, use with antacids should be avoided. If antacid therapy is needed, it should be given at least 2 hours before or 2 hours after the dose of dasatinib. Similarly, histamine H_2-receptor antagonists or proton pump inhibitors such as famotidine or omeprazole should not be given with dasatinib as long-term suppression of gastric acid secretion is likely to reduce dasatinib exposure.

Dasatinib prolongs the QT interval and the effect may be additive when given with other drugs with similar effects. Dasatinib also causes thrombocytopenia and bleeding, which may be additive with antiplatelet drugs, anticoagulants, and NSAIDs.

Pharmacokinetics

Peak plasma concentrations of dasatinib occur between 0.5 and 6 hours after an oral dose. The mean terminal half-life is about 5 hours. Consumption of a high-fat meal may increase exposure to dasatinib, but this effect is not considered to be of clinical significance. Dasatinib is extensively distributed and metabolised. Metabolism occurs mainly via the cytochrome P450 isoenzyme CYP3A4, forming an active metabolite. Plasma protein binding of dasatinib and its active metabolite is about 96% and 93%, respectively. Elimination is mainly via the faeces; about 4% is recovered in the urine.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Daunorubicin Hydrochloride). The hydrochloride of a substance produced by certain strains of *Streptomyces coeruleorubidus* or *S. peucetius* or obtained by any other means. It is manufactured by methods designed to minimise or eliminate the presence of histamine. An orange-red, hygroscopic, crystalline powder. It contains between 95 and 102% of the hydrochloride (anhydrous and solvent-free basis). Freely soluble in water and in methyl alcohol; slightly soluble in alcohol; practically insoluble in acetone. A 0.5% solution in water has a pH of 4.5 to 6.5. Store in airtight containers. Protect from light.

USP 36: (Daunorubicin Hydrochloride). An orange-red, hygroscopic, crystalline powder. It has a potency equivalent to not less than 842 and not more than 1030 micrograms of the base per mg. Freely soluble in water and in methyl alcohol; slightly soluble in alcohol; practically insoluble in acetone; very slightly soluble in chloroform. A 0.5% solution in water has a pH of 4.5 to 6.5. Store at a temperature not exceeding 40 degrees in airtight containers. Protect from light.

Incompatibility. Daunorubicin is incompatible with heparin sodium,[1] and has also been reported to be incompatible with a solution of dexamethasone sodium phosphate.

1. D'Arcy PF. Reactions and interactions in handling anticancer drugs. *Drug Intell Clin Pharm* 1983; 17: 532–8.

Stability. In a study[1] of the stability of anthracycline antineoplastic agents in 4 infusion fluids (glucose 5%, sodium chloride 0.9%, lactated Ringer's injection, and a commercial infusion fluid) daunorubicin hydrochloride was stable in all 4, the percentage remaining after 24 hours being 98.5%, 97.4%, 94.7%, and 95.4% respectively. Stability appeared to be partly related to pH; daunorubicin was more stable as the pH of the mixture became more acidic, with the best stability in glucose 5% with a pH of 4.5. Although daunorubicin solutions are degraded by light, the effect is reported not to be significant at concentrations of 500 micrograms/mL or above; however, below this concentration precautions should be taken to protect solutions from light, and storage should be in polyethylene or polypropylene containers to minimise adsorptive losses.[2] It has been suggested that formulation with the food colouring Scarlet GN, which absorbs light over the same spectral region as daunorubicin, would stabilise daunorubicin solutions to light.[3]

Liposomal daunorubicin citrate should be diluted with glucose 5% solution as aggregation of the liposomes may result with sodium chloride. In addition, licensed product information advises that liposomal daunorubicin should not be mixed with substances containing benzyl alcohol or other detergent-like molecules, which can lead to premature rupture of the liposomes.

3. Thoma K, Klimek R. Photostabilization of drugs in dosage forms without protection from packaging materials. *Int J Pharmaceutics* 1991; 67: 169–75.

Uses and Administration

Daunorubicin is an antineoplastic anthracycline antibiotic with actions similar to those of doxorubicin (p. 783.2), to which it is closely related. It is used with other antineoplastics to induce remissions in acute leukaemias. Daunorubicin is given in combination regimens for acute lymphoblastic leukaemia (see p. 692.3) and acute myeloid leukaemias (see p. 693.1). It has also been tried in some other malignancies. A liposomal formulation of daunorubicin has been developed for use in the management of advanced Kaposi's sarcoma in patients with AIDS (see also p. 718.1).

In the conventional formulation, daunorubicin is usually given as the hydrochloride, but doses are expressed in terms of the base. Daunorubicin hydrochloride 21.4 mg is equivalent to about 20 mg daunorubicin. The liposomal formulation contains daunorubicin citrate, equivalent to about 2 mg/mL of daunorubicin base.

In US treatment regimens for adult acute lymphoblastic or myeloid leukaemia, the usual dose of *conventional* daunorubicin hydrochloride is the equivalent of daunorubicin 45 mg/m² daily on days 1 to 3 of the first course; in acute myeloid leukaemia, this dose is also given on days 1 and 2 of subsequent courses. Courses may be repeated if needed, after bone-marrow evaluation. In the UK, for remission induction in acute leukaemias, a dose of 40 to 60 mg/m² can be given on alternate days for a course of up to 3 injections. Daunorubicin hydrochloride is given as a solution in sodium chloride 0.9% into a fast-running intravenous infusion of sodium chloride 0.9% or glucose 5%.

For doses in children and the elderly, see below. Dosage should be reduced in patients with impaired hepatic or renal function (see below).

In the treatment of Kaposi's sarcoma, *liposomal* daunorubicin citrate is given intravenously every 2 weeks starting with a dose of 40 mg/m², and continued for as long as disease control can be maintained. It is diluted with glucose 5% (sodium chloride 0.9% should not be used) to a daunorubicin concentration between 0.2 and 1 mg/mL, and given over 30 to 60 minutes.

Blood counts should be determined frequently during treatment as daunorubicin has a potent effect on bone-marrow function (see also Bone-marrow Depression, p. 730.3). Cardiac function should be monitored at regular intervals to detect signs of cardiotoxicity. The total cumulative dose of daunorubicin in adults should not exceed 550 to 600 mg/m²; in patients who have received radiotherapy to the chest it may be advisable to limit the total cumulative dose to about 400 mg/m². Product information for liposomal daunorubicin recommends determining left ventricular ejection fraction (LVEF) at baseline and after cumulative doses of 320 mg/m², and every 160 mg/m² thereafter. In patients who have received prior radiotherapy to the chest, or who have pre-existing cardiac disease, or who have had previous anthracycline therapy (equivalent to more than *doxorubicin* 300 mg/m²) LVEF should be assessed at baseline and after every 160 mg/m² of liposomal daunorubicin.

Administration. *HIGH-DOSE THERAPY.* Two multicentre studies in patients with acute myeloid leukaemia compared the use of a standard induction dose of a conventional daunorubicin formulation (45 mg/m²), with an escalated dose of 90 mg/m², given for 3 days in a regimen with cytarabine.[1,2] In patients aged 60 and under, the high-dose regimen was associated with an increased rate of complete remission (70.6 versus 57.3% in the conventional dose group), and improved overall survival (median values of 23.7 versus 15.7 months) on follow-up for a median of 25 months.[2] Although this study suggested little benefit in the subgroup of patients older than 50, in the other, which was restricted to those 60 and over, comparable improvements in remission and overall survival were seen with high-dose therapy in those between 60 and 65 years of age,[1] but patients older than this did not show any benefit. The higher doses of anthracycline were not associated with an increase in mortality or moderate to severe adverse events, even in older patients.

1. Löwenberg B, *et al.* Dutch-Belgian Cooperative Trial Group for Hemato-Oncology (HOVON), German AML Study Group (AMLSG), and Swiss Group for Clinical Cancer Research (SAKK) Collaborative Group. High-dose daunorubicin in older patients with acute myeloid leukemia. *N Engl J Med* 2009; 361: 1235–48. Correction. *ibid.* 2010; 362: 1155. [dose]
2. Fernandez HF, *et al.* Anthracycline dose intensification in acute myeloid leukemia. *N Engl J Med* 2009; 361: 1249–59.

Administration in children. Daunorubicin hydrochloride is licensed for the induction of remission in children with acute leukaemia. Doses may vary according to country, and the combination regimen used.

In the USA, a dose of daunorubicin 25 mg/m² is given intravenously once a week, in combination regimens, to children with acute lymphoblastic leukaemia. Complete remission is generally obtained within 4 courses; however, if only partial remission is obtained after 4 courses, up to 2 further courses may be given. For children less than 2 years of age, or with a body-surface of less than 0.5 m², a dose of 1 mg/kg is used instead.

In the UK, children with acute myeloid or lymphoblastic leukaemia who are 2 years and older may be given the same dose as adults (see Uses and Administration, above). Children under 2 years of age, or with a body-surface of less than 0.5 m² may be given an intravenous dose of 1 mg/kg daily.

Precautions and monitoring are as for adults; cardiotoxicity may occur more frequently in children. A total cumulative dose of 300 mg/m² should not be exceeded; in children under 2 years, the total cumulative dose should not exceed 10 mg/kg.

The safety and efficacy of *liposomal* daunorubicin citrate in paediatric patients has not been established. However, a study in 24 patients aged between 2 and 23 years, who were given doses of 30 or 60 mg/m², indicated that the pharmacokinetics showed less variability than has been reported for conventional formulations, and no substantial differences related to age.[1]

1. Hempel G, *et al.* Population pharmacokinetics of liposomal daunorubicin in children. *Br J Clin Pharmacol* 2003; 56: 370–7.

Administration in the elderly. Daunorubicin hydrochloride should be used with care in elderly patients with inadequate bone marrow reserves. In the UK, a dosage reduction of up to 50% is recommended. In the USA, for patients with acute myeloid leukaemia and aged 60 years and over, an intravenous dose of daunorubicin 30 mg/m² daily on days 1 to 3 of the first course, and days 1 and 2 of subsequent courses, is recommended for combination treatment regimens. Precautions and monitoring are as for younger adults (see Uses and Administration, above); cardiotoxicity may occur more frequently in the elderly. However, see also High-dose Therapy, above.

The safety and efficacy of *liposomal* daunorubicin citrate in elderly patients has not been established.

Administration in hepatic impairment. Doses of daunorubicin should be reduced in hepatic impairment. Some licensed product information for daunorubicin hydrochloride recommends that patients with serum-bilirubin concentrations of 12 to 30 micrograms/mL (or 20 to 50 micromoles/litre) should receive 75% of the usual daily dose, and those with concentrations greater than 30 micrograms/mL (or above 50 micromoles/litre) should be given 50% of the usual daily dose.

Limited data exist for liposomal daunorubicin citrate; in the USA, similar dosage reductions to those given for the hydrochloride are recommended.

Administration in renal impairment. Doses of daunorubicin should be reduced in renal impairment. Some licensed product information for daunorubicin hydrochloride recommends that patients with serum-creatinine concentrations of 12 to 30 micrograms/mL (or 105 to 265 micromoles/litre) should receive 75% of the usual daily dose, and those with concentrations greater than 30 micrograms/mL (or 265 micromoles/litre) should be given 50% of the usual daily dose.

Limited data exist for liposomal daunorubicin citrate; in the USA, similar dosage reductions to those given for the hydrochloride are recommended in patients with a serum-creatinine concentration greater than 30 micrograms/mL.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin, p. 784.1 and p. 785.1.

Cardiotoxicity is more likely when the total cumulative dose of daunorubicin exceeds 550 to 600 mg/m² in adults, 300 mg/m² in children, or in children aged under 2 years, 10 mg/kg. The total cumulative dose should be limited to 400 mg/m² in patients who have had previous radiation therapy to the chest. US licensed product information for the standard formulation of daunorubicin recommends an ECG and/or determination of left ventricular ejection fraction (LVEF) before each course. Product information for liposomal daunorubicin recommends evaluating cardiac function before each course of daunorubicin and determining LVEF at baseline and after cumulative doses of 320 mg/m², and every 160 mg/m² thereafter. In patients who have pre-existing cardiac disease, or who have had previous radiotherapy to the chest or anthracycline therapy (more than 300 mg/m² *doxorubicin* or equivalent) LVEF should be assessed at baseline and after every 160 mg/m² of liposomal daunorubicin. Daunorubicin should be used in reduced doses in hepatic and renal impairment.

Liposomal formulations of daunorubicin may be associated with a reduced potential for local tissue necrosis although current clinical experience is limited and such toxicity remains a possibility. An acute syndrome of back pain, flushing, and chest tightness may occur during infusion of such products, but generally resolves on slowing or temporarily stopping the infusion.

Effects on the heart. For a discussion of the cardiotoxicity of anthracyclines, and its management, see Effects on the Heart, under Doxorubicin, p. 784.1.

Effects on the skin and nails. For reports of hyperpigmentation in patients given daunorubicin, see under Doxorubicin, p. 784.3.

Handling and disposal. Daunorubicin hydrochloride is irritant; avoid contact with skin and mucous membranes.

For a method for the destruction of daunorubicin in wastes see under Doxorubicin, p. 785.1.

Pregnancy. For a report of a fetal sinusoidal heart rate pattern and neonatal pancytopenia after a woman was given combination chemotherapy including daunorubicin, see Pregnancy, under Etoposide, p. 791.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies daunorubicin as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

As for Doxorubicin, p. 785.2.

Antineoplastics. Hepatic dysfunction was reported[1] in 13 patients given cumulative doses of daunorubicin 180 to 450 mg/m². Ten of them had also received *tioguanine* or *cytarabine*, or a combination of these. The authors also noted that other studies had suggested that the related drug doxorubicin might enhance the hepatotoxicity of *mercaptopurine*, and thought that a similar interaction could occur between daunorubicin and tioguanine.

1. Penta JS, *et al.* Hepatotoxicity of combination chemotherapy for acute myelocytic leukemia. *Ann Intern Med* 1977; 87: 247–8.

Pharmacokinetics

After intravenous injection, daunorubicin is rapidly distributed into body tissues, particularly the liver, lungs, kidneys, spleen, and heart with an initial distribution half-life of about 45 minutes. It is rapidly metabolised in the liver, and is excreted in bile and urine as unchanged drug and metabolites. The major metabolite, daunorubicinol, has antineoplastic activity. Up to 25% of a dose is excreted in urine in an active form over several days (the terminal plasma elimination half-lives of daunorubicin and its major metabolite are reported to be 18.5 and 26.7 hours respectively); an estimated 40% is excreted in bile.

Daunorubicin does not appear to cross the blood-brain barrier, but crosses the placenta.

The pharmacokinetics of liposomal doxorubicin are significantly different from those of the conventional drug formulation, with a decreased uptake by normal tissues (although tumour neovasculature is reported to have increased permeability to the liposomes), and a terminal half-life of 4 to 5 hours.

Pharmacopoeial Preparations

USP 36: Daunorubicin Hydrochloride for Injection.

Decitabine *(BAN, USAN, rINN)*

5-Aza-2′-deoxycytidine; DAC; Decitabina; Décitabine; Decitabinum; NSC-127716; Децитабин.

4-Amino-1-(2-deoxy-β-D-*erythro*-pentofuranosyl)-1,3,5-triazin-2(1*H*)-one.

$C_8H_{12}N_4O_4$=228.2

CAS — 2353-33-5.

ATC — L01BC08.

ATC Vet — QL01BC08.

UNII — 776B62CQ27.

Uses and Administration

Decitabine is an antineoplastic antimetabolite structurally related to cytarabine (p. 774.1). It is reported to cause DNA hypomethylation by the inhibition of DNA methyltransferase, which has the potential to alter gene expression (reactivate silent genes) and limit disease progression and resistance. Decitabine is used in the treatment of myelodysplastic syndromes (p. 694.3); it is also used in the management of newly diagnosed or secondary acute myeloid leukaemia (p. 693.1) in patients 65 years of age or older who are not candidates for standard induction chemotherapy.

Decitabine is given by intravenous infusion, diluted to a final concentration of 0.1 to 1 mg/mL in sodium chloride 0.9%, glucose 5%, or lactated Ringer's injection.

For the treatment of **myelodysplastic syndromes** the recommended dose is 15 mg/m² infused over 3 hours and given every 8 hours for 3 days; this 3-day cycle is repeated every 6 weeks, for a minimum of 4 cycles. If haematological recovery from a cycle is incomplete, cycle length may be increased to as much as every 10 weeks and the dose reduced to 11 mg/m² every 8 hours upon restarting therapy; this dose may be maintained or increased in subsequent cycles as clinically indicated. An alternative regimen is decitabine 20 mg/m² infused over 1 hour and given once daily for 5 days; this 5-day cycle is repeated every 4 weeks, for at least 4 cycles. If myelosuppression occurs, subsequent cycles should be delayed until haematological recovery.

Decitabine treatment should be delayed if serum creatinine is 2 mg per 100 mL or greater, or if total bilirubin is 2 or more times the upper limit of normal, or if the patient has an active or uncontrolled infection.

For the treatment of **acute myeloid leukaemia** the recommended dose of decitabine is 20 mg/m² infused over 1 hour and given once daily for 5 days; this 5-day cycle is repeated every 4 weeks, for at least 4 cycles. If myelosuppression occurs, subsequent cycles should be delayed until haematological recovery.

Decitabine is also under investigation for the treatment of chronic myeloid leukaemia (p. 694.2). It is also reported to increase fetal haemoglobin in patients with sickle-cell disease (p. 1123.2).

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2. The most common adverse effect of decitabine is myelosuppression, which may be severe and dose-limiting. Fatalities have been reported. Other common adverse effects include fatigue, pyrexia, gastrointestinal disturbances, petechiae, and hyperglycaemia. Cardiorespiratory arrest, increased blood bilirubin, intracranial haemorrhage, abnormal liver function tests, pulmonary oedema, atrial fibrillation, central line infection, or febrile neutropenia may force treatment to be stopped or delayed. Other adverse effects which may be dose-limiting include lethargy, oedema, tachycardia, depression, or pharyngitis.

Pharmacokinetics

On intravenous dosage decitabine shows biphasic disposition. Plasma protein binding is negligible. The exact route of metabolism and excretion is not known; one pathway appears to be deamination by cytidine deaminase, which is found principally in the liver, but also in granulocytes, the intestinal epithelium, and whole blood. A terminal elimination half-life of about 0.5 hours has been reported after a 72-hour infusion.

Denileukin Diftitox *(USAN, rINN)*

$DAB_{389}IL2$; Denileucina diftitox; Denileukin Difitox (BAN); Dénileukine Diftitox; Denileukinum Diftitoxum; LY-335348; Денилейкин Дифтитокс.

CAS — 173146-27-5.

ATC — L01XX29.

ATC Vet — QL01XX29.

UNII — 25E79B5CTM.

Uses and Administration

Denileukin diftitox is a recombinant interleukin fusion toxin comprised of interleukin-2 linked to the A and B fragments of diphtheria toxin. It is given by intravenous infusion for the management of persistent or recurrent cutaneous T-cell lymphoma (see Mycosis Fungoides, p. 698.3), in patients whose malignant cells express the CD25 interleukin-2 receptor. The concentration of denileukin diftitox must be at least 15 micrograms/mL during all steps in the preparation of the solution for infusion. The recommended dose is 9 or 18 micrograms/kg daily, given over 15 minutes or more, for 5 consecutive days every 3 weeks.

9. Prince HM, *et al.* Phase III placebo-controlled trial of denileukin diftitox for patients with cutaneous T-cell lymphoma. *J Clin Oncol* 2010; **28**: 1870–7.

Adverse Effects and Precautions

Denileukin diftitox can cause an acute hypersensitivity reaction within 24 hours of infusion with symptoms reminiscent of a cytokine release syndrome. Anaphylaxis and death have also been reported. A more delayed flu-like syndrome may also occur up to several days after infusion. Vascular leak syndrome, characterised by hypotension, oedema, or hypoalbuminaemia, may also be delayed. Gastrointestinal disturbances, chills, fever, and asthenia are common. Other adverse effects include rash, predisposition to cutaneous infections, and thrombotic events. Visual loss has been reported; although recovery was reported in some patients, in most cases impairment persisted.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Gr.*: Ontak; *USA*: Ontak.

Diaziquone *(USAN, rINN)*

Aziridinylbenzoquinone; AZQ; CI-904; Diazicuona; Diaziquonum; NSC-182986; Диазихон.

Diethyl 2,5-bis-(1-aziridinyl)-3,6-dioxo-1,4-cyclohexadiene-1,4-dicarbamate.

$C_{16}H_{20}N_4O_6$=364.4

CAS — 57998-68-2.

UNII — FQL5EUP13W.

Profile

Diaziquone has been investigated as an antineoplastic in the treatment of malignant brain tumours and acute myeloid leukaemia. It is thought to act as an alkylating agent. Adverse effects include bone-marrow suppression, manifesting chiefly as leucopenia and thrombocytopenia, gastrointestinal disturbances, and alopecia. Anaphylactoid reactions have occurred.

Docetaxel *(BAN, USAN, rINN)*

Docetaksel; Docétaxel; Docetaxelum; Docetaxol; Docetaxolum; Dosetaksel; Dosetaksoli; NSC-628503; RP-56976; Доцетаксел.

(2*R*,3*S*)-*N*-Carboxy-3-phenylisoserine, *N*-*tert*-butyl ester, 13-ester with 5β-20-epoxy-1,2α,4,7β,10β,13α-hexahydroxytax-11-en-9-one 4-acetate 2-benzoate; *tert*-Butyl {(1*S*,2*S*)-2-[(2*S*,5*R*,7*S*,10*R*,13*S*)-4-acetoxy-2-benzoyloxy-1,7,10-trihydroxy-9-oxo-5,20-epoxytax-11-en-13-yloxycarbonyl]-2-hydroxy-1-phenylethyl}carbamate.

$C_{43}H_{53}NO_{14}$=807.9

CAS — 114977-28-5 (anhydrous docetaxel); 148408-66-6 (docetaxel trihydrate).

ATC — L01CD02.

ATC Vet — QL01CD02.

UNII — 15H5577CQD (docetaxel); o99121PHCA (anhydrous docetaxel).

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Docetaxel, Anhydrous). A white or almost white, crystalline, hygroscopic powder. Practically insoluble in water; freely soluble in dehydrated alcohol; soluble in dichloromethane. Store in airtight containers. Protect from light.

Ph. Eur. 8: (Docetaxel Trihydrate). A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in dehydrated alcohol; soluble in dichloromethane. Protect from light.

USP 36: (Docetaxel). A white or almost white, crystalline powder. Practically insoluble in water; soluble in methyl alcohol; freely soluble in acetone. Protect from light.

Incompatibility and stability. Various formulations of docetaxel are available; some require an initial reconstitution of a concentrate with a solvent (resulting in a premix solution) before further dilution for infusion, whereas others are available in vials as a solution ready for further dilution for infusion. Both the premix solutions and the vials should be used as soon as possible after reconstitution and opening, respectively. However, licensed product information (*Actavis, UK*) states that the premix solution is chemically and physically stable for 8 hours when stored between 2 degrees and 8 degrees or at room temperature (below 25 degrees). The same company states for its solution formulation that physical, chemical, and microbiological stability has been shown for 28 days at 2 degrees to 8

degrees and at 25 degrees under normal lighting conditions (after the first vial opening).

Docetaxel is further diluted with sodium chloride 0.9% or glucose 5% to a concentration not exceeding 740 micrograms/mL; chemical and physical stability, and maximum storage time varies between products:

- *Actavis, UK* (premix solution formulation): 4 hours at about 25 degrees under normal lighting; 4 hours at 5 degrees ± 3 degrees, protected from light; storage not longer than 24 hours at 2 degrees to 8 degrees
- *Actavis, UK* (concentrate solution): 8 hours at about 25 degrees under normal lighting; 3 days at 2 degrees to 8 degrees, protected from light
- *Hospira, UK*: 4 hours when stored below 25 degrees; storage not longer than 24 hours at 2 degrees to 8 degrees
- *Taxotere, Sanofi-Aventis, UK*: 6 hours when stored below 25 degrees; 48 hours at 2 degrees to 8 degrees (in non-PVC bags; see below for further information)

Product literature should therefore be consulted.

The chemical and physical stability of various docetaxel infusion solutions has been studied.[1-3] The *Taxotere* formulation was diluted to 300 or 900 micrograms/mL with sodium chloride 0.9% in polyolefin containers or glass bottles, and stored at 19 degrees to 21 degrees and protected from light.[1] There was no evidence of precipitation in the first 24 hours of storage. However, after this time, HPLC assay revealed concentrations with large standard deviations for some containers, suggesting the existence of microprecipitates. Precipitation was a generalised phenomenon at day 7, especially in glass containers. The results of this study supported the use of docetaxel within 4 hours of preparation, and the authors cautioned that docetaxel (*Taxotere* formulation) was very labile and physical stability could be strongly affected by small variations in handling conditions.[1]

Many docetaxel formulations contain polysorbate 80, which has the potential to leach the plasticiser diethylhexyl phthalate (DEHP) from PVC bags, and use in such containers is to be avoided.[3] In order to minimise patient exposure to DEHP, some manufacturers (*Hospira, UK*) recommend that docetaxel be stored in glass bottles or polypropylene or polyolefin containers, and given through polyethylene-lined giving sets. Similar recommendations are made for paclitaxel, see under Incompatibility, p. 839.3.

Uses and Administration

Docetaxel is a semisynthetic taxane similar to paclitaxel (see p. 839.3). It is manufactured from a taxane precursor derived from the needles of the European yew tree *Taxus baccata*. Docetaxel is used for locally advanced or metastatic breast cancer (p. 702.1). It may be used as first-line treatment with doxorubicin; in the treatment of refractory disease, it is used alone or with capecitabine. In the treatment of metastatic breast cancer that overexpresses HER2 (human epidermal growth receptor 2), docetaxel may be used with trastuzumab as initial therapy. For adjuvant treatment of operable, node-positive breast cancer, docetaxel is given with doxorubicin and cyclophosphamide. Docetaxel is also indicated for the treatment of locally advanced or metastatic non-small cell lung cancer (p. 710.2), either with cisplatin for initial treatment of unresectable disease, or after failure of previous platinum-based chemotherapy. It is used with prednisone or prednisolone in hormone-refractory metastatic prostate cancer (p. 712.3). Docetaxel is given with cisplatin and fluorouracil in the first-line treatment of patients with metastatic gastric adenocarcinoma, including adenocarcinoma of the gastro-oesophageal junction (see Malignant Neoplasms of the Stomach, p. 706.1); it is also used in this combination for the induction treatment of patients with locally advanced squamous cell carcinoma of the head and neck (p. 708.1).

Docetaxel is given by intravenous infusion in glucose 5% or sodium chloride 0.9% at a concentration not exceeding 740 micrograms/mL. Infusion is normally over 1 hour. Premedication with an oral corticosteroid, such as dexamethasone 16 mg daily, for 3 days starting 1 day before docetaxel is recommended with many regimens.

The licensed dose for docetaxel as a single agent in the treatment of **breast cancer** after failure of previous chemotherapy is 60 to 100 mg/m^2 once every 3 weeks. A dose of 75 mg/m^2 once every 3 weeks is given in combination therapy with doxorubicin, or capecitabine, or when used as adjuvant therapy with doxorubicin and cyclophosphamide. When used with trastuzumab, docetaxel is given at a dose of 100 mg/m^2 once every 3 weeks.

The dose for **non-small cell lung cancer** is 75 mg/m^2 once every 3 weeks, for both first-line combination therapy and monotherapy after failure of previous chemotherapy.

For **gastric adenocarcinoma** docetaxel 75 mg/m^2 is given before cisplatin and fluorouracil; treatment is repeated every 3 weeks.

In the induction treatment of **head and neck cancer**, the recommended dose of docetaxel is 75 mg/m^2, given before cisplatin and fluorouracil; treatment is given every 3 weeks for 3 cycles, followed by chemoradiotherapy, or for 4 cycles when followed by radiotherapy alone.

For **prostate cancer**, the dose of docetaxel is 75 mg/m^2 once every 3 weeks, with prednisone or prednisolone 5 mg orally twice daily given continuously. The use of prednisone or prednisolone reduces the need for a premedication corticosteroid; dexamethasone 8 mg may be given at 12 hours, 3 hours, and 1 hour before docetaxel.

Regular blood counts are required, and dosage in subsequent courses should be reduced in patients who develop severe or febrile neutropenia (see also Bone-marrow Depression, p. 730.3), or severe cutaneous reactions or peripheral neuropathy. The dose of docetaxel should be reduced in hepatic impairment, see below. A dose reduction is also suggested when docetaxel is used with strong cytochrome P450 isoenzyme CYP3A4 inhibitors, see Administration with Other Drugs, below.

Novel formulations of docetaxel are under investigation, including a pegylated conjugate, a lyophilised emulsion, and a docetaxel prodrug nanoparticle formulation.

Administration. Docetaxel has been investigated as a low-dose weekly infusion, in patient groups such as the elderly, those with poor performance status, or refractory disease.[1-6] Weekly doses of 30 to 40 mg/m^2 are considered to be of similar efficacy to the standard three-weekly dosage regimen[7] (see also under Paclitaxel, p. 840.2). A pharmacokinetic study in 20 elderly patients suggested that a suitable starting dose might be 26 mg/m^2, increased provided there was no toxicity, but see also below.[8]

8. Hurria A, *et al.* Pharmacokinetics and toxicity of weekly docetaxel in older patients. *Clin Cancer Res* 2006; 12: 6100–5.

Administration in the elderly. A review[1] found no significant data to support dose modifications of docetaxel based on age alone. While elderly patients may be more vulnerable to adverse effects, interpatient variability appears to be more important than age-related variability.

See also Administration, above.

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; 25: 1832–43.

Administration in hepatic impairment. UK licensed product information recommends that doses of docetaxel monotherapy should be reduced from 100 mg/m^2 to 75 mg/m^2 in mild to moderate hepatic impairment, defined as alanine aminotransferase (ALT/SGPT) and/or aspartate aminotransferase (AST/SGOT) more than 1.5 times the upper limit of normal (ULN), and alkaline phosphatase more than 2.5 times the ULN. Hepatic function should be monitored; use should be avoided if possible in severe hepatic impairment. US licensed information advises against the use of docetaxel in patients with bilirubin above ULN, or in those with mild to moderate hepatic impairment (defined as for the UK, above).

Administration with other drugs. Use of docetaxel with strong cytochrome P450 isoenzyme CYP3A4 inhibitors may affect exposure to docetaxel (see Interactions, p. 782.1). Clinical data on appropriate dose adjustment of docetaxel are limited. US licensed product information recommends a 50% dose reduction of docetaxel when use with strong CYP3A4 inhibitors cannot be avoided; this is based on extrapolation from a small pharmacokinetic study of the use of docetaxel with ketoconazole (but see Antifungals, p. 782.2).

For doses of docetaxel when given as part of licensed chemotherapy combination regimens, see Uses and Administration, above.

It has been suggested that administration with inhibitors of CYP3A4 or P-glycoprotein or both might allow *oral* administration of docetaxel to produce viable exposure to the drug; see Antiretrovirals and Immunosuppressants, p. 782.2.

Adverse Effects, Treatment, and Precautions

As for Paclitaxel, p. 841.1. Neutropenia, anaemia and skin reactions are common with docetaxel and may be severe. Fluid retention, resulting in oedema, ascites, pleural and pericardial effusion, and weight gain, is also common, and may be cumulative; premedication with a corticosteroid can reduce fluid retention as well as the severity of hypersensitivity reactions. Asthenia and fatigue have also been reported. Rare cases of ototoxicity, hearing impairment or loss have occurred. Very rare cases of acute myeloid leukaemia and myelodysplastic syndrome have been reported with combination chemotherapy regimens containing docetaxel; haematological follow-up may be required.

Docetaxel should not be used in patients hypersensitive to polysorbate 80, which is contained in the formulation. Patients with hepatic impairment show increased sensitivity to toxic effects of docetaxel, and should be given the drug with great care and in reduced doses, if at all.

A review of 6 adverse effects that have been seen with most docetaxel-based regimens (febrile neutropenia, hypersensitivity reactions, fluid retention, nail toxicity, asthenia, and neuropathy) and their management.[1]

1. Baker J, *et al.* Docetaxel-related side effects and their management. *Eur J Oncol Nurs* 2009; 13: 49–59.

Effects on the eyes. Excessive tear formation (epiphora) severe enough to interfere with reading and driving has been reported in patients given docetaxel. Canalicular stenosis has been described as the mechanism for this effect, and docetaxel has been measured in tear fluid suggesting that irritation of the ocular surface and fibrosis of the tear drainage ducts may be caused by direct contact with docetaxel.[1] Epiphora and canalicular stenosis are more severe and occur more frequently in patients given weekly docetaxel than in those who receive the drug every 3 weeks.[2,3] The mean cumulative dose of docetaxel was found to be higher in those patients who developed stenosis.[2] Management of this adverse effect includes probing and irrigation of the lachrymal ducts and canalicular silicone tubing placement, alone or after surgery. The condition is generally reversible and tubing can be removed 4 to 6 weeks after stopping docetaxel therapy.[4] The use of topical tobramycin and dexamethasone on a tapering regimen can sometimes eliminate the need for silicone intubation or surgery.[3]

Very rare cases of transient visual disturbances such as flashing lights and scotomata have occurred during docetaxel infusion, and in association with hypersensitivity reactions. These were reversible upon stopping the infusion. For reference to a report of glaucoma possibly related to docetaxel, see Paclitaxel, p. 841.2.

4. Ahmadi MA, Esmaeli B. Surgical treatment of canalicular stenosis in patients receiving docetaxel weekly. *Arch Ophthalmol* 2001; 119: 1802–4.

Effects on the gastrointestinal tract. Ischaemic colitis has occurred in patients treated with docetaxel.[1-3] Some

patients also received vinorelbine, which may have exacerbated this complication.[1,2]

1. Ibrahim NK, *et al.* Colitis associated with docetaxel-based chemotherapy in patients with metastatic breast cancer. *Lancet* 2000; 355: 281–3.

3. Hussein MAR, *et al.* Docetaxel-related ischemic colitis. *J Clin Oncol* 2005; 23: 9424–5.

Effects on the heart. For comment on the increased risk of heart failure when docetaxel is given with trastuzumab and after anthracyclines, see under Interactions, below.

Effects on the lungs. Reviews[1,2] of interstitial lung disease associated with docetaxel.

1. Grande C, *et al.* Docetaxel-induced interstitial pneumonitis following non-small-cell lung cancer treatment. *Clin Transl Oncol* 2007; 9: 578–81.
2. Alsamarai S, *et al.* Pneumonitis related to docetaxel: case report and review of the literature. *In Vivo* 2009; 23: 635–7.

Effects on the musculoskeletal system. For reference to cases of taxane-induced arthralgia and myalgia successfully treated with gabapentin, see Paclitaxel, p. 841.3.

Effects on the skin, hair, and nails. Palmar-plantar erythrodysesthesia syndrome (p. 730.1) has been reported with the use of docetaxel.[1,2] For reference to the use of vitamin E to alleviate palmar-plantar erythrodysesthesia syndrome caused by docetaxel and capecitabine, see Chemotherapy-induced Toxicity, under Uses of Vitamin E, p. 2120.1. Cases of radiation recall dermatitis associated with docetaxel have also been reported.[3-5] There is a further report of recall dermatitis at sites previously treated with a laser.[6] A hyperpigmented eruption developed in a patient at the site of docetaxel injection after insufficient venous flushing; no eruption occurred after a second infusion with abundant venous flushing.[7] Licensed product information states that very rare cases of bullous eruption such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis have been reported with docetaxel, but that other factors may have contributed to the development of these reactions.

In a multicentre study, patients given docetaxel wore a frozen glove on the right hand, leaving the left hand unprotected to serve as a control. The use of the glove significantly reduced skin and nail toxicity.[8]

For reference to reports of scleroderma, alopecia, and further adverse effects on the nails after the use of docetaxel, see Paclitaxel, p. 841.3.

Hypersensitivity. For a discussion of taxane-induced hypersensitivity, including references to desensitisation protocols, see under Paclitaxel, p. 842.1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies docetaxel as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Pregnancy. For discussion of the use of taxanes during pregnancy, see Paclitaxel, p. 842.1.

Tumour lysis syndrome. Fatal cases of tumour lysis syndrome (p. 730.2) have been reported after the second-line use of docetaxel.[1,2]

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Docetaxel is metabolised by the cytochrome P450 isoenzyme CYP3A4 and use with inducers or inhibitors or other substrates of this enzyme may affect exposure to docetaxel. It should be given with caution to patients taking strong CYP3A4 inhibitors including HIV-protease inhibitors such as ritonavir, and azole antifungals like ketoconazole or itraconazole. Ketoconazole has been reported to reduce the clearance of docetaxel (but see below); based on this, US licensed product information recommends a dose reduction of docetaxel when it is given with strong CYP3A4 inhibitors if use together cannot be avoided (see Administration with Other Drugs, p. 781.3).

Antifungals. In a pharmacokinetic study, no consistent effects on docetaxel concentrations were seen with the addition of *ketoconazole*. Significant inter- and intrapatient variability was noted and a potential interaction could not be excluded.[1] In another study in 7 patients, however, the clearance of docetaxel was significantly reduced by 49% when given with ketoconazole.[2]

2. Engels FK, *et al.* Effect of cytochrome P450 3A4 inhibition on the pharmacokinetics of docetaxel. *Clin Pharmacol Ther* 2004; 75: 448–54.

Antineoplastics. The clearance of a dose of docetaxel was markedly reduced[1] when it was given after 4 days of treatment with *topotecan*, rather than on day 1; this resulted in worsened neutropenia.

Sorafenib may increase systemic exposure to docetaxel.

An increased incidence of febrile neutropenia and gastrointestinal disorders, including 2 fatalities, was reported in patients given docetaxel with *doxorubicin*,[2] although others[3] considered this high incidence unrepresentative of usual toxicity rates with this combination.

Heart failure has been reported in patients given docetaxel with other cytotoxic drugs, especially *trastuzumab*, and particularly after anthracycline-containing therapy. UK licensed product information therefore recommends that patients given docetaxel with trastuzumab should undergo baseline cardiac assessment and cardiac function should be monitored during treatment.

Antiretrovirals. *HIV-PROTEASE INHIBITORS.* Severe toxicity has been reported after the use of intravenous docetaxel with *ritonavir*, probably due to ritonavir-induced inhibition of cytochrome P450 isoenzyme CYP3A4, causing a significant increase in exposure to docetaxel.[1]

Subsequently, the use of ritonavir to boost systemic exposure to oral docetaxel (which has a low bioavailability) has been investigated.[2,3] Use of these two drugs together was well tolerated,[2] and resulted in enhanced oral absorption and reduced elimination of docetaxel.[3] A pharmacokinetic model has been developed[3] to establish optimal combination regimens.

Immunosuppressants. Oral bioavailability of the taxanes docetaxel and paclitaxel is low, partly due to their affinity for P-glycoprotein;[1,2] metabolism by cytochrome P450 isoenzyme CYP3A4 and poor solubility may also contribute. Studies have found that exposure to oral docetaxel[1,2] and paclitaxel[2] can be increased by use with *ciclosporin*, a P-glycoprotein inhibitor. P-glycoprotein inhibitors might be used to boost the bioavailability of an oral formulation, although ciclosporin is not an ideal candidate because of its immunosuppressive effects.[2]

Pharmacokinetics

On intravenous dosage docetaxel is rapidly distributed to body tissues. Docetaxel is more than 95% bound to plasma proteins. It is extensively metabolised via hepatic cytochrome P450 isoenzyme CYP3A4 and excreted chiefly in the faeces as metabolites. Only about 6% of a dose is excreted in urine. The terminal elimination half-life is about 11 hours. Clearance is reduced in hepatic impairment.

Doxifluridine *(rINN)*

5-DFUR; Doxifluridina; Doxifluridinum; FUDR; Ro-21-9733; Доксифлуридин; 5′-Deoxy-5-fluorouridine.

$C_9H_{11}FN_2O_5$=246.2

CAS — 3094-09-5.

UNII — V1JK16Y2JP.

Pharmacopoeias. In *Jpn*.

Profile

Doxifluridine is an antineoplastic that probably acts through its conversion in the body to fluorouracil (p. 795.2). It is given orally in the management of malignant neoplasms of the breast (p. 702.1) and gastrointestinal tract (p. 705.2), and of other solid tumours, in doses of 0.8 to 1.2 g daily in divided doses. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* Doxifluridine has also been given by the intravenous route.

Pharmacokinetics. Doxifluridine is metabolised to fluorouracil and 5,6-dihydrofluorouracil. It is orally active with a bioavailability of 34 to 47%.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *China*: Ai Feng (艾丰); Furtulon (氟铁龙); Ke Fu (可弗); Ke Tuo (克托); Qi Nuo Bi Tong (奇诺必通); Shu Qi (枢绮); Tan Nuo (坦诺); Yi Di An (谊迪安); Zhi Ai (知爱); *Jpn*: Furtulon.

Doxorubicin *(BAN, USAN, rINN)*

Adriamycin; Doksorubisiini; Doxorubicina; Doxorubicine; Doxorubicinum; FI-106; 3-Hydroxyacetyldaunorubicin; 14-Hydroxydaunomycin; Доксорубицин.

8-Hydroxyacetyl (8S,10S)-10-[(3-amino-2,3,6-trideoxy-α-L-lyxo-hexopyranosyl)oxy]-6,8,11-trihydroxy-1-methoxy-7,8,9,10-tetrahydronaphthacene-5,12-dione.
$C_{27}H_{29}NO_{11}$=543.5
CAS — 23214-92-8.
ATC — L01DB01.
ATC Vet — QL01DB01.
UNII — 80168379AG.

NOTE. In many countries the name Adriamycin is a trademark.

Doxorubicin Citrate *(BANM, rINNM)*

Citrato de doxorubicina; Doxorubicin Citrate Liposome; Doxorubicine, Citrate de; Doxorubicini Citras; Liposomal Doxorubicin Citrate; Доксорубицина Цитрат.
$C_{27}H_{29}NO_{11}.xC_6H_8O_7$
CAS — 111266-55-8.
ATC — L01DB01.
ATC Vet — QL01DB01.

NOTE. Doxorubicin citrate complex is a constituent of some liposomal products. It is prepared from doxorubicin hydrochloride (below).

Doxorubicin Hydrochloride *(BANM, rINNM)*

Cloridrato de Doxorrubicina; Doksorubicino hidrochloridas; Doksorubicyny chlorowodorek; Doksorubisilinihydrokloridi; Doksorubisin Hidroklorür; Doxorubicin Hydrochloride Liposome; Doxorubicina, hidrocloruro de; Doxorubicine, Chlorhydrate de; Doxorubicin-hidroklorid; Doxorubicin-hydrochlorid; Doxorubicinhydrochlorid; Doxorubicinhydroklorid; Doxorubicini hydrochloridum; Hidrocloruro de doxorubicina; Liposomal Doxorubicin Hydrochloride; NSC-123127; Доксорубицина Гидрохлорид.
$C_{27}H_{29}NO_{11}.HCl$=580.0
CAS — 25316-40-9.
ATC — L01DB01.
ATC Vet — QL01DB01.
UNII — 82F2G78L4E.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Doxorubicin Hydrochloride). The hydrochloride of a substance isolated from certain strains of *Streptomyces coeruleorubidus* or *S. peucetius* or obtained by any other means. It contains between 98 and 102% of the hydrochloride, calculated on the anhydrous substance. An orange-red, hygroscopic, crystalline powder. Soluble in water; slightly soluble in methyl alcohol. A 0.5% solution in water has a pH of 4.0 to 5.5. Store in airtight containers.

USP 36: (Doxorubicin Hydrochloride). A red-orange, hygroscopic, crystalline or amorphous powder. It contains not less than 98% and not more than 102% of $C_{27}H_{29}NO_{11}$.HCl, calculated on the anhydrous, solvent-free basis. Soluble in water, in sodium chloride 0.9%, and in methyl alcohol; practically insoluble in chloroform, in ether, and in other organic solvents. A 0.5% solution in water has a pH of 4.0 to 5.5. Store in airtight containers. It may exist in an amorphous form, which should be stored at -25 degrees to -10 degrees.

Incompatibility. Admixture of doxorubicin hydrochloride with cefalotin sodium, dexamethasone, diazepam, or hydrocortisone sodium succinate is reported to result in immediate precipitation;[1] similarly precipitation has occurred when doxorubicin hydrochloride was mixed with furosemide or heparin sodium.[2] A mixture of fluorouracil or aminophylline with doxorubicin hydrochloride is reported to darken in colour from red to purple, indicating degradation of doxorubicin.[1] For mention of the compatibility of doxorubicin with paclitaxel, see p. 839.3.

Liposomal doxorubicin differs in its incompatibilities from conventional formulations: whereas the latter are reportedly incompatible with allopurinol, cefepime, and ganciclovir, there was no visual evidence of this with the liposomal formulation. However, it was incompatible with several solutions including amphotericin B, docetaxel, gallium nitrate, hydroxyzine hydrochloride, metoclopramide hydrochloride, miconazole, mitoxantrone hydrochloride, morphine sulfate and some other opioids, paclitaxel, sodium bicarbonate, and some antibacterials.[3]

1. Dorr RT. Incompatibilities with parenteral anticancer drugs. *Am J Intravenous Ther* 1979; 6: 42–52.
2. Cohen MH, *et al.* Drug precipitation within IV tubing: a potential hazard of chemotherapy administration. *Cancer Treat Rep* 1985; 69: 1325–6.
3. Trissel LA, *et al.* Compatibility of doxorubicin hydrochloride liposome injection with selected other drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1997; 54: 2708–13.

Stability. Although sensitive to light at low concentrations, doxorubicin is not subject to significant photodegradation at clinical concentrations and special precautions to protect solutions from light during use do not appear to be necessary.[1,2]

UK licensed product information for conventional formulations of doxorubicin hydrochloride state that, from a microbiological perspective, reconstituted solutions should be used immediately, and that storage time should not be longer than 24 hours at 2 degrees to 8 degrees, unless dilution has taken place under controlled and validated aseptic conditions. Chemical and physical stability varies between products:

- *Hameln, UK*: 48 hours at 2 degrees to 8 degrees and 24 hours at 25 degrees, in either sodium chloride 0.9% or glucose 5%, when prepared in glass containers and protected from light
- *Hospira, UK*: 21 days at 2 degrees to 8 degrees after reconstitution in either sodium chloride 0.9% or water for injection, in glass or polypropylene containers
- Doxorubicin 0.2% solution, *Medac, UK*: undiluted, 7 days at 15 degrees to 25 degrees, in glass containers and protected from light
- Doxorubicin powder for solution for injection, *Medac, UK*: 2 mg/mL in sodium chloride 0.9%—7 days at 15 degrees to 25 degrees and 14 days at 2 degrees to 8 degrees; 500 micrograms/mL in water for injection—24 hours below 25 degrees; 50 micrograms/mL to 5 mg/mL in sodium chloride 0.9%—7 days at 15 degrees to 25 degrees

Solutions of doxorubicin in sodium chloride solution 0.9% were reported[3] to be stable for 24 days when stored in PVC minibags at 25 degrees and for even longer if stored in minibags or polypropylene syringes at 4 degrees. Stability in solution seems to be partly related to pH, with doxorubicin becoming more stable[3-5] at acid pH. A fall in pH of the solution also significantly decreases the loss of doxorubicin by adsorption and precipitation onto the surface of a positively-charged in-line filter.[6]

Pegylated liposomal doxorubicin formulations (*Caelyx, UK* and *Doxil, USA*) should be diluted only with glucose 5%. If not used immediately, they may be stored for 24 hours at 2 degrees to 8 degrees.

Uses and Administration

Doxorubicin is an anthracycline antineoplastic antibiotic. It is thought to have multiple modes of action including intercalation of DNA leading to an inhibition of DNA and RNA synthesis, inhibition of topoisomerase II, free radical formation, and alterations in cell membranes. Doxorubicin is a cell-cycle non-specific agent. It also has antibacterial and immunosuppressant properties.

Doxorubicin is effective against many tumours as indicated by the cross-references given below. It is used, often with other antineoplastics, in the treatment of Hodgkin's disease, non-Hodgkin's lymphomas, acute leukaemias, bone and soft-tissue sarcomas, neuroblastoma, Wilms' tumour, and malignant neoplasms of the bladder, breast, lung, ovary, and stomach. It has also been used in other tumours. Liposomal doxorubicin is used in the management of Kaposi's sarcoma in patients with AIDS, for the treatment of metastatic breast and ovarian cancers, and with bortezomib for the treatment of multiple myeloma.

Doxorubicin hydrochloride is given by intravenous injection into a fast-running infusion of sodium chloride 0.9% or glucose 5% over 3 minutes or more. When used as a single agent, the dose of the *conventional* formulation is 60 to 75 mg/m² once every 3 or 4 weeks, or 1.2 to 2.4 mg/kg, once every 3 weeks. Alternatively, doses of 20 to 25 mg/m² have been given daily for 3 days every 3 or 4 weeks, although dividing the dose in this way may increase the incidence of mucositis. A regimen of 20 mg/m² as a single weekly dose may be used, and is reported to be associated with a lower incidence of cardiotoxicity.

Doses may need to be reduced if doxorubicin is given with other antineoplastics: a dose of 30 to 60 mg/m² every 3 weeks has been suggested. Obese patients may need a reduced dose, as may children, elderly patients, and patients with hepatic impairment (see below).

The total cumulative dose should not exceed 450 to 550 mg/m²; in patients who have received radiotherapy to the chest, or other cardiotoxic drugs, it may be advisable to further limit the total cumulative dose.

In the management of AIDS-related Kaposi's sarcoma *pegylated liposomal* doxorubicin hydrochloride is given in an intravenous dose of 20 mg/m² infused over 30 minutes once every 2 to 3 weeks. For the treatment of breast and ovarian cancers, the suggested dose of this liposomal formulation is 50 mg/m² infused over 1 hour once every 4 weeks. In the treatment of multiple myeloma, liposomal doxorubicin hydrochloride is given at a dose of 30 mg/m² on day 4 of the bortezomib regimen (see p. 752.1); it is given as an infusion over 1 hour immediately after the bortezomib infusion. In all these conditions, treatment should be continued for as long as the patient responds satisfactorily and tolerates treatment. The pegylated liposomal formulation should be diluted only with glucose 5%; generally, doses below 90 mg are diluted in 250 mL, and doses over 90 mg are diluted in 500 mL.

A *non-pegylated liposomal* formulation is also available and contains a doxorubicin citrate complex prepared with the aid of doxorubicin hydrochloride. It is given in the treatment of metastatic breast cancer in doses equivalent to doxorubicin hydrochloride 60 to 75 mg/m² every 3 weeks, with cyclophosphamide 600 mg/m². Doses are given by intravenous infusion over 1 hour, diluted in sodium chloride 0.9% or glucose 5% to a final concentration of 0.4 to 1.2 mg/mL doxorubicin hydrochloride.

Blood counts should be made routinely during treatment with doxorubicin (see also Bone-marrow Depression, p. 730.3) and cardiac function should be monitored at regular intervals for early signs of cardiotoxicity.

Doxorubicin hydrochloride has also been instilled into the bladder in the local treatment of malignant neoplasms. For this purpose 50 mL of a 1 mg/mL solution may be instilled into the bladder for about one hour; treatment may be given at weekly to monthly intervals. Doxorubicin has also been given intra-arterially.

Various novel formulations of doxorubicin have been investigated. Doxorubicin with carbon/iron carrier particles (MTC-DOX) is a magnetically targeted treatment, using an external magnet to keep the drug at the tumour site, that has been investigated for hepatocellular carcinoma. A polymer of doxorubicin and polyisohexylcyanoacrylate in nanoparticle form is under investigation for the treatment of hepatocellular carcinoma. Doxorubicin-eluting beads, for injection directly into the brain, and glutathione-pegylated liposomal doxorubicin are under investigation for the treatment of glioma. Hydrophilic microspheres reconstituted with a solution of doxorubicin hydrochloride have been used for chemoembolisation of hepatic tumours. Doxorubicin linked to a gonadotrophin-releasing hormone agonist is being investigated for the treatment of ovarian cancer.

Administration in children. Doxorubicin is used for paediatric malignancies; UK licensed product information for conventional formulations advises that adult dosage regimens (see above) may be suitable for children, but dose reductions may be needed, particularly in young children.

References.

1. Creutzig U, *et al.* Favourable outcome of patients with childhood acute promyelocytic leukaemia after treatment with reduced cumulative anthracycline doses. *Br J Haematol* 2010; 149: 399–409.

Administration in the elderly. UK licensed product information for doxorubicin in conventional formulations advises that the dose may need to be reduced in the elderly; in patients over 70 years of age, a total cumulative dose of 450 mg/m² has been recommended.

Administration in hepatic impairment. Doses of doxorubicin should be adjusted as follows in patients with liver dysfunction:

- serum-bilirubin concentrations of 12 to 30 micrograms/mL: half the normal dose
- serum-bilirubin greater than 30 micrograms/mL: quarter of the usual dose.

Slightly different schedules may apply to liposomal products but may vary between preparations.

Amyloidosis. For mention of the use of doxorubicin in patients with amyloidosis (and of the increased risk this may carry in cardiac amyloidosis) see p. 819.3.

Malignant neoplasms. Doxorubicin plays a major role in combination regimens for chemotherapy of solid malignancies; it is often employed for tumours of the breast and lung (see p. 702.1 and p. 710.2) and for Wilms' tumour and neuroblastoma or retinoblastoma in children (see p. 709.1, p. 716.2, and p. 717.2) and has been used for malignancies of the bladder (p. 700.2); for various gynaecological cancers including those of the endometrium, and ovary (see p. 704.3, and p. 711.2); for cancer of the liver, stomach, and pancreas (p. 709.3, p. 706.1, p. 712.1); and for neoplasms of prostate, and thymus (p. 712.3 and p. 715.3). It is also used in the treatment of sarcomas of bone and soft-tissue (see p. 717.3 and p. 718.2) and liposomal doxorubicin is used in patients with Kaposi's sarcoma (see p. 718.1).

In addition, doxorubicin is a component of the ABVD regimen used to treat Hodgkin's disease (see p. 696.1) and is part of the CHOP regimen used for non-Hodgkin's lymphoma (p. 696.3). Doxorubicin is also used in Burkitt's lymphoma (p. 697.3), mycosis fungoides (p. 698.3), and the lymphomas associated with AIDS (see p. 697.2). It has been employed in acute lymphoblastic leukaemia (p. 692.3), in chronic lymphocytic leukaemia as part of the CHOP regimen (though with uncertain benefit—see p. 693.3), and in multiple myeloma (p. 699.2).

Adverse Effects and Treatment

For general discussions see Antineoplastics, p. 726.1 and p. 730.2.

Doxorubicin and other anthracyclines cause pronounced bone-marrow depression, which may be dose-limiting. White cell count reaches a nadir 10 to 15 days after a dose and usually recovers by about 21 days.

The anthracyclines may produce cardiotoxicity, both as an acute, usually transient disturbance of cardiac function marked by ECG abnormalities and, sometimes, arrhythmias; and as a delayed, sometimes fatal, irreversible congestive heart failure, which may occur suddenly. Severe cardiotoxicity is more likely in adults given total cumulative doses of doxorubicin greater than 450 to 550 mg/m^2, and may occur months or even years after use. However, congestive heart failure has been reported even with doses of 240 to 300 mg/m^2. Cardiotoxicity may occur at lower cumulative doses in those previously treated with other anthracyclines or antineoplastics, or with radiotherapy to the chest.

Gastrointestinal disturbances include moderate or sometimes severe nausea and vomiting; mucositis (stomatitis and oesophagitis) may progress to ulceration. Alopecia, usually reversible, occurs in the majority of patients. The urine may be coloured red. Occasional hypersensitivity reactions may occur. Hyperuricaemia may occur due to tumour lysis syndrome. Other adverse effects include conjunctivitis, lachrymation, urticarial rashes, hyperpigmentation of the oral mucosa and/or nails, onycholysis, drowsiness, renal or hepatic damage, and transient increases in liver enzymes.

Doxorubicin and other anthracyclines are very irritant and thrombophlebitis can occur; extravasation is serious and may produce extensive local necrosis and ulceration. If extravasation occurs, the injection should be immediately stopped and restarted in another vein; the appropriate management of such events is contentious (see p. 731.3) but may include ice packs, tissue irrigation, corticosteroids, and if necessary, surgery. Local erythematous streaking along the vein and facial flushing may be indicative of too rapid an injection. Intravesical instillation can cause bladder and urethral irritation, haematuria, and haemorrhagic cystitis.

Combination therapy including doxorubicin has rarely been associated with secondary acute myeloid leukaemia (see also Carcinogenicity, p. 726.2). *Animal* data have shown doxorubicin to be embryotoxic, teratogenic, and mutagenic. Doxorubicin may cause infertility.

Formulations of liposomal doxorubicin appear to be associated with a reduced potential for local tissue necrosis, and possibly a reduced incidence of cardiotoxicity. Conversely, palmar-plantar erythrodysesthesia (p. 730.1) appears to be more common, and may be dose-limiting. In addition, an acute anaphylactoid-like reaction may be seen on initial infusion, but this generally resolves on slowing or temporarily stopping the infusion.

Effects on the heart. Cardiotoxicity has been a major factor in limiting the use of the anthracyclines, doxorubicin and daunorubicin. Anthracycline derivatives have been developed with the aim of reducing the inherent cardiotoxicity of this class of compounds, including aclarubicin (p. 735.2), epirubicin (p. 787.1), idarubicin (p. 805.2), mitoxantrone (p. 833.1), and pixantrone (p. 847.2). However, although this strategy has met with some success, all these compounds exhibit some degree of cardiotoxicity.

Toxicity is essentially of 2 kinds: acute, usually reversible ECG changes, including a wide range of arrhythmias, and a delayed, usually irreversible dose-related cardiomyopathy, resulting in congestive heart failure.[1-3] The latter may be further subdivided into early-onset, occurring up to about a year afterwards, and late-onset toxicity occurring years after treatment,[2,4,5] which may be fatal. Late cardiac failure may occur up to 18 years after anthracycline therapy.[2,6,7] The 1-year mortality rate for patients with doxorubicin-induced New York Heart Association (NYHA) class III to IV heart failure is 40%, and the 2-year mortality rate is 60%.[8]

- The single most important determinant of cardiotoxicity appears to be the *total cumulative dose*, with the risk of toxicity becoming ever greater at total cumulative doxorubicin doses of 550 mg/m^2 or more.[8-14] However, patients vary widely in sensitivity,[2,10,13] and these values represent relatively arbitrary choices on a continuum of risk: there is no single safe dose.[1,5,13] Even at doses that produce no symptoms, subclinical myocardial damage may occur, and in children this may result in diminished cardiac reserve and heart disease in later life.[1,15,16]
- The *dosage schedule* also appears to be important; relatively high single doses on an infrequent schedule appear to be more cardiotoxic than lower, more closely spaced doses, suggesting that cardiotoxicity is related to peak blood concentrations of doxorubicin.[10]
- Cardiotoxicity is also reported to be more likely in *children and elderly* patients, and in those who have received prior *radiotherapy* to the chest.[3,4,9,10,12] Previous *cardiovascular disease* also increases the risk.[1,2,9] *Females* appear to be at greater risk than males.[8,17] *Other risk factors* include hypertension, liver disease, whole body hyperthermia, African American ancestry, and trisomy-21.[3,5,9]
- Use with cyclophosphamide, trastuzumab, or *other antineoplastics* with cardiotoxic potential may increase the likelihood of cardiomyopathy.[9,10]

Prevention. Much effort has gone into ways of predicting and preventing anthracycline-induced cardiotoxicity. Although ECG changes are commonly monitored, most of the changes are not predictive of cardiomyopathy and severe cardiotoxicity can occur without ECG changes. However, a persistent reduction in the voltage of the QRS wave is generally indicative of the need to perform further tests. Non-invasive cardiac *monitoring*, by means of echocardiography or radionuclide angiography, is useful in predicting the development of cardiomyopathy, but may give normal results until damage is quite advanced; sensitivity may be improved with exercise stress tests.[1-3] Measurement of left ventricular ejection fraction (LVEF) is frequently used for baseline evaluation, and at regular intervals thereafter.[9,18] Indium-111 antimyosin imaging detects abnormal cardiac uptake of indium-111 antimyosin, which can be seen even in the absence of any change in LVEF, and can be predictive of an impending fall in LVEF; this technique is highly sensitive but is time-consuming and not widely available.[10] Endomyocardial biopsy is the most sensitive indicator of cardiomyopathy, but it is invasive and again not widely available.[9,10,18] The Childrens Cancer Study Group[19] has issued guidelines for monitoring using ECG, echocardiography, and radionuclide angiocardiography in patients receiving anthracyclines. The role of such techniques in predicting late-onset cardiotoxicity remains to be clarified,[2] and there is disagreement on the best manner of monitoring anthracycline-induced cardiotoxicity. This reflects conflicting data and the scarcity of well-designed studies, but the Childrens Cancer Study Group guideline, or one that incorporates a baseline cardiac evaluation with follow-up as the anthracycline dose increases, has been advocated as a reasonable approach to monitoring anthracycline-induced cardiotoxicity.[13]

There is some preliminary evidence to suggest that concentrations of cardiac troponins and natriuretic peptides could be used as predictive markers of myocardial damage.[9,10,18,20,21]

Dexrazoxane (p. 1548.1) has shown some protective effect against the cardiotoxicity of doxorubicin and other anthracyclines, and is used to reduce cardiomyopathy in women receiving doxorubicin for metastatic breast cancer.

Alteration of the dosage schedule to weekly rather than three-weekly dosage, or the use of continuous infusion, have been advocated as ways of reducing doxorubicin cardiotoxicity; an anthracycline infusion time of six hours or longer has been shown to reduce the risk of heart failure and seemed to reduce the risk of subclinical cardiac damage.[22] Anthracyclines formulated in *liposomes* have also been used to reduce the risk.[2,5,8-11,13,18] The cardiac safety of liposomal daunorubicin has not been established, but non-pegylated liposomal doxorubicin has better cardiac safety than conventional doxorubicin,[11,21,23] while pegylated liposomal doxorubicin has a significanly reduced risk of cardiotoxicity.[11,21] (However, haematological and mucocutaneous toxicity, and palmar-plantar erythrodysesthesia are greater with liposomal formulations and may limit their use.[24])

Treatment. Management is essentially that of standard cardiac failure (p. 1262.3), with diuretics, beta blockers, ACE inhibitors, and ultimately, cardiac transplantation (p. 1938.2).[3,8,9,21]

Effects on the liver. Hepatitis and non-specific hepatocellular damage has been reported in patients receiving doxorubicin as part of combination therapy.[1] A characteristic hepatotoxicity can also be produced by the combination of radiotherapy with doxorubicin.[2]

Effects on the skin and nails. Hyperpigmentation has occurred in patients given daunorubicin, doxorubicin, or idarubicin.[1-6] Reports described pigmentation of the skin and transverse hyperpigmented bands of the nails. Effects on the skin resolved over several weeks, and bands on the nails moved with normal nail growth. Dark-skinned patients appear to be more susceptible to this adverse effect. Biopsy has found an increase in melanin granules in the affected tissues. An unusual blue-grey pigmentation of the face was reported in a patient given doxorubicin.[7]

There have been reports of subacute cutaneous lupus erythematosus after treatment with doxorubicin plus cyclophosphamide for breast cancer.[8,9] A change of chemotherapy regimen and corticosteroids successfully treated some patients, but lesions continued to flare after each cycle in one patient with Sjögren's syndrome despite a change to paclitaxel and trastuzumab; symptoms eventually resolved when chemotherapy was complete.[9] In another case[8] skin lesions kept developing even after the chemotherapy regimen was complete, and although oral corticosteroids improved the lesions, they reappeared when the corticosteroids were withdrawn; complete resolution was seen with thalidomide.

Palmar-plantar erythrodysesthesia syndrome. Palmar-plantar erythrodysesthesia syndrome (p. 730.1) is associated with the use of liposomal doxorubicin, and recommendations have been made for its management.[1] The most effective way of preventing the syndrome was to maintain doses at not more than 10 mg/m² weekly (typically as a single infusion of 40 mg/m² every 4 weeks). At such doses, the syndrome, if it occurred was typically mild and easily managed. Dose-intensity modification was also thought likely to be beneficial in managing the syndrome if it developed, although evidence to support this was lacking.

UK licensed product information states that pyridoxine (in daily doses of 50 to 150 mg) and corticosteroids have been used for the prophylaxis and treatment of this condition although clinical data for their efficacy are lacking; other strategies include keeping the hands and feet cool with cold water soaks or baths, avoiding heat or hot water, and not wearing socks, gloves, or tight-fitting shoes.

Precautions

For a general discussion see Antineoplastics, p. 732.2.

Doxorubicin and other anthracyclines are generally contra-indicated in patients with heart disease. The total cumulative dose should be limited, and cardiac function, including left ventricular ejection fraction, should be assessed before and monitored during treatment (see Effects on the Heart, p. 784.1). Blood counts should be monitored and doses should not be repeated while there is bone-marrow depression or ulceration of the mouth. Doxorubicin should be given with great care in reduced doses to patients with hepatic impairment; dosage reduction may also be necessary in children and the elderly. Extravasation results in severe tissue damage and doxorubicin and other anthracyclines should not be given by intramuscular or subcutaneous injection. The adverse effects of irradiation may be enhanced by doxorubicin and skin reactions previously induced by radiotherapy may recur; the total cumulative dose should be reduced to no more than 400 mg/m² in patients who have received radiotherapy to the chest or heart. Different liposomal formulations may not be interchangeable with conventional formulations, or with each other.

Breast feeding. Doxorubicin and its metabolites have been detected in breast milk.[1] The American Academy of Pediatrics considers[2] that doxorubicin is concentrated in breast milk, that it may possibly cause immune suppression in the infant, has unknown effects on growth, and an association with carcinogenesis.

1. Egan PC, *et al.* Doxorubicin and cisplatin excretion into human milk. *Cancer Treat Rep* 1985; **69**: 1387–9.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108**: 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 29/06/04)

Handling and disposal. Doxorubicin hydrochloride is irritant; avoid contact with skin and mucous membranes.

A method for the destruction of doxorubicin or daunorubicin *wastes* using sulfuric acid and potassium permanganate.[1] Residues produced by degradation of daunorubicin by this method showed no mutagenicity *in vitro*; some mutagenicity was seen with high concentrations of residues from doxorubicin.

Urine and faeces produced for up to 7 days after a dose of doxorubicin should be handled wearing protective clothing.[2]

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235**: 289–91.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies doxorubicin as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Pregnancy. Although doxorubicin has been reported to be undetectable in amniotic fluid[1,2] it has been found in fetal tissue (liver, kidney, and lungs) at concentrations several times those in maternal plasma,[2] indicating that it does cross the placenta. The effect of anthracyclines on the outcome of 160 pregnancies has been analysed.[3] Most women had received combination chemotherapy that included doxorubicin or daunorubicin, for haematological malignancies or breast cancer. Most outcomes (73%) were normal. There were 5 malformations, most often associated with regimens that also included antimetabolites or alkylating agents; the malformations were highly variable. Fetal toxicity was associated with chemotherapy use for solid tumours during the first trimester, and the risk of severe fetal toxicity was significantly increased with doxorubicin doses above 70 mg/m² per cycle. Fetal cardiotoxicity occurred in 2 cases and was associated with anthracycline use during the second and third trimesters. It has been suggested that the use of epirubicin may reduce the risk of fetal myocardiopathy, but a brief review of the literature[4] suggested that its toxicity profile in pregnancy was very similar to that of doxorubicin. Fetal death was more frequent in women with acute leukaemia; it was associated with disease progression and the authors recommended that chemotherapy should not be postponed.

For a report of a healthy infant born to a woman treated with a doxorubicin-containing chemotherapy regimen, see Pregnancy, under Teniposide, p. 867.2.

UK licensed product information for doxorubicin cautions against use in pregnancy. Recommendations vary, but some advise that men and women both take effective contraceptive measures during treatment and for 3 to 6 months after therapy.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. The total cumulative dose of doxorubicin should be reduced in patients who have received other cardiotoxic drugs such as daunorubicin or cyclophosphamide. Doxorubicin is reported to inhibit the intracellular activation of stavudine and hence its antiviral effect.

Antibacterials. Hypersensitivity reactions to doxorubicin or daunorubicin have been reported in 2 patients with recent exposure to *clindamycin*, one of whom had exhibited hypersensitivity to that antibiotic.[1] The possibility of cross-sensitivity between anthracyclines and clindamycin should be considered.

1. Arena FP, Sherlock S. Doxorubicin hypersensitivity and clindamycin. *Ann Intern Med* 1990; **112**: 150.

Antineoplastics. Giving doxorubicin with or after drugs, such as *streptozocin*[1] or *methotrexate*,[2] that can impair hepatic function, has resulted in increased doxorubicin toxicity, possibly due to reduced hepatic clearance. A high incidence of cardiotoxicity (manifest as congestive heart failure) has been reported in patients given doxorubicin with *paclitaxel* (which also has cardiotoxic effects).[3] Any interaction may be schedule dependent.[4] Similarly an increased incidence of cardiotoxicity has been seen when *trastuzumab* was given with or after anthracyclines (see Effects on the Heart under Trastuzumab, p. 876.3).

Valspodar inhibits P-glycoprotein, and a pharmacokinetic study[5] found that it decreased clearance of doxorubicin and prolonged the terminal half-life, increasing exposure to doxorubicin and myelosuppressive effects. The authors suggested that the dose of doxorubicin might need to be reduced by about 60%.

Sorafenib may increase systemic exposure to doxorubicin.

For a suggestion that doxorubicin might enhance the hepatotoxicity of *mercaptopurine*, see under Daunorubicin Hydrochloride, p. 779.3.

For a report of an increased incidence of febrile neutropenia and gastrointestinal complications when doxorubicin is used with *docetaxel*, see Antineoplastics, under Docetaxel, p. 782.2.

In a pharmacokinetic study, both paclitaxel and docetaxel increased exposure to liposomal doxorubicin, although the effect was less pronounced with docetaxel.[6]

For mention of changes in exposure to pegylated or liposomal doxorubicin and *vinflunine* when these drugs were used together, see Interactions, under Vinflunine, p. 885.2.

General anaesthetics. For reference to QT-interval prolongation during anaesthesia with *isoflurane* in women who had received anthracycline-based chemotherapy for breast cancer, see p. 1907.3.

Immunosuppressants. Increased plasma-doxorubicin concentrations and myelotoxicity have occurred when *ciclosporin* was used to modulate tumour resistance.[1] Severe neurological toxicity occurred in another patient given doxorubicin after long-term ciclosporin therapy.[2] It has been suggested that the use of ciclosporin or its analogues (see Antineoplastics, above for the effect of valspodar) to modulate doxorubicin resistance should be undertaken with caution.[3]

1. Rushing DA, *et al.* The effects of cyclosporine on the pharmacokinetics of doxorubicin in patients with small cell lung cancer. *Cancer* 1994; **74**: 834–41.

3. Beck WT, Kuttesch JF. Neurological symptoms associated with cyclosporin plus doxorubicin. *Lancet* 1992; **340**: 496.

Thalidomide. In a comparison of two treatment regimens for multiple myeloma (thalidomide, dexamethasone, cisplatin, cyclophosphamide, and etoposide, with or without doxorubicin), there was an increased risk of deep-vein thrombosis in those patients who received the combination that included doxorubicin.[1] The authors cited a previous study[2] in which the addition of thalidomide to an antineoplastic regimen increased the risk of deep-vein thrombosis, and concluded that patients with multiple myeloma treated with the combination of doxorubicin and thalidomide are at increased risk.

1. Zangari M, *et al.* Thrombogenic activity of doxorubicin in myeloma patients receiving thalidomide: implications for therapy. *Blood* 2002; **100**: 1168–71.
2. Zangari M, *et al.* Increased risk of deep-vein thrombosis in patients with multiple myeloma receiving thalidomide and chemotherapy. *Blood* 2001; **98**: 1614–15.

Pharmacokinetics

After intravenous injection, doxorubicin is rapidly cleared from the blood, and distributed into tissues including lungs, liver, heart, spleen, and kidneys. It undergoes rapid metabolism in the liver to metabolites including the active metabolite doxorubicinol (adriamycinol). About 40 to 50% of a dose is stated to be excreted in bile within 7 days, of which about half is as unchanged drug. Only about 5% of a dose is excreted in urine within 5 days. It does not cross the blood-brain barrier but may cross the placenta and is distributed into breast milk. The disappearance of doxorubicin from the blood is triphasic: mean half-lives are 12 minutes, 3.3 hours and about 30 hours.

The pharmacokinetics of *liposomal* formulations are somewhat different from the conventional drug. The use of macrogols in the surface layer of the liposomes (pegylation) reduces removal of liposomes by macrophages. This results in prolonged circulation in the plasma, with relatively little tissue distribution, but tumour neovasculature is reported to permit penetration of liposomes into tumour tissue. Pharmacokinetics are reported to be biphasic with mean half-lives of 5 hours and 55 to 75 hours respectively. A non-pegylated liposomal formulation also exists and is reported to produce higher peak plasma concentrations of total doxorubicin than conventional formulations, but lower free (not liposome-encapsulated) concentrations. Clearance is reduced, and peak plasma concentrations of doxorubicinol delayed.

Edrecolomab *(USAN, rINN)*

17-1A Antibody; C1; Édrécolomab; Edrecolomabum; Monoclonal Antibody 17-1A; Эдреколомаб.
Immunoglobulin G2a (mouse monoclonal 17-1A γ-chain anti-human colon cancer tumor-associated antigen), disulfide with mouse monoclonal 17-1A light chain, dimer.
CAS — 156586-89-9.
ATC — L01XC01.
ATC Vet — QL01XC01.
UNII — 0KYI9U9FSJ.

Profile

Edrecolomab is a monoclonal antibody of murine origin directed at epithelial cell surface glycoproteins that has been used as adjuvant therapy after surgery in patients with colorectal cancer (p. 706.3), although reports of improved survival do not seem to have been borne out.

Efaproxiral *(USAN, rINN)* ⊗

Efaproxiral; Efaproxiralum; RSR-13; Эфапроксирал.
2-(4-[2-[(3,5-Dimethylphenyl)amino]-2-oxoethyl]phenoxy)-2-methyl propanoic acid.
$C_{20}H_{23}NO_4$=341.4
CAS — 131179-95-8.
ATC — L01XD06.
ATC Vet — QL01XD06.
UNII — J81E81G364.

NOTE. The names Efaproxyn and Revaproxyn have been used as trade marks for efaproxiral.

Efaproxiral Sodium *(USAN, rINNM)* ⊗

Efaproxiral sódico; Efaproxiral Sodique; Natrii Efaproxiralum; Натрий Эфапроксирал.
$C_{20}H_{22}NNaO_4$=363.4
CAS — 170787-99-2.
ATC — L01XD06.
ATC Vet — QL01XD06.
UNII — 3L83QP52XI.

Profile

Efaproxiral is an allosteric modifier of haemoglobin that enhances the diffusion of oxygen to hypoxic tumour tissue, making it more sensitive to radiotherapy. It has been investigated in the treatment of brain metastases from solid tumours.

Elacytarabine *(USAN, rINN)*

CP-4055; Elacitarabina; Élacytarabine; Elacytarabinum; Элацитарабин.
4-Amino-1-{5-*O*-[(9*E*)-octadec-9-enoyl]-β-D-arabinofuranosyl}pyrimidin-2(1*H*)-one.
$C_{27}H_{45}N_3O_6$=507.7
CAS — 188181-42-2.
UNII — TA7WJG93AR.

NOTE. The name Elacyt has been used as a trade mark for elacytarabine.

Profile

Elacytarabine is a lipid-conjugated derivative of cytarabine (p. 774.1) that is under investigation for the treatment of acute myeloid leukaemia.

Elesclomol *(USAN, rINN)*

Élesclomol; Elesclomolum; STA-4783; Элескломол.
Propanedioic acid, bis[2-methyl-2-(phenylthioxomethyl) hydrazide]; 1-*N*′-benzenecarbothioyl-3-(2-benzenecarbothioyl-2-methylhydrazinyl)-*N*′-methyloxopropanehydrazide.
$C_{19}H_{20}N_4O_2S_2$=400.5
CAS — 488832-69-5.
UNII — 6UK191M53P.

Profile

Elesclomol is an oxidative stress inducer that is under investigation as a treatment for metastatic melanoma.

References.

Endostatin

rhEndostatin (recombinant human endostatin); YH-16 (recombinant human endostatin).

NOTE. The name Endu has been used as a trade mark for recombinant human endostatin.

Profile

Endostatin is an endogenous human protein fragment of collagen type XVIII that has anti-angiogenic properties. A recombinant human form has been used for non-small cell lung cancer and is under investigation for the treatment of other malignancies such as metastatic melanoma and gastrointestinal tumours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***China***: Endostar (恩度).

Enocitabine *(rINN)*

Behenoyl Cytarabine; Behenoylcytosine Arabinoside; BH AC; Enocitabina; Énocitabine; Enocitabinum; NSC-239136; Эноцитабин.
N-(1-β-D-Arabinofuranosyl-1,2-dihydro-2-oxo-4-pyrimidinyl) docosanamide.
$C_{31}H_{55}N_3O_6$=565.8
CAS — 55726-47-1.
UNII — 9YVR68W306.

Profile

Enocitabine is an antineoplastic that is converted in the body to cytarabine (p. 774.1). It has been used similarly in the treatment of acute leukaemias.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Jpn***: Sunrabin.

Entinostat *(USAN, rINN)*

Entinostatum; MS-27-275; MS-275; SNDX-275; Энтиностат.
Pyridin-3-ylmethyl ([4-[[2-aminophenyl)carbamoyl]phenyl} methyl)carbamate.
$C_{21}H_{20}N_4O_3$=376.4
CAS — 209783-80-2.
UNII — 1ZNY4FKK9H.

Profile

Entinostat is an orally active histone deacetylase inhibitor that is under investigation for the treatment of Hodgkin's disease.

For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.

References.

Enzalutamide *(USAN, pINN)*

Enzalutamida; Enzalutamidum; MDV-3100; Энзалутамид.
4-{3-[4-Cyano-3-(trifluoromethyl)phenyl]-5,5-dimethyl-4-oxo-2-sulfanylideneimidazolidin-1-yl}-2-fluoro-*N*-methylbenzamide.
$C_{21}H_{16}F_4N_4O_2S$=464.4
CAS — 915087-33-1.
UNII — 93T0T9GKNU.

Uses and Administration

Enzalutamide is a nonsteroidal anti-androgen that competitively inhibits binding to androgen receptors. It is used in the treatment of metastatic castration-resistant prostate cancer (p. 712.3) in patients who have previously been treated with docetaxel. The usual oral dose is 160 mg once daily. Treatment should be withheld if severe toxicity occurs and then restarted after 1 week, or when symptoms have improved, at either the usual dose or a reduced dose (80 or 120 mg once daily) if warranted.

Use with strong cytochrome P450 isoenzyme CYP2C8 inhibitors should be avoided. If a strong CYP2C8 inhibitor must be used, the dose of enzalutamide should be reduced to 80 mg once daily. The original dose may be resumed after the inhibitor has been stopped.

References.

3. Pal SK, *et al.* Enzalutamide for the treatment of prostate cancer. *Expert Opin Pharmacother* 2013; 14: 679–85.

Adverse Effects and Precautions

The most commonly reported adverse effects with enzalutamide are asthenia or fatigue, muscular weakness, arthralgia, musculoskeletal and back pain, diarrhoea, peripheral oedema, headache, flushing, hypertension, respiratory-tract infections, dizziness, insomnia, anxiety, paraesthesia, and haematuria. Seizures have occurred in patients taking enzalutamide and it should be used with caution in those with predisposing factors.

Interactions

Enzalutamide is metabolised by the cytochrome P450 isoenzymes CYP2C8 and CYP3A4, and use with inhibitors or inducers of these isoenzymes may affect exposure to

enzalutamide. The strong CYP2C8 inhibitor gemfibrozil increased exposure to enzalutamide and its active metabolite by 2.2-fold; consequently, the use of strong CYP2C8 inhibitors with enzalutamide should be avoided, or the dose of enzalutamide reduced if use together is necessary (see Uses and Administration, p. 786.3). The increase in exposure to enzalutamide and its active metabolite was less prominent (1.3-fold) with the strong CYP3A4 inhibitor itraconazole. The effects of strong or moderate inducers of CYP2C8 or CYP3A4 on enzalutamide have not been evaluated and licensed product information recommends that their use together should be avoided.

Enzalutamide itself is a strong inducer of CYP3A4 and a moderate inducer of CYP2C9 and CYP2C19. The exposure of drugs that are substrates of these isoenzymes may be decreased when given with enzalutamide; use with enzalutamide should be avoided for those that also have a narrow therapeutic index.

Pharmacokinetics

Peak plasma concentrations of enzalutamide occur about 1 hour after an oral dose and with daily dosing steady state is reached after 28 days. Enzalutamide is about 97% bound to plasma proteins, mainly albumin; the major active metabolite *N*-desmethyl enzalutamide is about 95% bound to plasma proteins. Enzalutamide is metabolised in the liver by the cytochrome P450 isoenzymes CYP3A4 and CYP2C8, the latter of which is mainly responsible for the formation of the active metabolite. Over 70% of a dose is excreted as metabolites in the urine, and 14% in the faeces. The mean terminal half-life after a single dose is about 6 days for enzalutamide and about 8 days for *N*-desmethyl enzalutamide.

$C_{27}H_{29}NO_{11}$,HCl=580.0

CAS — 56420-45-2 (epirubicin); 56390-09-1 (epirubicin hydrochloride).

ATC — L01DB03.

ATC Vet — QL01DB03.

UNII — 22966TX7J5.

Pharmacopoeias. In *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Epirubicin Hydrochloride). A substance obtained by chemical transformation of a substance produced by certain strains of *Streptomyces peucetius*. An orange-red powder. Soluble in water and in methyl alcohol; slightly soluble in dehydrated alcohol; practically insoluble in acetone. A 0.5% solution in water has a pH of 4.0 to 5.5. Store at 2 degrees to 8 degrees in airtight containers. Protect from light.

USP 36: (Epirubicin Hydrochloride). An orange-red powder. Soluble in water and methyl alcohol; slightly soluble in anhydrous alcohol; practically insoluble in acetone. Store in airtight containers at a temperature of 2 degrees to 8 degrees. Protect from light.

Incompatibility. Licensed product information states that epirubicin hydrochloride is incompatible with heparin or fluorouracil, resulting in precipitation, and that it is hydrolysed in alkaline solutions.

Stability. Epirubicin was not subject to significant photodegradation at clinical concentrations,[1,2] and special precautions to protect solutions from light during use do not appear to be necessary. However, photodegradation may be significant at lower concentrations (below 500 micrograms/mL).[1]

1. Wood *MJ, et al.* Photodegradation of doxorubicin, daunorubicin and epirubicin measured by high-performance liquid chromatography. *J Clin Pharm Ther* 1990; 15: 291–300.
2. Pujol M, *et al.* Stability study of epirubicin in NaCl 0.9% injection. *Ann Pharmacother* 1997; 31: 992–5.

Uses and Administration

Epirubicin is an anthracycline antibiotic with antineoplastic actions similar to those of doxorubicin (p. 783.2). It is used, alone or with other antineoplastics, in acute leukaemias, lymphomas, multiple myeloma, and in solid tumours including Wilms' tumour (p. 709.1), cancer of the bladder (p. 700.2), breast (p. 702.1), and stomach (p. 706.1).

Epirubicin hydrochloride is given by intravenous injection of a solution in sodium chloride 0.9% or Water for Injections into a fast-running infusion of sodium chloride 0.9% or glucose 5% over 3 to 5 minutes, or by infusion over up to 30 minutes. It is given as a single agent in usual doses of 60 to 90 mg/m² as a single dose every 3 weeks; this dose may be divided over 2 or 3 days if desired. A regimen of 20 to 30 mg/m² once a week has been tried in palliative care or in those who do not tolerate the higher dose. High-dose regimens, of 120 mg/m² or more every 3 weeks, or 45 mg/m² for 3 consecutive days every 3 weeks have been used.

Doses may need to be reduced if epirubicin is given with other antineoplastics. Doses should also be reduced in patients with liver impairment (see below) and in those whose bone-marrow function is impaired by age or previous chemotherapy or radiotherapy.

A total cumulative dose of 0.9 to 1 g/m² should not generally be exceeded, because of the risk of cardiotoxicity.

Epirubicin has also been given by intravesical instillation in the local treatment of bladder cancer. Instillation of 50 mg weekly as a 0.1% solution (in sodium chloride 0.9% or sterile water) for 8 weeks has been suggested, reduced to 30 mg in 50 mL weekly if chemical cystitis develops; for carcinoma *in-situ*, the dose may be increased, if tolerated, to 80 mg in 50 mL weekly. For the prophylaxis of recurrence in patients who have undergone transurethral resection, 50 mg weekly for 4 weeks, followed by 50 mg instilled once a month for 11 months is the suggested regimen. The solution should be retained in the bladder for 1 hour.

Blood counts should be made routinely during treatment with epirubicin (see also Bone-marrow Depression, p. 730.3) and cardiac function should be carefully monitored. Liver function should be assessed before and if possible during therapy.

Administration in hepatic impairment. Doses of epirubicin should be halved in patients with moderate liver dysfunction (serum bilirubin concentrations of 12 to 30 micrograms/mL), while those with severe liver impairment (serum bilirubin greater than 30 micrograms/mL) should be given a quarter of the usual dose.

Amyloidosis. For reference to a regimen including epirubicin used to control disease in a patient with amyloidosis, see p. 819.3.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin, p. 784.1. Cardiotoxicity and myelotoxicity may be less than with doxorubicin. Cardiotoxicity is more likely when the total cumulative dose exceeds 0.9 to 1 g/m².

Effects on the heart. For further discussion of the cardiotoxicity of anthracyclines, see under Adverse Effects of Doxorubicin, p. 784.1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies epirubicin as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 29/09/11)

Interactions

As for Doxorubicin, p. 785.2.

Antineoplastics. Increased exposure to epirubicin, and a consequent increase in myelotoxicity, has been reported in patients given epirubicin immediately after *paclitaxel*, compared with patients who received epirubicin before paclitaxel.[1] Similar interactions have been seen when paclitaxel was given before other anthracyclines.[2] These and other studies[3,4] have suggested that paclitaxel given in this way is associated with a reduced conversion of epirubicin to the less myelotoxic metabolite, epirubicinol, although the interaction is complex, and may involve both disposition and pharmacodynamics.

2. Danesi R, *et al.* Pharmacokinetic optimisation of treatment schedules for anthracyclines and paclitaxel in patients with cancer. *Clin Pharmacokinet* 1999; 37: 195–211.
3. Grasselli G, *et al.* Clinical and pharmacologic study of the epirubicin and paclitaxel combination in women with metastatic breast cancer. *J Clin Oncol* 2001; 19: 2222–31.
4. Danesi R, *et al.* Pharmacokinetics and pharmacodynamics of combination chemotherapy with paclitaxel and epirubicin in breast cancer patients. *Br J Clin Pharmacol* 2002; 53: 508–18.

Cimetidine. Cimetidine increased the formation of the active metabolite of epirubicin in a study in 8 patients; there was also a substantial increase in systemic exposure to unchanged epirubicin.[1] The mechanisms and potential clinical significance of the interaction were unclear.

1. Murray LS, *et al.* The effect of cimetidine on the pharmacokinetics of epirubicin in patients with advanced breast cancer: preliminary evidence of a potentially common drug interaction. *Clin Oncol* 1998; 10: 35–8.

Pharmacokinetics

After intravenous doses epirubicin is rapidly and extensively distributed into body tissues, and undergoes metabolism in the liver, with the formation of epirubicinol (13-hydroxyepirubicin) and appreciable amounts of glucuronide derivatives. Epirubicin is eliminated mainly in bile, with a terminal plasma elimination half-life of about 30 to 40 hours. About 10% of a dose is recovered in urine within 48 hours. Epirubicin does not cross the blood-brain barrier.

Epratuzumab *(rINN)*

AMG-412; Epratuzumab; Epratuzumabum; Эпратузумаб. Immunoglobulin G (human-mouse monoclonal IMMU-hLL2 γ-chain anti-human antigen CD22), disulfide with human-mouse monoclonal IMMU-hLL2 κ-chain, dimer.
CAS — 205923-57-5.
UNII — 3062P60MH9.

Profile

Epratuzumab is a humanised anti-CD22 monoclonal antibody under investigation, alone or conjugated with yttrium-90 (p. 2230.1), for the treatment of non-Hodgkin's lymphoma. It is also under investigation for the treatment of moderate to severe SLE.

ATC Vet — QL01XX41.
UNII — AV9U0660CW.

Uses and Administration

Eribulin is a synthetic analogue of halichondrin B, a substance isolated from marine sponges. It inhibits tubulin polymerisation and is used in the treatment of refractory locally advanced or metastatic breast cancer (p. 702.1) in patients previously treated with at least 2 chemotherapy regimens, including an anthracycline and a taxane. Eribulin is given as the mesilate, although in some countries the dose is expressed as the base. The recommended dose is eribulin mesilate 1.4 mg/m² (equivalent to eribulin 1.23 mg/m²) given by intravenous injection over 2 to 5 minutes, on days 1 and 8 of a 21-day cycle. The start of treatment should be delayed in patients with absolute neutrophil counts less than 1000 cells/mm³, or platelet counts less than 75 000 cells/mm³, or grade 3 or 4 non-haematological toxicity, until recovery occurs, and similar precautions apply in subsequent cycles once treatment has started. More severe toxicity may also require dose reduction (see Administration in Subsequent Cycles, below). For doses in hepatic or renal impairment, see below.

Eribulin is also under investigation for the treatment of various other malignancies including non-small cell lung cancer, prostate cancer, and sarcoma.

References.

1. Twelves C, *et al.* Phase III trials of eribulin mesylate (E7389) in extensively pretreated patients with locally recurrent or metastatic breast cancer. *Clin Breast Cancer* 2010; 10: 160–3.
2. Cigler T, Vahdat LT. Eribulin mesylate for the treatment of breast cancer. *Expert Opin Pharmacother* 2010; 11: 1587–93.
3. Cortes J, *et al.* EMBRACE (Eisai Metastatic Breast Cancer Study Assessing Physician's Choice Versus E7389) investigators. Eribulin monotherapy versus treatment of physician's choice in patients with metastatic breast cancer (EMBRACE): a phase 3 open-label randomised study. *Lancet* 2011; 377: 914–23.

Administration in hepatic impairment. Exposure to eribulin is increased by hepatic impairment and lower doses are recommended. The intravenous dose of eribulin mesilate for mild impairment (Child-Pugh class A) is 1.1 mg/m² (equivalent to eribulin 970 micrograms/m²), and for moderate impairment (Child-Pugh class B) 700 micrograms/m² (equivalent to eribulin 620 micrograms/m²), given on days 1 and 8 of a 21-day cycle. Eribulin has not been studied in those with severe hepatic impairment (Child-Pugh class C).

Administration in renal impairment. No dose adjustment is considered necessary when eribulin is used in those with mild renal impairment, defined by US licensed product information as creatinine clearance (CC) 50 to 80 mL/min; however, exposure to eribulin is increased by moderate renal impairment (CC 30 to 50 mL/min) and a lower intravenous dose of eribulin mesilate 1.1 mg/m² is recommended in the USA, given on days 1 and 8 of a 21-day cycle. The safety of eribulin has not been studied in those with severe renal impairment (CC < 30 mL/min). UK licensed product information states that patients with severe renal impairment (CC < 40 mL/min) may need a reduction in dose, but gives no specific dose recommendation.

Administration in subsequent cycles. If any of the following occur after an intravenous dose of eribulin mesilate:
- absolute neutrophil count (ANC) < 500 cells/mm³ and lasting more than 7 days
- ANC < 1000 cells/mm³ complicated by fever or infection
- platelet count < 25 000 cells/mm³
- platelet count < 50 000 cells/mm³ complicated by haemorrhage or the need for transfusion
- grade 3 or 4 non-haematological toxicity

then subsequent doses should be reduced from 1.4 mg/m² eribulin mesilate (1.23 mg/m² eribulin) to 1.1 mg/m² eribulin mesilate (970 micrograms/m² eribulin).

If such toxicities recur despite dose reduction, then subsequent doses should be further reduced to 700 micrograms/m² eribulin mesilate (620 micrograms/m² eribulin); if severe toxicity continues at this lower dose, then treatment should be stopped. Doses should not be increased again in subsequent cycles once they have been reduced.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The most common adverse effects associated with eribulin are neutropenia, anaemia, leucopenia, fatigue, fever, alopecia, peripheral neuropathy, headache, arthralgia, myalgia, anorexia, and gastrointestinal disturbances. Infections, including urinary-tract or upper respiratory-tract infections, nasopharyngitis, rhinitis, and oral candidiasis, are also common, as are pain, especially in the back, bone, chest, or oropharyngeal area, and electrolyte disturbances including hypokalaemia, hypomagnesaemia, and hypophosphataemia.

Other adverse effects include febrile neutropenia, thrombocytopenia, lymphopenia, tachycardia, hot flushes, cough, dyspnoea, abdominal pain, stomatitis, mouth ulceration, dry mouth, peripheral oedema, muscle spasms or weakness, epistaxis, rhinorrhoea, increased lachrymation, conjunctivitis, dysgeusia, vertigo, dizziness, insomnia, depression, and increased liver enzymes. Skin disorders include rash, pruritus, hyperhidrosis, dry skin, erythema, and palmar-plantar erythrodysesthesia; nail disorders have also been reported. Hyperglycaemia and dehydration have occurred, as have chills and flu-like illness.

Less common adverse effects include deep-vein thrombosis, pulmonary embolism, interstitial lung disease, hyperbilirubinaemia, angioedema, and tinnitus. Renal disorders that have been reported include dysuria, haematuria, proteinuria, and renal failure.

Complete blood counts should be measured before each dose of eribulin, and more frequently in those who develop severe cytopenias. Treatment should be delayed or the dose reduced if febrile neutropenia occurs or if severe neutropenia lasts longer than 7 days, see Uses and Administration, above. Severe neutropenia may be more common in patients with elevated liver enzymes or bilirubin.

Patients should be monitored closely for peripheral motor and sensory neuropathy. Treatment should be withheld for severe peripheral neuropathy, see Uses and Administration, above.

Eribulin may prolong the QT interval and ECG monitoring is recommended in patients at higher risk, including those with heart failure, bradyarrhythmias, electrolyte abnormalities, or patients also taking other drugs that prolong the QT interval such as some antiarrhythmics. Hypokalaemia and hypomagnesaemia should be corrected before starting eribulin, and these electrolytes monitored periodically during treatment. Eribulin should not be used in patients with congenital long QT syndrome.

Pharmacokinetics

Eribulin is a substrate for, and a weak inhibitor of, P-glycoprotein. Eribulin is rapidly distributed, and has a large volume of distribution. Plasma protein binding ranges from 49 to 65%. It is eliminated by biliary excretion, mainly as unchanged drug, with 82% of the dose in the faeces and 9% in the urine. The mean elimination half-life is about 40 hours.

Erlotinib Hydrochloride

(BANM, USAN, rINNM)

CP-358774-01; Erlotinib, Chlorhydrate d'; Erlotinibi Hydrochloridum; Hidrocloruro de erlotinib; NSC-718781; OSI-774 Эрлотиниба Гидрохлорид.
N-(3-Ethynylphenyl)-6,7-bis(2-methoxyethoxy)quinazolin-4-amine hydrochloride.
$C_{22}H_{23}N_3O_4.HCl$=429.9
CAS — 183321-74-6 (erlotinib); 183319-69-9 (erlotinib hydrochloride).
ATC — L01XE03.
UNII — DA87705X9K.

Uses and Administration

Erlotinib inhibits the intracellular phosphorylation of tyrosine kinase associated with the epidermal growth factor receptor. It is used for the management of locally advanced or metastatic non-small cell lung cancer (p. 710.2) either in disease that is unresponsive to other therapy, or, in some

countries, as maintenance monotherapy in those with stable disease after platinum-based first-line chemotherapy. It is also used with gemcitabine in the first-line treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer (p. 712.1). It is given orally as the hydrochloride but doses are expressed in terms of the base: erlotinib hydrochloride 109 mg is equivalent to about 100 mg of erlotinib. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

The usual dose for non-small cell lung cancer is 150 mg daily, taken at least 1 hour before or 2 hours after food. In the treatment of pancreatic cancer, the recommended dose is 100 mg daily, taken at least 1 hour before or 2 hours after food. Treatment is continued until disease progression or unacceptable toxicity occurs. Where dosage adjustment is necessary, reductions are made in 50 mg steps. Caution is advised in some patients with hepatic or renal impairment (see below).

If concurrent use of potent inhibitors or inducers of cytochrome-P450 isoenzyme CYP3A4 cannot be avoided, dose adjustments of erlotinib are considered necessary.

- When used with a potent CYP3A4 inhibitor, the dose of erlotinib may need to be *reduced*, especially if severe adverse effects occur.
- When given with a potent CYP3A4 inducer, *increases* in the dose of erlotinib should be considered at 2-week intervals with monitoring. The maximum daily dose of erlotinib when used with rifampicin is 450 mg. If the inducer is then stopped, the erlotinib dose will need to be immediately reduced to the indicated starting dose.

Erlotinib is also under investigation in the treatment of malignant glioma.

Administration in hepatic or renal impairment. Erlotinib is metabolised by the liver. UK licensed product information states that although erlotinib exposure was similar in patients with moderate hepatic impairment (Child-Pugh score 7 to 9) compared with those with adequate hepatic function, caution is advised when using erlotinib in hepatic impairment. Dose reduction or interruption of therapy should be considered if adverse effects occur. Use in severe hepatic impairment is not recommended due to a lack of data.

UK licensed product information also states that no dose adjustments appear necessary in patients with mild to moderate renal impairment, but that use of erlotinib in patients with severe renal impairment is not recommended. There are no data available for patients with a creatinine clearance less than 15 mL/minute or those with a serum creatinine concentration greater than 1.5 times the upper normal limit.

Malignant neoplasms of the skin. Erlotinib has been reported to initially cause inflammation at the site of actinic keratoses, followed by partial regression.[1] A patient with nonresectable, refractory, locally aggressive keratoacanthoma centrifugum marginatum of the scalp, a squamous neoplasm known to be abundant in epidermal growth factor receptors (EGFR), was treated with erlotinib. No new lesions developed and an almost complete regression of existing lesions was seen after 2 months of treatment. The authors suggested that EGFR inhibitors such as erlotinib should be considered for well-differentiated EGFR-expressing squamous skin neoplasms, especially if lesions are recalcitrant, multiple, or surgically nonresectable.[2]

2. Buij TK, *et al.* Refractory aggressive keratoacanthoma centrifugum marginatum of the scalp controlled with the epidermal growth factor receptor inhibitor erlotinib. *Br J Dermatol* 2010; 163: 633–7.

Adverse Effects, Treatment, and Precautions

The most common adverse effects associated with erlotinib hydrochloride are rash and diarrhoea. Generally, rash manifests as a mild or moderate erythematous and papulopustular rash, which may occur or worsen in sun-exposed areas; protective clothing and/or use of sunscreen is advisable, and dose reduction may be needed. Bullous, blistering, and exfoliative skin conditions have been reported, including rare cases suggestive of Stevens-Johnson syndrome or toxic epidermal necrolysis, some of which were fatal; erlotinib therapy should be interrupted or stopped if such bullous symptoms occur. Moderate or severe diarrhoea should be treated with an appropriate antidiarrhoeal such as loperamide; dose reduction may be needed. In more severe or persistent cases leading to dehydration, therapy should be stopped temporarily. Hypokalaemia and renal failure (including fatalities) have been reported; some cases were secondary to dehydration or concurrent chemotherapy. Renal function and electrolytes should be monitored in patients at risk of dehydration.

Other common adverse effects include nausea, vomiting, stomatitis, gastrointestinal bleeding, abdominal pain, anorexia, alopecia, pruritus, dry skin, paronychia, conjunctivitis, epistaxis, and fatigue. Alterations in liver function tests have occurred. Rare cases of hepatic failure and hepatorenal syndrome, including fatalities, have been reported. Liver function should be periodically monitored, and treatment interrupted or stopped if liver function changes are severe. Interstitial lung disease has also been reported; again, deaths have occurred. Erlotinib treatment should be interrupted if unexplained pulmonary symptoms occur, such as dyspnoea, cough, and fever. Cases of gastrointestinal perforation, some fatal, have occurred; patients taking anti-angiogenic drugs, taxanes, corticosteroids, or NSAIDs or with a history of peptic ulcer or diverticular disease are at increased risk. Erlotinib should be permanently stopped if perforation occurs. Ocular disorders including abnormal eyelash growth, keratoconjunctivitis sicca or keratitis can also occur, and are risk factors for corneal perforation or ulceration, which has been reported very rarely; erlotinib should be interrupted or stopped in the event of acute or worsening eye pain.

Effects on the ears. Bilateral eardrum perforation with resultant hearing loss has been reported after 1 year of therapy with oral erlotinib.[1] Dosage was reduced from 150 mg daily to 100 mg daily, and 6 months later the left tympanic membrane had healed.

1. Lee SM, *et al.* Bilateral eardrum perforation after long-term treatment with erlotinib. *J Clin Oncol* 2008; 26: 2582–4.

Effects on the liver. Acute hepatitis developed in an elderly man 12 days after starting erlotinib; he was also taking metformin for type 2 diabetes mellitus. Lactic acidosis, which may have been exacerbated by the metformin, developed rapidly, and the patient died. Liver toxicity may be worse in frail elderly patients with comorbidities and multiple medications. Careful monitoring of liver function tests and renal function was advised.[1]

The manufacturers reported on fatalities that had occurred in patients with advanced solid tumours and moderate hepatic impairment as defined by the Child-Pugh criteria; 6 of 10 patients who died had baseline bilirubin values more than 3 times the upper normal limit (ULN), suggesting severe, rather than moderate, hepatic impairment. All patients had liver involvement such as hepatocellular carcinoma, cholangiosarcoma, or liver metastases, and the manufacturers warned that there may be limitations to using Child-Pugh criteria in an oncology population.[2] US licensed product information states that patients with hepatic impairment should be closely monitored and therapy interrupted or stopped if liver function changes are severe, such as doubling of total bilirubin and/or tripling of transaminases in patients with pretreatment values outside the normal range. Therapy should also be interrupted or stopped if total bilirubin is more than 3 times the ULN and/or transaminases are greater than 5 times the ULN in those with normal pretreatment values.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies erlotinib as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 27/09/11)

Interactions

Inhibitors of the cytochrome P450 isoenzyme CYP3A4, such as ketoconazole, can increase erlotinib concentrations and use with potent inhibitors should be avoided as increased toxicity may occur. Conversely, CYP3A4 inducers, such as rifampicin, can reduce erlotinib concentrations and may reduce its efficacy. Dose adjustments may be required (see Uses and Administration, p. 788.3). Caution is also required with ciprofloxacin or potent inhibitors of CYP1A2, as erlotinib exposure may be increased, and dose reductions may be needed if adverse effects occur. Use with P-glycoprotein inhibitors such as ciclosporin and verapamil may cause altered distribution or elimination of erlotinib. Drugs that increase the pH of the gastrointestinal tract such as antacids, H_2-receptor antagonists, or proton pump inhibitors may reduce the solubility of erlotinib and hence lower its bioavailability. Use of proton pump inhibitors with erlotinib should be avoided. If the use of antacids or H_2-receptor antagonists cannot be avoided, dosing should be staggered; licensed product information recommends that antacids should be taken at least 4 hours before or 2 hours after erlotinib, and erlotinib at least 2 hours before or 10 hours after ranitidine. Exposure to erlotinib is reduced in smokers compared with non-smokers. Exposure to erlotinib may be increased by capecitabine.

Erlotinib is a strong inhibitor of glucuronidation by the uridine diphosphate glucuronosyltransferase isoenzyme UGT1A1 *in vitro* and may affect exposure to UGT1A1 substrates. Increased INR and bleeding events have been reported with erlotinib, some associated with the use of warfarin and some with the use of NSAIDs, see p. 1532.2 and p. 107.3, respectively.

Fibrates. Progression of lung adenocarcinoma in a patient treated with erlotinib was attributed to suboptimal exposure to erlotinib, and the dose was increased. Concomitant medications included escitalopram, alprazolam, and *fenofibrate*. Given the potential induction of cytochrome P450 isoenzyme CYP3A4 by fenofibrate, this was withdrawn; a reduction in erlotinib dosage was subsequently needed.

1. Mir O, *et al.* Drug-induced effects on erlotinib metabolism. *N Engl J Med* 2011; 365: 379–80.

Tobacco smoking. Exposure to erlotinib is reduced in smokers (see Interactions, above). A study determined that the maximum tolerated dose of oral erlotinib was 300 mg daily in lung cancer patients who were also current smokers. Steady-state trough plasma concentrations and incidence of rash and diarrhoea were similar to those in other studies of former smokers or those who had never smoked, who were taking the usual recommended dose of 150 mg daily.[1]

1. Hughes AN, *et al.* Overcoming CYP1A1/1A2 mediated induction of metabolism by escalating erlotinib dose in current smokers. *J Clin Oncol* 2009; 27: 1220–6.

Pharmacokinetics

Erlotinib is absorbed from the gastrointestinal tract, with a bioavailability of about 60%; this may increase up to almost 100% in the presence of food. Peak plasma concentrations occur about 4 hours after a dose, and it is about 93% bound to plasma proteins. Erlotinib is metabolised mainly by the cytochrome P450 isoenzyme CYP3A4, and to a lesser extent by CYP1A2. Metabolic pathways include demethylation, to metabolites OSI-420 and OSI-413, oxidation, and aromatic hydroxylation. Erlotinib has an elimination half-life of

about 36 hours. More than 80% of a dose is excreted as metabolites in the faeces.

CAS — 2998-57-4 (estramustine); 4891-15-0 (estramustine phosphate); 52205-73-9 (estramustine sodium phosphate).

ATC — L01XX11.

ATC Vet — QL01XX11.

UNII — 75F375MT2N.

Pharmacopoeias. In *Br.*

BP 2014: (Estramustine Sodium Phosphate). A white or almost white powder. Freely soluble in water and in methyl alcohol; very slightly soluble in dehydrated alcohol and in chloroform. A 0.5% solution in water has a pH of 8.5 to 10.0. Protect from light.

Uses and Administration

Estramustine is a combination of estradiol and normustine, a homologue of chlormethine (p. 765.1). It has weaker oestrogenic activity than estradiol and weaker antineoplastic activity than most other alkylating agents. Estramustine phosphate is given orally as the disodium salt. Doses are calculated in terms of estramustine phosphate; 108 mg of estramustine sodium phosphate is equivalent to about 100 mg of estramustine phosphate. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* Estramustine phosphate with meglumine has been given by intravenous injection.

Estramustine sodium phosphate is licensed for use in the treatment of advanced prostatic carcinoma (p. 712.3). An estramustine phosphate dose of about 14 mg/kg daily in divided doses is used. The usual initial dose is 560 to 840 mg daily, which may be adjusted to between 140 mg and 1.4 g daily according to the response and gastrointestinal tolerance. It should be given not less than 1 hour before or 2 hours after meals.

Adverse Effects, Treatment, and Precautions

Oestrogenic adverse effects with estramustine are fairly common, and may include gynaecomastia, fluid retention, and cardiovascular effects. Gastrointestinal disturbances, hepatic dysfunction, loss of libido, hypersensitivity reactions, and occasionally leucopenia and thrombocytopenia may occur. Estramustine is contra-indicated in patients with peptic ulceration and severe hepatic or cardiovascular disease. Diabetes mellitus may be exacerbated, and the drug should be given with care to patients with disorders such as congestive heart failure, epilepsy, hypertension, migraine, and renal impairment which may be adversely affected by additional fluid retention. Care is also required in patients with conditions predisposing to hypercalcaemia, and serum calcium should be monitored in hypercalcaemic patients.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies estramustine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 28/09/11)

Interactions

Estramustine sodium phosphate should not be given with milk products or products high in calcium, which may interfere with its absorption. Hypersensitivity reactions including angioedema have occurred rarely in patients given estramustine who were also receiving an ACE inhibitor.

Pharmacokinetics

Up to 75% of a dose of estramustine sodium phosphate is absorbed from the gastrointestinal tract and rapidly dephosphorylated. Estramustine is found in the body mainly as its oxidised isomer estromustine; both forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have plasma half-lives of 10 to 20 hours, and are excreted with their metabolites mainly in the faeces.

$C_{29}H_{33}O_{16}P$=668.5

CAS — 117091-64-2.

ATC — L01CB01.

ATC Vet — QL01CB01.

UNII — 528XYJ8L1N.

Incompatibility. For reference to precipitation when mannitol or potassium chloride was added to mixtures of etoposide and cisplatin in sodium chloride injection see Cisplatin, p. 766.1.

For incompatibility of etoposide formulations with various plastics see Administration, p. 791.1.

Stability. UK licensed product information states that etoposide (diluted to a concentration of 200 or 400 micrograms/mL) has been shown to be physically and chemically stable for 24 hours at 15 degrees to 25 degrees. For microbiological reasons, the diluted solution should be used immediately; if not immediately used, the solution should not be stored longer than 12 hours at 15 degrees to 25 degrees, unless it has been diluted under aseptic conditions.

US licensed product information states that etoposide, diluted to a concentration of 200 or 400 micrograms/mL, is stable for 96 and 24 hours, respectively, at room temperature (25 degrees) under normal fluorescent light in either glass or plastic containers.

Etoposide phosphate, after reconstitution and further dilution, can be stored under refrigeration (at 2 degrees to 8 degrees) or at room temperature (20 degrees to 25 degrees) for 24 hours.

Uses and Administration

Etoposide is a semisynthetic derivative of podophyllotoxin with antineoplastic properties; it interferes with the function of topoisomerase II thus inhibiting DNA synthesis, and is most active against cells in the late S and G_2 phases of the cell cycle.

It is used, usually with other antineoplastics, in the treatment of tumours of the testis, small cell cancer of the lung, and in acute leukaemias. It has also been tried in other solid tumours including those of the brain, gastrointestinal tract, ovary, and thymus, and some childhood neoplasms; in lymphomas, and in the treatment of Kaposi's sarcoma associated with AIDS. For further discussion, see the cross-references indicated under Malignant Neoplasms, p. 791.2.

Etoposide may be given orally or intravenously. *Antineoplastic dose regimens may be complex and doses of a drug may differ widely. For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Etoposide is given by slow intravenous infusion over at least 30 minutes, as a solution in sodium chloride 0.9% or glucose 5% injection. In general, the concentration of the infusion should be between 200 to 400 micrograms/mL, although recommendations vary depending on the preparation; precipitation may occur at higher concentrations. Etoposide phosphate, a prodrug, has improved solubility in water. 113.6 mg of etoposide phosphate is equivalent to 100 mg of etoposide. Intravenous doses are calculated in terms of etoposide, and are identical to those of the base, but it may be given in concentrations up to the

equivalent of etoposide 20 mg/mL. Etoposide phosphate solutions may be infused over 5 minutes to 3.5 hours.

Regimens vary; the usual *intravenous* dose of etoposide ranges from 50 to 120 mg/m² daily for 5 days. Somewhat lower doses have been suggested in lung cancer. Alternatively, 100 mg/m² has been given on alternate days to a total of 300 mg/m². The usual *oral* dose of etoposide is 100 to 240 mg/m² daily for 5 consecutive days. Courses may be repeated after 3 to 4 weeks. Doses should be reduced in renal impairment (see below).

Administration. Although precipitation of etoposide may occur at high infusion concentrations (see Uses and Administration, p. 790.3), high doses of etoposide have been infused undiluted to avoid giving large volumes of fluid to the patient.[1-3] Etoposide was infused through a central line, and this method has been reported to be safe and effective;[2] pharmacokinetic studies suggested unaltered systemic bioavailability when compared with diluted infusions.[3] However, cracking of plastic syringes and infusion cassettes has been reported, possibly due to the polyethylene glycol component of the formulation. This appears particularly problematic when devices containing ABS plastic (a polymer produced from acrylonitrile, butadiene, and styrene) are used; alternative devices may be preferable.[1] Leaching of the plasticiser diethylhexyl phthalate (which is potentially toxic and carcinogenic) from PVC bags and tubing has been reported with etoposide, and it has been suggested that these should also not be used if possible when preparing and giving the drug.[4]

Etoposide has been injected into the ventricles of the brain in the treatment of patients with neoplastic meningitis.[5]

3. Ehninger G, *et al.* Unaltered pharmacokinetics after the administration of high-dose etoposide without prior dilution. *Cancer Chemother Pharmacol* 1991; 28: 214–16.
4. de Lemos ML, *et al.* Leaching of diethylhexyl phthalate from polyvinyl chloride materials into etoposide intravenous solutions. *J Oncol Pharm Pract* 2005; 11: 155–7.
5. Chamberlain MC, *et al.* Phase II trial of intracerebrospinal fluid etoposide in the treatment of neoplastic meningitis. *Cancer* 2006; 106: 2021–7.

Administration in the elderly. Increasing age was reported to correlate with higher etoposide concentrations during oral therapy; increasing age and higher etoposide concentrations also correlated with lower white blood cell and absolute neutrophil counts.[1] A review noted that, compared with intravenous etoposide, there is more variability in the pharmacokinetics and toxicity of oral etoposide, and the oral route may appear less effective and more toxic as a result. In elderly patients taking etoposide, a small dose reduction and careful monitoring has thus been advised, even in those with normal renal and hepatic function.[2]

1. Miller AA, *et al.* Pharmacology of 21-day oral etoposide given in combination with i.v. cisplatin in patients with extensive-stage small cell lung cancer: a cancer and leukemia group B study (CALGB 9062). *Clin Cancer Res* 1997; 3: 719–25.
2. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; 25: 1832–43.

Administration in renal impairment. Some licensed product information for etoposide or etoposide phosphate recommends that patients with a creatinine clearance of between 15 and 50 mL/minute be given 75% of the recommended dose. No recommendations are given for those patients having a creatinine clearance of below 15 mL/minute, although one product (*Vepesid; BMS, USA*) suggests that further dose reduction in these patients be considered.

Histiocytic syndromes. Systemic chemotherapy is often tried in patients with extensive Langerhans-cell histiocytosis (p. 692.1), although its value is uncertain. Etoposide is one of the drugs widely used for this purpose.

Hypereosinophilic syndrome. Etoposide has been reported to produce clinical responses in patients with the hypereosinophilic syndrome.[1]

1. Bourrat E, *et al.* Etoposide for treating the hypereosinophilic syndrome. *Ann Intern Med* 1994; 121: 899–900.

Influenza. A patient was diagnosed with pandemic (H1N1) 2009 influenza infection (p. 960.2). During the course of this, he developed secondary haemophagocytic lymphohistiocytosis, and was treated with etoposide and betamethasone. He had a prompt clinical response within one week. It has been hypothesised that cytotoxic therapy might be beneficial for severe influenza infection, and the authors suggested that further studies in this area are needed.[1]

1. Henter J-I, *et al.* Cytotoxic therapy for severe swine flu A/H1N1. *Lancet* 2010; 376: 2116.

Malignant neoplasms. Etoposide has been used for a variety of solid tumours: in particular it is part of curative regimens used in the treatment of testicular cancer and germ-cell tumours of the ovary (see p. 715.1 and p. 711.2), and is used with cisplatin and other drugs in the treatment of lung cancer (p. 710.2). Other solid neoplasms in which it is sometimes employed include those of the brain (p. 701.2), stomach (p. 706.1), and thymus (p. 715.3), as well as in neuroblastoma (p. 716.2), Wilms' tumour (p. 709.1), retinoblastoma (p. 717.2), and rhabdomyosarcoma (p. 718.2); it has also formed part of systemic regimens for bone sarcomas (p. 717.3), disseminated Kaposi's sarcoma (see p. 718.1), and gestational trophoblastic tumours (p. 691.2). Etoposide is used in regimens for Hodgkin's disease (see p. 696.1); it is also sometimes used in aggressive intermediate- and high-grade non-Hodgkin's lymphomas (p. 696.3), and may produce short-term responses in mycosis fungoides (p. 698.3). It is also used in Burkitt's lymphoma (p. 697.3). Etoposide may have benefits when added to induction protocols for acute myeloid leukaemia (p. 693.1), and when used as part of intensification therapy in acute lymphoblastic leukaemia (p. 692.3). It has formed part of salvage regimens in multiple myeloma (p. 699.2).

Vasculitic syndromes. For mention of the use of etoposide to induce remission in patients with Wegener's granulomatosis resistant to standard therapy with cyclophosphamide and corticosteroids, see p. 1615.2.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

The dose-limiting toxicity of etoposide is myelosuppression, mainly seen as leucopenia, but also thrombocytopenia, and sometimes anaemia. The nadir of the granulocyte count usually occurs 7 to 14 days after a dose, with recovery by about 21 days. Nausea and vomiting are common; there may also be anorexia, diarrhoea, and mucositis. Gastrointestinal toxicity may be more common after oral dosage. Reversible alopecia occurs in about two-thirds of all patients. Hypersensitivity or anaphylactoid reactions can occur, characterised by flushing, chills, fever, tachycardia, bronchospasm, dyspnoea, and hypotension. Apnoea and fatal reactions associated with bronchospasm have been reported. Peripheral or central neuropathies, including transient cortical blindness, have been reported rarely, as have weakness, fatigue, somnolence, aftertaste, fever, rashes, urticaria, skin pigmentation, pruritus, and dysphagia. Stevens-Johnson syndrome and toxic epidermal necrolysis have occurred rarely. Tumour lysis syndrome, sometimes fatal, has been reported after use of etoposide with other chemotherapeutic drugs. Disturbances of liver function have been reported, mainly at high doses. There have been occasional reports of cardiotoxicity. Local irritation and thrombophlebitis may occur at the site of injection. Care should be taken to avoid extravasation although tissue damage (possibly associated with the vehicle) is rare.

Rapid intravenous doses may cause hypotension; etoposide should be given by infusion over at least 30 minutes. Etoposide should not be given to patients with severe hepatic impairment nor by the intracavitary route.

Some adverse effects associated with intravenous etoposide may be due to the formulation of the vehicle.

There is evidence that etoposide may be associated with the development of secondary leukaemias—see Carcinogenicity, p. 726.2.

Breast feeding. Some licensed product information states that it is unknown whether etoposide is excreted into breast milk. However, in breast milk samples from a woman given consolidation therapy, including etoposide,[1] for acute promyelocytic leukaemia, etoposide concentrations were maximal just after a dose, but decreased rapidly to undetectable levels within 24 hours on each of three days. She started to breast feed her baby 3 weeks after the completion of therapy, and no abnormalities were seen in the infant up to 16 months of age. It has been suggested[2] that breast feeding be withheld for 24 to 36 hours after a dose.

2. *et al.*, eds. *Drugs during pregnancy and lactation: treatment options and risk assessment.* 2nd ed. London: Elsevier, 2007.

Effects on the gastrointestinal tract. Pneumatosis intestinalis (the presence of gas within the bowel wall), a rare condition, has been reported after intravenous[1] and oral[2] etoposide. It is supposed that myelosuppressive drugs might interfere with the mucosal integrity of the intestinal tract, and that the intestinal mucosa might be highly sensitive to etoposide.

2. Shih I-L, *et al.* Pneumatosis coli after etoposide chemotherapy for breast cancer. *J Clin Oncol* 2007; 25: 1623–5.

Effects on the nervous system. A report of an acute dystonic reaction in a child given etoposide as part of a combined maintenance regimen for acute lymphoblastic leukaemia;[1] the patient had been receiving the same regimen uneventfully for over a year but symptoms (which responded to diphenhydramine) recurred on rechallenge with etoposide.

1. Ascher DP, Delaney RA. Acute dystonia from etoposide. *Drug Intell Clin Pharm* 1988; 22: 41–2.

Handling and disposal. *Urine and faeces* produced for up to 4 and 7 days respectively after a dose of etoposide should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; 235: 289–91.

Hypersensitivity. Hypersensitivity reactions to intravenous etoposide are characterised by one or more of: hypotension, bronchospasm, flushing, exanthema, dyspnoea, fever, chills, tachycardia, tightness in the chest, cyanosis, and hypertension. Although originally thought rare, some investigators[1] have reported an incidence of up to about 50%, particularly in younger patients. The mechanism is uncertain, but a literature review[1] supported the hypothesis that it might not be antibody-mediated, since reducing the rate of infusion can prevent reactions, as can reducing etoposide concentration in the infusion solution. However, an immunogenic mechanism cannot be excluded as hypersensitivity appears to have been reported less frequently with the oral formulation, which unlike the infusion does not contain polysorbate 80. In addition, there are reports[2-4] of successful use of etoposide phosphate formulations (which do not contain polysorbate 80) after hypersensitivity reactions to etoposide, suggesting that the solvent may be responsible. Successful desensitisation in a patient hypersensitive to etoposide has been reported.[5]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies etoposide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/08/11)

Pregnancy. A 22-year-old woman, who was diagnosed with acute myelogenous leukaemia at 20 weeks of gestation, was treated with combination chemotherapy including cytarabine and daunorubicin at 22 weeks, but the response was unsatisfactory, and the regimen was altered to cytarabine, mitoxantrone, and etoposide at 31 weeks. After the second course of chemotherapy was completed, an intermittent sinusoidal fetal heart rate pattern was detected, along with intra-uterine fetal growth retardation. Complete remission was achieved at 35 weeks and a caesarean section was performed a week later due to fetal distress. The neonate was underweight and had pancytopenia requiring blood transfusion and antibacterial therapy; he was discharged at 2 months of age in good health. The authors concluded that the fetal sinusoidal heart rate pattern may have been induced by tissue hypoxia due to severe anaemia, and that the leucopenia and thrombocytopenia resulted from bone marrow suppression caused by the transplacental effects of maternal chemotherapy; they considered that mitoxantrone and etoposide might be responsible for the neonatal pancytopenia.[1]

For a report of hair loss in an infant, attributed to etoposide given to the mother before delivery, see Pregnancy, under Cisplatin, p. 768.2.

1. Hsu K-F, *et al.* Sinusoidal fetal heart rate pattern during chemotherapy in a pregnant woman with acute myelogenous leukemia. *J Formos Med Assoc* 1995; 94: 562–5.

Interactions

For a general outline of antineoplastic drug interactions, see p. 733.3. Phenylbutazone, salicylic acid, and sodium salicylate can affect the protein binding of etoposide.

Caution is advised when etoposide phosphate is given with drugs such as levamisole hydrochloride that are known to inhibit phosphatase activities.

Antineoplastics. Giving etoposide 2 days after a dose of *cisplatin* was associated with a marked decrease in etoposide clearance and more toxicity, compared with the same dose given 21 days after a dose of cisplatin, in a study involving 17 children.[1] There was no evidence of a persistent decrease in etoposide clearance associated with the cumulative dose of cisplatin, however. In a randomised, crossover study,[2] cisplatin or *carboplatin* were given alternately during 2 courses of etoposide. Although increases in the area under the concentration-time curve of etoposide were seen in the second course, effects were modest and, given the pharmacokinetic variability seen with etoposide, the authors considered any clinical impact to be small.

2. Thomas HD, *et al.* Randomized cross-over clinical trial to study potential pharmacokinetic interactions between cisplatin or carboplatin and etoposide. *Br J Clin Pharmacol* 2002; 53: 83–91.

Ciclosporin. High-dose ciclosporin therapy was found to increase the exposure to etoposide by 80%, and to reduce etoposide clearance by 38%. Leucopenia was increased. Etoposide doses should be halved when the drug is given with high-dose ciclosporin.[1] In a study[2] of children who received etoposide and mitoxantrone for acute myeloid leukaemia, the addition of ciclosporin with a 40% reduction in the doses of the antineoplastics still resulted in a 71% reduction in the clearance of etoposide, and a 42% reduction for mitoxantrone. However, there was wide interpatient variability, and the rates of stomatitis and infection were similar between the groups, with or without ciclosporin.

2. Lacayo NJ, *et al.* Pharmacokinetic interactions of cyclosporine with etoposide and mitoxantrone in children with acute myeloid leukemia. *Leukemia* 2002; 16: 920–7.

Grapefruit juice. In a randomised crossover study[1] of 6 patients, grapefruit juice appeared to reduce the oral bioavailability of etoposide. Initially the authors had expected the opposite since etoposide is demethylated by cytochrome P450 isoenzyme CYP3A4. Although no definite conclusions could be made due to the small number of patients studied, a possible mechanism might have been alteration of P-glycoprotein mediated transport.

1. Reif S, *et al.* Effect of grapefruit juice intake on etoposide bioavailability. *Eur J Clin Pharmacol* 2002; 58: 491–4.

Pharmacokinetics

Absorption after oral doses is variable, but on average about 50% of the dose of etoposide is absorbed. The pharmacokinetics of etoposide are subject to considerable interindividual variation. It is rapidly distributed, and concentrations in plasma fall in a biphasic manner, with a terminal half-life of 4 to 11 hours. Etoposide is about 94% bound to plasma protein. It is metabolised by the cytochrome P450 isoenzyme CYP3A4. Etoposide is excreted in urine and faeces as unchanged drug and metabolites: about 45% of a dose is reported to be excreted in urine over 72 hours. It crosses the blood-brain barrier poorly; concentrations in CSF are 1 to 10% of those in plasma. It is distributed into breast milk (see Breast Feeding, p. 791.2).

Exemestane *(BAN, USAN, rINN)* ⊗

Eksemestaani; Eksemestan; Exemestan; Exémestane; Exemestano; Exemestanum; FCE-24304; Экземестан.

6-Methyleneandrosta-1,4-diene-3,17-dione.

$C_{20}H_{24}O_2$=296.4

CAS — 107868-30-4.

ATC — L02BG06.

ATC Vet — QL02BG06.

UNII — NY22HMQ4BX.

Uses and Administration

Exemestane is a selective inhibitor of the aromatase (oestrogen synthetase) system responsible for the conversion of androgens to oestrogens in peripheral tissues, but unlike anastrozole (p. 742.2) or letrozole (p. 817.2) it has a steroidal structure. It is used in the treatment of advanced breast cancer (p. 702.1), in postmenopausal women who are no longer responsive to anti-oestrogen therapy. It is also used for adjuvant treatment of postmenopausal women with oestrogen-receptor positive early breast cancer, after 2 to 3 years of initial adjuvant tamoxifen treatment; a total of 5 years of adjuvant hormonal therapy should be given. The recommended oral dose is 25 mg once daily, preferably after a meal.

In patients receiving potent inducers of the cytochrome P450 isoenzyme CYP3A4 (such as rifampicin or phenytoin), the recommended oral dose of exemestane is 50 mg once daily, after a meal.

Adverse Effects and Precautions

The adverse effects of exemestane are similar to those seen with other aromatase inhibitors such as anastrozole (p. 742.3), and similar precautions should be taken. Fatigue and increased sweating are common with exemestane. Visual disturbances have been reported. Thrombocytopenia and leucopenia have been reported rarely. For the suggestion that exemestane may have more pro-atherogenic effects on blood lipids than anastrozole or letrozole, see below.

Breast feeding. Studies show that exemestane is distributed into the milk of *rats*. Licensed product information states that it is unknown whether exemestane is excreted into human milk; in the UK use during breast feeding is contra-indicated while in the USA a decision may be made based on clinical judgement. It has been suggested[1] that breast feeding be stopped if using multiple doses of exemestane, and to withhold breast feeding for at least 5 days after the last dose.

1. *et al.*, eds. *Drugs during pregnancy and lactation: treatment options and risk assessment.* 2nd ed. London: Elsevier, 2007.

Effects on blood lipids. A comparison of the adverse effects of letrozole, anastrozole, and exemestane in postmenopausal women indicated[1] that although all had similar effects on markers of bone turnover, exemestane was associated with a markedly greater decrease in high-density lipoprotein (HDL) cholesterol. This resulted in an increase in the atherogenic ratio of low-density (LDL) to HDL-cholesterol. Since some studies have suggested that low HDL-cholesterol may be a more important risk factor for cardiovascular disease in women than men it was suggested that further study was needed to see if this difference had clinical significance.

1. McCloskey EV, *et al.* Effects of third generation aromatase inhibitors on bone health and other safety parameters: results of an open, randomised, multi-centre study of letrozole, exemestane and anastrozole in healthy postmenopausal women. *Eur J Cancer* 2007; 43: 2523–31.

Effects on the musculoskeletal system. Exemestane therapy has been found to decrease bone mineral density (BMD) in postmenopausal women with early breast cancer.[1,2] In one study, the decrease in BMD was seen within 6 months of switching therapy from tamoxifen, and was significant at the lumbar spine and hip.[2] In a Scandinavian study, BMD loss with exemestane compared with placebo was modest from the femoral neck, and not significant at the lumbar spine;[1] however, it was noted that the changes in the placebo group were greater than expected, possibly due to the lack of calcium and vitamin D supplementation, and that there is a high incidence of hip fracture in Scandinavia. Patients starting exemestane therapy should be assessed for baseline BMD;[1] while those with normal BMD are considered to not need further assessment beyond lifestyle advice, those with osteopenia should have their BMD monitored, and therapeutic interventions made as appropriate.[2]

See also Effects on the Musculoskeletal System, under Anastrozole, p. 743.1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies exemestane as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/09/11)

Interactions

The metabolism of exemestane is mediated by the cytochrome P450 isoenzyme CYP3A4. Rifampicin, a potent inducer of CYP isoenzymes, can decrease plasma concentrations of exemestane. Use with other drugs that induce this isoenzyme may reduce the efficacy of exemestane; dose adjustments are recommended in these patients (see Uses and Administration, above). Exemestane should also be used cautiously with drugs that are substrates for CYP3A4 and that have a narrow therapeutic index. Significant effects on exemestane clearance by cytochrome P450 isoenzyme inhibitors are considered unlikely. Exemestane should not be given with oestrogen-containing drugs as these would negate its pharmacological action

Pharmacokinetics

Exemestane is rapidly absorbed from the gastrointestinal tract. Its bioavailability is limited by first-pass metabolism, but is increased when taken with food. Exemestane is widely distributed, and is 90% bound to plasma proteins. It is metabolised via oxidation by the cytochrome P450 isoenzyme CYP3A4, and via reduction by aldoketoreductase. Metabolites are excreted in the urine and faeces, and less than 1% of a dose is excreted unchanged in the urine. Exemestane has a terminal elimination half-life of about 24 hours.

Exisulind *(rINN)*

Exisulindum; FGN-1; Sulfona de sulindac; Sulindac Sulfone; Эксисулинд.

5-Fluoro-2-methyl-1-[(*Z*)-*p*-(methylsulfonyl)benzylidene] indene-3-acetic acid.

$C_{20}H_{17}FO_4S$=372.4

CAS — 59973-80-7.

UNII — K619IIG2R9.

NOTE. The names Aptosyn and Prevatec have been used as trade marks for exisulind.

Profile

Exisulind is a sulfone metabolite of sulindac (p. 134.2) that is reported to induce apoptosis in cancerous and precancerous cells. It has been studied for the treatment of familial adenomatous polyposis, with variable results. It is also being investigated for the prevention and treatment of malignant neoplasms, including those of the breast, prostate, and lung.

CAS — 286942-97-0.

UNII — D59N834676.

NOTE. The name Telintra has been used as a trade mark for ezatiostat.

Profile

Ezatiostat hydrochloride is an inhibitor of glutathione S-transferase P1-1. It is under investigation in the treatment of myelodysplastic syndrome and has been granted orphan drug status in the USA. Ezatiostat has been given orally and intravenously. Adverse effects following oral use have included nausea, diarrhoea, vomiting; chills, back pain, and flushing were seen following intravenous use. Ezatiostat has also been investigated in the treatment of idiopathic chronic neutropenia.

Fadrozole Hydrochloride *(USAN, rINNM)* ⊗

CGS-16949 (fadrozole); CGS-16949A; Fadrozol, hidrocloruro de; Fadrozole, Chlorhydrate de; Fadrozoli Hydrochloridum; Hidrocloruro de fadrozol; Фадрозола Гидрохлорид.

(±)-*p*-(5,6,7,8-Tetrahydroimidazo[1,5-*a*]pyridin-5-yl)benzonitrile monohydrochloride.

$C_{14}H_{13}N_3$,HCl=259.7

CAS — 102676-47-1 (fadrozole); 102676-96-0 (fadrozole hydrochloride).

UNII — H0Q44H4ECQ.

Profile

Fadrozole hydrochloride is a selective nonsteroidal inhibitor of the aromatase (oestrogen synthetase) system, similar to anastrozole (p. 742.1). It has been used for the treatment of breast cancer.

Farletuzumab *(USAN, rINN)*

Farletuzumabum; MORAb-003; Фарлетузумаб.

CAS — 896723-44-7.

UNII — 2O09BG0OWA.

Profile

Farletuzumab is a humanised monoclonal antibody that binds to and blocks the function of folate receptor alpha (FRA), a cell surface protein that is over-expressed in ovarian and other cancers. Farletuzumab is under investigation for the treatment of ovarian cancer.

Fenretinide *(USAN, rINN)*

Fenretinida; Fenrétinide; Fenretinidum; 4-HPR; 4-Hydroxyphenylretinamide; McN-R-1967; Фенретинид.

all-trans-4′-Hydroxyretinanilide.

$C_{26}H_{33}NO_2$=391.6

CAS — 65646-68-6.

UNII — 187EJ7QEXL.

Profile

Fenretinide is a retinoid derivative that is given orally and is being studied in the management of haematological malignancies such as lymphoma and solid malignancies such as brain and bone tumours, Ewing's sarcoma, and breast, prostate, ovarian, and cervical cancer. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.*

Fenretinide has also been tried in oral lichen planus and leucoplakia. It is also under investigation as an adjunct to antipsychotic treatment in schizophrenia, for atrophy in age-related macular degeneration, and for insulin resistance in obese patients. It has been tried in the treatment of psoriasis, but was associated with unacceptable adverse effects such as night blindness and severe toxic erythema.

Fenretinide has been studied for the treatment of breast cancer and cutaneous malignancies but early results were disappointing and night blindness and mucocutaneous effects have been associated with this use.[1] Fenretinide has been investigated for the prevention of breast cancer (p. 703.2), but a large randomised study of secondary prevention failed to show any benefit.[2] A follow-up of the same study[3] found that patients receiving fenretinide had a lower incidence of ovarian carcinoma during the 5-year treatment period, but that this apparently protective effect disappeared after treatment was stopped. Combinations of tamoxifen and fenretinide, given intermittently (for treatment or prevention), have been reported to be well tolerated.[4-6] Its actions may be due to anti-angiogenic properties.[7]

$C_9H_{11}FN_2O_5$=246.2

CAS — 50-91-9.

UNII — 039LU44I5M.

Pharmacopoeias. In *US.*

USP 36: (Floxuridine). Store in airtight containers at a temperature of 25 degrees, excursions permitted between 15 degrees and 30 degrees. Protect from light.

Uses and Administration

Floxuridine is an antineoplastic which acts as an antimetabolite, either by conversion to fluorouracil (after rapid injection), or, when given by slow intra-arterial infusion, partly via floxuridine monophosphate (F-dUMP), which produces greater inhibition of DNA synthesis.

Floxuridine is used in the palliative treatment of hepatic metastases of colorectal cancer (p. 706.3). It has been tried in some other solid neoplasms. Doses of 100 to 600 micrograms/kg daily are given by continuous hepatic arterial infusion, usually with the aid of an infusion pump, until toxicity occurs.

White cell and platelet counts should be carried out regularly during therapy and treatment should be stopped if the white cell count falls rapidly or if the white cell or platelet count falls below acceptable levels (see also Bone-marrow Depression, p. 730.3), or if major adverse effects occur.

6. Power DG, Kemeny NE. The role of floxuridine in metastatic liver disease. *Mol Cancer Ther* 2009; **8**: 1015–25.

Adverse Effects, Treatment, and Precautions

As for Fluorouracil, p. 797.1. Adverse reactions after intra-arterial infusion often include local reactions, thromboembolic complications, and infection or bleeding at the catheter site, or blockage of the catheter. Erythema, stomatitis, and gastrointestinal disturbances are relatively common. There have also been signs of liver dysfunction.

Effects on the liver. Serious biliary toxicity has been reported in over half of all patients receiving hepatic arterial infusions of floxuridine, usually manifesting as sclerosing cholangitis or acalculous cholecystitis;[1] as a result some surgeons routinely remove the gallbladder at the time of infusion pump implantation.[2] Extrahepatic biliary stenosis with jaundice and cholestasis has also been described;[3] the authors suggest that this could lead to intrahepatic biliary damage from bile stasis and infection, recurrent cholangitis, and biliary sclerosis. Floxuridine infusions have also been associated with a case of fatal progressive cirrhosis of the liver in the absence of overt cholestasis.[4] Pseudoaneurysms of the hepatic artery, lead-

ing to serious retroperitoneal or gastrointestinal bleeding, have also been described.[3]

Interactions

As for Fluorouracil, p. 797.3.

Pharmacokinetics

Floxuridine is poorly absorbed from the gastrointestinal tract and it is usually given by injection. Floxuridine is metabolised mainly in the liver to fluorouracil after rapid injection. When given by slow intra-arterial infusion, more of the drug is metabolised to floxuridine monophosphate (F-dUMP). It is excreted as carbon dioxide via the lungs; some is excreted, as unchanged drug and metabolites, in urine. Floxuridine crosses the blood-brain barrier to some extent and is found in CSF.

ATC — L01BB05.

ATC Vet — QL01BB05.

UNII — 1X9VK9O1SC.

NOTE. The name FluCam has been used for a regimen of fludarabine with alemtuzumab. Distinguish from Flucam, which is a proprietary name for ampiroxicam (p. 21.1).

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Fludarabine Phosphate). A white or almost white, hygroscopic, crystalline powder. Slightly soluble in water; very slightly soluble in dehydrated alcohol; freely soluble in dimethylformamide. Store in airtight containers at a temperature of 2 degrees to 8 degrees. Protect from light.

USP 36: (Fludarabine Phosphate). A white to off-white, hygroscopic, crystalline powder. Slightly soluble in water and in 0.1M hydrochloric acid; practically insoluble in dehydrated alcohol; freely soluble in dimethylformamide. Store at 2 degrees to 8 degrees. Protect from light.

Uses and Administration

Fludarabine phosphate is a fluorinated nucleotide analogue of the antiviral vidarabine (p. 1023.1); it is a purine analogue that acts as an antimetabolite antineoplastic to inhibit DNA synthesis. Fludarabine is used for the treatment of B-cell chronic lymphocytic leukaemia (p. 693.3). Fludarabine phosphate is given intravenously or orally. *For warnings and recommendations regarding the safe prescribing, dispensing, and use of oral antineoplastic drugs, see Administration, p. 732.3.* For intravenous use, fludarabine phosphate is either given by bolus injection, usually in 10 mL sodium chloride 0.9%, or by infusion over 30 minutes, usually in 100 mL sodium chloride 0.9%. The usual *intravenous* dose is 25 mg/m² daily for 5 consecutive days. Alternatively it may be given *orally* in a dose of 40 mg/m² daily for 5 consecutive days. Courses may be repeated every 28 days, usually for up to 6 cycles.

Haematological function should be monitored regularly; the dosage may need to be reduced, or further courses delayed, if blood counts indicate severe or persistent myelosuppression (see Administration in Subsequent Cycles, below). Doses should be reduced in renal impairment (see below).

General references.

2. Plosker GL, Figgitt DP. Oral fludarabine. *Drugs* 2003; 63: 2317–23.

Administration in the elderly. US licensed product information states that patients of advanced age are predisposed to increased toxicity from fludarabine, and that such patients should be monitored closely, and the dose modified accordingly. UK licensed product information states that data are limited for patients over the age of 75 years; in patients over the age of 65 years, creatinine clearance (CC) should be measured and patients treated accordingly, see Administration in Renal Impairment, below.

A review[1] stated that fludarabine may be used safely and effectively in older patients, but that supportive measures were important. Response rates tend to be lower in older patients, and dose reductions are recommended in the setting of reduced CC in an effort to minimise treatment-related toxicity.

1. Lichtman SM, *et al.* International Society of Geriatric Oncology Chemotherapy Taskforce: evaluation of chemotherapy in older patients—an analysis of the medical literature. *J Clin Oncol* 2007; 25: 1832–43.

Administration in renal impairment. US licensed product information for intravenous fludarabine recommends that patients with moderate renal impairment, defined as creatinine clearance (CC) of 30 to 70 mL/min per 1.73 m² should have a 20% dose reduction of fludarabine. Fludarabine should not be given to those with severe renal impairment (CC less than 30 mL/min per 1.73 m²).

UK licensed product information for intravenous and oral fludarabine states that for those patients with a CC of between 30 and 70 mL/min, the dose should be reduced by up to 50% and close haematological monitoring used to assess toxicity; the drug is contra-indicated in those with CC less than 30 mL/min.

Administration in subsequent cycles. US licensed product information for *intravenous* fludarabine states that the dose may need to be decreased or treatment delayed based on haematological or non-haematological toxicity; if neurotoxicity occurs, therapy may need to be delayed, or stopped.

UK licensed product information for *oral* fludarabine states that if cell numbers are too low at the start of a subsequent cycle and there is evidence of treatment-related myelosuppression, the planned treatment cycle should be postponed until the granulocyte count is above 1000 cells/mm³ and the platelet count is above 100 000 cells/mm³. Treatment should only be postponed up to a maximum of 2 weeks; if the counts have not recovered after 2 weeks, the daily dose of fludarabine phosphate should be reduced accordingly to the following:

- granulocytes 500 to 1000 cells/mm³ and/or platelets 50 000 to 100 000 cells/mm³: 30 mg/m²
- granulocytes less than 500 cells/mm³ and/or platelets less than 50 000 cells/mm³: 20 mg/m²

The dose is not reduced if thrombocytopenia is disease related. If the patient does not respond to treatment after 2 cycles and shows little or no haematological toxicity, the dose may be increased cautiously in subsequent cycles.

Malignant neoplasms. Fludarabine is the preferred second-line therapy for chronic lymphocytic leukaemia once initial alkylating agent therapy fails,[1] and may also be used for initial therapy (see p. 693.3). It has also been tried in other malignancies. Listed below are some references to the use of fludarabine phosphate for the treatment of chronic lymphocytic leukaemia,[2-4] and its potential activity against a variety of other malignancies, including indolent low-grade non-Hodgkin's lymphoma[5,6] (p. 696.3), mycosis fungoides,[7] heavy chain disease,[8] prolymphocytic leukaemia,[9,10] hairy cell leukaemia,[11] and Waldenström's macroglobulinaemia.[12-14]

Organ and tissue transplantation. Fludarabine is commonly used in non-myeloablative or reduced-intensity conditioning regimens before haematopoietic stem cell transplantation (p. 1937.1).[1,2] Fludarabine-based conditioning appears to be most effective in slowly proliferating malignancies, which give time for a graft-versus-leukaemia effect to develop. Although toxicity is generally mild with fludarabine, graft-versus-host disease is still a significant problem and the optimal conditioning regimen remains to be determined.[1]

1. Carella AM. Treatment of hematological malignancies with allogeneic nonmyeloablative stem cell transplantation: conditioning regimens with fludarabine. *Hematol J* 2004; 5 (suppl 1): S68–S75.
2. Blaise D, *et al.* Current status of reduced-intensity-conditioning allogeneic stem cell transplantation for acute myeloid leukemia. *Haematologica* 2007; 92: 533–41.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p. 726.1, p. 730.2, and p. 732.2.

Bone-marrow suppression from fludarabine is very common and dose-limiting, manifesting as neutropenia, thrombocytopenia, and anaemia; the nadir of the white cell and platelet counts usually occurs after about 13 and 6 days, respectively. Myelosuppression can be severe and cumulative; prolonged lymphopenia with concomitant risk of opportunistic infections may occur. Bone marrow hypoplasia or aplasia resulting in pancytopenia may sometimes be fatal. Careful haematological monitoring is required. Infections can be severe and sometimes fatal; these include opportunistic infections and reactivations of latent viral infections such as herpes zoster, Epstein-Barr virus, and JC virus (causing progressive multifocal leukoencephalopathy). Hepatitis B has been reported; in hepatitis B virus carriers, aggravation of hepatitis or fulminant hepatitis can occur.

Auto-immune disorders (including auto-immune haemolytic anaemia, thrombocytopenic purpura, acquired haemophilia, and Evan's syndrome) have been reported, and may be life-threatening or fatal. Patients should be monitored for signs of haemolysis and therapy stopped if it occurs. Use of fludarabine should be avoided in patients with decompensated haemolytic anaemia.

Peripheral neuropathy is common with fludarabine. Other neurological disturbances include agitation, confusion, visual disturbances, and seizures; high intravenous doses of fludarabine have been associated with severe neurological effects, including blindness, coma, and death.

Other common adverse effects include fever, fatigue, chills, cough, weakness, malaise, anorexia, gastrointestinal disturbances, mucositis, stomatitis, oedema, and rashes. Less commonly, pulmonary toxicity (including pulmonary fibrosis, pneumonitis, and dyspnoea), gastrointestinal haemorrhage, and abnormalities in hepatic or pancreatic enzymes can occur. Tumour lysis syndrome has been reported, especially in patients with large tumour burdens. Rarely reported effects include heart failure, arrhythmias, pemphigus, toxic epidermal necrolysis, and Stevens-Johnson syndrome. Cerebral haemorrhage, pulmonary haemorrhage, and haemorrhagic cystitis can occur.

Exacerbation of existing skin cancer lesions as well as new onset of skin cancer has been reported in some patients. Transfusion-associated graft-versus-host disease has been seen after transfusion of non-irradiated blood in patients treated with fludarabine, and fatalities have occurred; patients should only receive irradiated blood.

Dosage should be reduced in renal impairment (see above).

Carcinogenicity. A study in patients with chronic lymphocytic leukaemia who were treated with fludarabine found that there was no significantly increased risk of secondary malignancy after therapy, despite the immunosuppressive properties of this drug.[1] A review[2] of this and other studies concluded that no significant increase in the risk of secondary malignancy had been shown, but also that long-

term follow-up of patients treated with fludarabine was needed.

1. Cheson BD, *et al.* Second malignancies as a consequence of nucleoside analog therapy for chronic lymphoid leukaemias. *J Clin Oncol* 1999; 17: 2454–60.
2. Van Den Neste E, *et al.* Second primary tumors and immune phenomena after fludarabine or 2-chloro-2′-deoxyadenosine treatment. *Leuk Lymphoma* 2001; 40: 541–50.

Effects on the eyes. See Effects on the Nervous System, below.

Effects on the lungs. Pulmonary toxicity manifest as dyspnoea, fever, hypoxaemia, and radiographic evidence of interstitial and alveolar infiltrates was diagnosed in 9 patients of a cohort of 105 treated with fludarabine.[1] Lung biopsies were performed in 6 patients and showed diffuse chronic interstitial inflammation and fibrosis. Patients with chronic lymphocytic leukaemia appeared to be at greater risk of developing this complication than those with non-Hodgkin's lymphoma.

1. Helman DL, *et al.* Fludarabine-related pulmonary toxicity: a distinct clinical entity in chronic lymphoproliferative syndromes. *Chest* 2002; 122: 785–90.

Effects on the nervous system. High doses (of the order of 100 mg/m^2 daily intravenously) of fludarabine are associated with severe, life-threatening neurotoxicity. However, a few cases of progressive multifocal leukoencephalopathy have also been reported in patients given fludarabine in usual doses.[1-4] The prolonged immunosuppression caused by fludarabine might increase the risk of developing this fatal demyelinating disease, which is caused by opportunistic JC virus infection. Ocular toxicity, including irreversible loss of vision, has also been reported occasionally, including with low-dose regimens.[5]

5. Ding X, *et al.* Ocular toxicity of fludarabine: a purine analog. *Expert Rev Ophthalmol* 2008; 3: 97–109.

Graft-versus-host disease. Transfusion-associated graft-versus-host disease has been reported when blood products were used in patients treated with fludarabine.[1] Fludarabine-treated patients should receive irradiated red cells and platelets (to inactivate any viable T-cells) if they require a transfusion.

1. Williamson LM, *et al.* Fludarabine treatment and transfusion-associated graft-versus-host disease. *Lancet* 1996; 348: 472–3.

Infection. A review[1] of patients treated with fludarabine-containing regimens showed that therapy was associated with serious infections including listeriosis, pneumocystis pneumonia, mycobacterial infections, and opportunistic fungal and viral infections. The risk was exacerbated by previous or current corticosteroid therapy. Prophylactic therapy with co-trimoxazole, triazole antifungals, aciclovir, and colony-stimulating factors was recommended in at-risk patients. A high incidence of herpesvirus infections was also found in another review[2] of patients treated with fludarabine. Combination therapy using chlorambucil and fludarabine resulted in more infections than when either was used alone,[3] but single-agent fludarabine was associated with more major infections and herpesvirus infections than chlorambucil alone. The frequency of serious infection has also been reported[4] to be increased in patients after their conditions became refractory to fludarabine and they were being treated with conventional chemotherapy.

For reports of progressive multifocal leukoencephalopathy caused by opportunistic JC virus infection in patients receiving fludarabine, see Effects on the Nervous System, above.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies fludarabine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

Psoriasis. Although incidental resolution of psoriatic lesions has been reported[1,2] in a few patients being treated with fludarabine, there is also a report[3] of a patient with fulminant exacerbation of psoriatic plaques and generalised erythroderma after starting fludarabine therapy. Symptoms resolved on stopping the drug and treatment with corticosteroids, emollients, and phototherapy.

Interactions

Increased pulmonary toxicity, sometimes fatal, has been reported in patients given fludarabine with pentostatin. Pretreatment with cytarabine may reduce the metabolic activation of fludarabine, but pretreatment with fludarabine results in increased intracellular concentrations of cytarabine—see p. 775.3. The therapeutic efficacy of fludarabine may also be reduced by dipyridamole and other inhibitors of adenosine uptake.

Aminoglycosides. Severe ototoxicity occurred when a short course of *gentamicin* was given to a patient who had recently completed a course of fludarabine.[1]

1. O'Brien RK, Sparling TG. Gentamicin and fludarabine ototoxicity. *Ann Pharmacother* 1995; 29: 200–1.

Corticosteroids. For a suggestion that use of fludarabine with corticosteroids may increase the risk of infection, see Infection, above.

Pharmacokinetics

Intravenous fludarabine phosphate is rapidly dephosphorylated to fludarabine which is taken up by lymphocytes and rephosphorylated via the enzyme deoxycytidine kinase to the active triphosphate nucleotide. Peak intracellular concentrations of fludarabine triphosphate occur about 4 hours after a dose. Fludarabine has a bioavailability of about 50 to 65% after oral doses of the phosphate.

Clearance of fludarabine from the plasma is triphasic with a terminal half-life of about 20 hours. Elimination is mostly via renal excretion: 40 to 60% of an intravenous dose is excreted in the urine. The pharmacokinetics of fludarabine show considerable interindividual variation.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Arg.***: Fludakebir; Fludara; Fluradosa; Forclina; ***Austral.***: Fludara; ***Austria***: Fludara; Neoflubin; ***Belg.***: Fludara; ***Braz.***: Fludalibbs; Fludara; ***Canad.***: Fludara; ***Chile***: Fludara; ***China***: Fludara (福达华); ***Cz.***: Fludara; Tazumara†; ***Denm.***: Fludara; ***Fin.***: Fludara; ***Fr.***: Fludara; ***Ger.***: Bendarabin; Fludara; Neoflubin†; ***Gr.***: Fludara; ***Hong Kong***: Fludara; ***Hung.***: Fludara; ***India***: Fludabine; Fludacel; Fludara; Fludarin; Naprobin; ***Indon.***: Fludara; ***Irl.***: Fludara; ***Israel***: Fludara; ***Ital.***: Fludara; ***Malaysia***: Fludara; ***Mex.***: Beneflur; Fludara†; ***Neth.***: Fludara; ***Norw.***: Fludara; ***NZ***: Fludara; ***Philipp.***: Fludara; ***Pol.***: Fludalym; Fludara; ***Port.***: Fludara; ***Rus.***: Fludara (Флудара); Flugarda (Флугарда); ***S.Afr.***: Fludara; ***Singapore***: Fludara; ***Spain***: Beneflur; ***Swed.***: Fludara; ***Switz.***: Fludara†; ***Thai.***: Fludara; ***Turk.***: Fludara; Flumen; ***UK***: Fludara; ***USA***: Fludara†; Oforta†; ***Venez.***: Fludara.

Pharmacopoeial Preparations

USP 36: Fludarabine Phosphate for Injection; Fludarabine Phosphate Injection.

Fluorouracil *(BAN, USAN, rINN)*

5-Fluorouracil; Fluorouracilas; Fluorouracile; Fluorouracilo; Fluorouracilum; Fluoruracyl; Fluorourasill; 5-Fluorourasil; Fluorourasil; Fluouracil; 5-FU; NSC-19893; Ro-2-9757; WR-69596; Фторурацил.

5-Fluoropyrimidine-2,4(1*H*,3*H*)-dione.

$C_4H_3FN_2O_2$=130.1.

CAS — 51-21-8.
ATC — L01BC02.
ATC Vet — QL01BC02.
UNII — U3P01618RT.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Fluorouracil). A white or almost white, crystalline powder. Sparingly soluble in water; slightly soluble in alcohol. A 1% solution in water has a pH of 4.5 to 5.0. Protect from light.

USP 36: (Fluorouracil). A white to practically white, practically odourless, crystalline powder. Sparingly soluble in water; slightly soluble in alcohol; practically insoluble in chloroform and in ether. Store in airtight containers. Protect from light.

Incompatibility. Preparations of fluorouracil are alkaline, and compatibility problems may be expected with acidic drugs and preparations, or those which are unstable in the presence of alkali. Fluorouracil is reported to be incompatible with cytarabine,[1] diazepam,[2] doxorubicin[2] (and presumably other anthracyclines that are unstable at alkaline pH), and calcium folinate.[3] Although fluorouracil has been stated to be incompatible with methotrexate[4] a study of the long-term stability of an admixture of the 2 drugs in sodium chloride 0.9% injection suggests otherwise.[4]
