Osteomalacia. Vitamin D deficiency, or its abnormal metabolism, is the most usual cause of osteomalacia and rickets (p. 1168.1); however, phosphate depletion may also contribute, and phosphate supplementation may be given as appropriate.

A suggested oral dose for vitamin-D-resistant hypophosphataemic osteomalacia in adults is 65 to 100 mmol phosphate daily. The *BNFC* suggests the following oral phosphate doses:

- for neonates, 1 mmol/kg daily given as a single dose or in 2 divided doses; alternatively it may be given via fortified breast milk
- older children may be given 2 to 3 mmol/kg daily, in 2 to 4 divided doses; a maximum dose of 48 mmol daily is recommended in those up to 5 years of age, and a maximum of 97 mmol daily for those aged 5 years and over.

If parenteral administration is indicated, an intravenous infusion of 1 mmol/kg daily may be given to neonates, 0.7 mmol/kg daily to children aged 1 month to 2 years, and 0.4 mmol/kg daily to those aged 2 to 18 years. Doses should be adjusted as necessary.

RICKETS OF PREMATURITY. Dietary deficiency of phosphorus is unusual, but can occur in small premature infants fed exclusively on human breast milk. The phosphate intake in these infants appears to be inadequate to meet the needs of bone mineralisation, and hypophosphataemic rickets can develop. This condition, variably called metabolic bone disease of prematurity, or rickets of prematurity, can be prevented by ensuring an adequate phosphate intake by very low-birth-weight babies. Adequate intake of calcium and vitamin D is also essential. Phosphate supplementation, with calcium and vitamin D, may be given orally either in formula feeds or as fortification of human breast milk, or intravenously in parenteral nutrition solutions.[1,2]

Dosage recommendations for phosphate may vary, but the *BNFC* suggests a daily dose of 1 mmol/kg; if given orally, this may be as a single dose or in 2 divided doses.

Adverse Effects and Treatment

Excessive doses of intravenous phosphate cause hyperphosphataemia, particularly in patients with renal failure. Hyperphosphataemia leads in turn to hypocalcaemia, which may be severe, and to ectopic calcification, particularly in patients with initial hypercalcaemia. Tissue calcification may cause hypotension and organ damage and result in acute renal failure. Hyperphosphataemia, hypocalcaemia, and tissue calcification are rare after oral or rectal doses (but see Effects on Electrolytes, and Effects on the Kidneys, below).

Adverse effects of oral phosphates may include nausea, vomiting, diarrhoea, and abdominal pain. When they are being used for indications other than their laxative effects, diarrhoea may necessitate a reduction in dosage. Sodium phosphates given rectally for bowel evacuation may cause local irritation.

Phosphates are given as the potassium or sodium salts or both, and may thus be associated with hyperkalaemia, and hypernatraemia and dehydration. Sodium phosphate may cause hypokalaemia.

Treatment of adverse effects involves withdrawal of phosphate, general supportive measures, and correction of serum-electrolyte concentrations, especially calcium. Measures to remove excess phosphate such as oral phosphate binders and haemodialysis may be required (see also Hyperphosphataemia, p. 1776.3).

Effects on electrolytes. Although less common than after intravenous therapy, hyperphosphataemia, accompanied by hypocalcaemia or other severe electrolyte disturbances and resulting in tetany[1,2] and even death,[2] has been reported after the use of phosphate enemas. Similar effects have also been reported with the use of oral phosphate laxatives,[3–7] and in the USA, the FDA has issued warnings of the risk of electrolyte disturbances after the use of high oral doses of sodium phosphate, particularly in vulnerable patients.[8] Infants or children,[2,9,10] the elderly,[4,11] and those with renal impairment,[1,4,11] or congestive heart failure[4] have often had these adverse effects. Licensed product information for one oral sodium phosphate bowel cleanser (*Visicol; Salix, USA*) states that there have been reports of generalised tonic-clonic seizures and/or loss of consciousness in patients with no history of seizures; these cases were associated with electrolyte abnormalities, and low serum osmolality.

Hyperphosphataemia may precipitate nephrocalcinosis, causing an acute phosphate nephropathy, see Effects on the Kidneys, below.

Effects on the kidneys. Acute renal failure and nephrocalcinosis have been reported after the use of oral phosphate-based cathartics for bowel cleansing.[1,2] Although relatively rare with oral preparations, this acute phosphate nephropathy is a serious adverse effect; most patients were left with chronic renal insufficiency, and some developed end-stage renal disease. Potential contributing factors include inadequate hydration, increased age, a history of hypertension and arteriosclerosis, and concurrent use of ACE inhibitors, angiotensin receptor antagonists, diuretics, or NSAIDs.[2] The FDA has issued warnings[3] about the use of oral sodium phosphate products, especially in patients with impaired renal function, hypovolaemia, decreased intravascular volume, or dehydration, or in those taking drugs likely to contribute to the risk of nephropathy. Patients with bowel obstruction or active colitis may also be at risk. Patient advice includes the need to take the correct dose of oral sodium phosphate, to drink sufficient liquid during bowel cleansing, and to avoid other phosphate-containing laxatives. Patients at increased risk should have their electrolytes and renal function monitored.

Nephrocalcinosis has also been reported in children with hypophosphataemic rickets treated with calcitriol and phosphate supplements; this was found to be associated with the phosphate dose.[4]

Local toxicity. Rectal gangrene has been associated with the use of phosphate enemas in elderly patients and was believed to be due to a direct necrotising effect of the phosphate on the rectum.[1]

1. Sweeney JL, *et al.* Rectal gangrene: a complication of phosphate enema. *Med J Aust* 1986; 144: 374–5.

Precautions

Phosphates should not generally be given to patients with severe renal impairment. They should be avoided in patients who may have low serum-calcium concentrations, as these may decrease further, and in patients with infected phosphate renal calculi. Potassium phosphates should be avoided in patients with hyperkalaemia and sodium phosphates should generally be avoided in patients with congestive heart failure, hypertension, and oedema. Serum electrolytes and renal function should be monitored during therapy, particularly if phosphates are given parenterally.

Oral or rectal sodium phosphate preparations for bowel evacuation should not be used in patients with gastrointestinal obstruction, inflammatory bowel disease, and conditions where there is likely to be increased colonic absorption. They should be used cautiously in elderly and debilitated patients, and in those with pre-existing electrolyte disturbances (see Effects on Electrolytes, above).

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies potassium and sodium phosphates as not porphyrinogenic; they may be used as drugs of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/10/11)

Interactions

Oral phosphate supplements should not be used with aluminium, calcium, or magnesium salts as these will bind phosphate and reduce its absorption. Vitamin D increases the gastrointestinal absorption of phosphates and therefore increases the potential for hyperphosphataemia.

Hyperphosphataemia, hypocalcaemia, and hypernatraemia are more likely to occur with phosphate enemas or oral laxatives if these are given to patients receiving diuretics or other drugs that may affect serum electrolytes. The risk of ectopic calcification may be increased by concurrent use of calcium supplements or calcium-containing antacids.

The risk of hyperkalaemia is increased if potassium phosphates are given with drugs that can increase serum-potassium concentrations.

Pharmacokinetics

About two-thirds of ingested phosphate is absorbed from the gastrointestinal tract. Excess phosphate is mainly excreted in the urine, the remainder being excreted in the faeces.

Human Requirements

Phosphorus requirements are usually regarded as equal to those of calcium.

Most foods contain adequate amounts of phosphate, particularly meat and dairy products, hence deficiency is virtually unknown except in certain disease states, in patients receiving total parenteral nutrition, or in those who have received phosphate-binding drugs for prolonged periods; for further details see under Hypophosphataemia, p. 1777.1.

UK and US recommended dietary intake. In the UK dietary reference values (DRV—see Human Requirements, p. 2046.1)[1] and in the USA dietary reference intakes including recommended dietary allowances (RDA)[2] have been published for phosphorus. In the UK the reference nutrient intake (RNI) for adults is about 550 mg (17.5 mmol) daily; no additional amount is recommended for pregnancy although an additional amount of about 440 mg (14.3 mmol) daily is advised during lactation. In the USA the RDA is 1250 mg daily for those aged 9 to 18 years and 700 mg daily in adults; no increase in RDA is recommended during pregnancy and lactation. A tolerable upper intake level of 4 g daily has been set in adults aged up to 70 years; in those older than 70 a maximum of 3 g daily is recommended.[2]

Pharmacopoeial Preparations

BP 2014: Dipotassium Hydrogen Phosphate Injection; Phosphate Oral Solution; Phosphates Enema; Potassium Dihydrogen Phosphate Oral Solution; Sterile Potassium Dihydrogen Phosphate Concentrate;

Ph. Eur.: Anticoagulant Citrate-Phosphate-Glucose Solution (CPD);

USP 36: Anticoagulant Citrate Phosphate Dextrose Adenine Solution; Anticoagulant Citrate Phosphate Dextrose Solution; Multiple Electrolytes and Invert Sugar Injection Type 1; Potassium Phosphates Injection; Sodium Phosphates Injection; Sodium Phosphates Oral Solution; Sodium Phosphates Rectal Solution.

Potassium

Kalium; Potasio; Калий.

K=39.0983

UNII — RWP5GA015D (potassium); 295O53K152 (potassium ion).

Description. Potassium salts covered in this section are those principally given as a source of potassium ions, but consideration should also be given to the effect of the anion. Phosphate salts of potassium are covered under Phosphate, p. 1790.3, and the bicarbonate and citrate salts under Bicarbonate, p. 1780.3.

Potassium Acetate

Acetato potásico; E261; Kalii Acetas; Kalio acetatas; Kaliumacetat; Kálium-acetát; Kaliumasetaatti; Octan draselný; Potasio, acetato de; Potassium, acétate de; Potasu octan; Калия Ацетат; Уксуснокислый Калий.

CH_3CO_2K=98.14

CAS — 127-08-2.

ATC — B05XA17.

ATC Vet — QB05XA17.

UNII — M911911U02.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Potassium Acetate). Deliquescent white or almost white, crystalline powder or colourless crystals. Very soluble in water; freely soluble in alcohol. A 5% solution in water has a pH of 7.5 to 9.0. Protect from moisture.

USP 36: (Potassium Acetate). Colourless, monoclinic crystals, or a white crystalline powder. It is odourless or has a faint acetous odour. Deliquesces on exposure to moist air. Soluble 1 in 0.5 of water, 1 in 0.2 of boiling water, and 1 in 3 of alcohol. pH of a 5% solution in water is between 7.5 and 8.5. Store in airtight containers.

Equivalence. Each g of potassium acetate (anhydrous) represents about 10.2 mmol of potassium. Potassium acetate (anhydrous) 2.51 g is equivalent to about 1 g of potassium.

Potassium Aspartate

Aspartate monopotassique hémihydraté; Kalii Hydrogenoaspartas Hemihydricus; Kalio-divandenillo aspartatas hemihidratas; Kaliumhydrogenaspartat-Hemihydrat; Kaliumhydrogen-aspartát hemihydrát; Kaliumvateaspartathemihydraatti; Kaliumvetyaspartaatti hemihydraatti; Potassium Hydrogen Aspartate Hemihydrate; Калия Аспарат.

Potassium aminosuccinate hemihydrate.

$C_4H_6KNO_4.½H_2O$=180.2

CAS — 7259-25-8 (hemihydrate).

UNII — OC4598NZEO.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Potassium Hydrogen Aspartate Hemihydrate). A white or almost white, powder or crystalline powder, or colourless crystals. Very soluble in water; practically insoluble in alcohol and in dichloromethane. pH of a 2.5% solution in water is between 6.0 and 7.5.

Equivalence. Each g of potassium aspartate represents about 5.5 mmol of potassium. Potassium aspartate 4.61 g is equivalent to about 1 g of potassium.

Potassium Chloride

Chlorid draselný; Cloreto de Potássio; Cloruro potásico; E508; Kalii chloridum; Kalio chloridas; Kalium Chloratum; Kaliumchlorid; Kaliumklorid; Kálium-klorid; Kaliumkloridi; Potasio, cloruro de; Potassium, chlorure de; Potasu chlorek; Хлорид Калия.

KCl=74.55

CAS — 7447-40-7.

ATC — A12BA01; B05XA01.

ATC Vet — QA12BA01; QB05XA01.

UNII — 660YQ98I10.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 8: (Potassium Chloride). A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; practically insoluble in dehydrated alcohol.

USP 36: (Potassium Chloride). Colourless, elongated, prismatic, or cubical crystals, or a white, granular powder. Is odourless. Soluble 1 in 2.8 of water, and 1 in 2 of boiling water; insoluble in alcohol. Its solutions are neutral to litmus.

Equivalence. Each g of potassium chloride represents about 13.4 mmol of potassium. Potassium chloride 1.91 g is equivalent to about 1 g of potassium.

Potassium Gluconate

E577; Gluconato potásico; Potasio, gluconato de; Калия Глюконат.

Potassium D-gluconate.

$CH_2OH.[CH(OH)]_4.CO_2K$=234.2

CAS — 299-27-4 (anhydrous potassium gluconate); 35398-15-3 (potassium gluconate monohydrate).

ATC — A12BA05.

ATC Vet — QA12BA05.

UNII — 12H3K5QKN9.

Pharmacopoeias. In *Fr.*

US permits anhydrous or the monohydrate.

USP 36: (Potassium Gluconate). It is anhydrous or contains one molecule of water of hydration. A white or yellowish-white, odourless, crystalline powder or granules. Soluble 1 in 3 of water; practically insoluble in dehydrated alcohol, in chloroform, in ether, and in benzene. Its solutions are slightly alkaline to litmus. Store in airtight containers.

Equivalence. Each g of potassium gluconate (anhydrous) represents about 4.3 mmol of potassium. Each g of potassium gluconate (monohydrate) represents about 4 mmol of potassium. Potassium gluconate (anhydrous) 5.99 g and potassium gluconate (monohydrate) 6.45 g are each equivalent to about 1 g of potassium.

Potassium Sulfate *(USAN)*

E515; Kalii Sulfas; Kalio sulfatas; Kalium Sulfuricum; Kaliumsulfaatti; Kaliumsulfat; Potasio, sulfato de; Potassii Sulphas; Potassium, sulfate de; Potassium Sulphate; Síran draselný; Sulfato potásico; Tartarus Vitriolatus; Калия Сульфат.

K_2SO_4=174.3

CAS — 7778-80-5.

UNII — 1K573LC5TV.

Pharmacopoeias. In *Eur.* (see p. vii) and *Jpn.*

Ph. Eur. 8: (Potassium Sulfate). A white or almost white, crystalline powder or colourless crystals. Soluble in water; practically insoluble in dehydrated alcohol.

Equivalence. Each g of potassium sulfate represents about 11.5 mmol of potassium. Potassium sulfate 2.23 g is equivalent to about 1 g of potassium.

Potassium Tartrate

E336; Potasio, tartrato de; Potasu winian; Tartrato potásico; Тартрат Калия.

$C_4H_4K_2O_6.½H_2O$=235.3

CAS — 921-53-9 (anhydrous potassium tartrate).

UNII — O9WLL1ZL8S.

Equivalence. Each g of potassium tartrate (hemihydrate) represents about 8.5 mmol of potassium. Potassium tartrate (hemihydrate) 3.00 g is equivalent to about 1 g of potassium.

Uses and Administration

Potassium salts in this section are used for the prevention and treatment of potassium depletion and/or **hypokalaemia** (p. 1777.2) and have been used in the prevention of **diuretic-induced hypokalaemia** (see Hydrochlorothiazide, Effects on Electrolyte Balance, p. 1404.2). Doses may be expressed in terms of mmol or mEq of potassium, mass (mg) of potassium, or mass of potassium salt (for comparative purposes see Table 3, below). Treatment should be monitored by plasma-potassium estimations because of the risk of inducing hyperkalaemia, especially where there is renal impairment.

Potassium chloride is probably the most commonly used potassium salt; this is because hypochloraemic alkalosis, which is often associated with hypokalaemia, can be corrected by the chloride ions. An alkalinising salt such as potassium acetate, potassium bicarbonate, or potassium citrate may be preferable if a metabolic acidosis, such as occurs in renal tubular acidosis, accompanies the hypokalaemia (see p. 1775.2). Other salts that are or have been used in the management of potassium deficiency include potassium ascorbate, potassium aspartate, potassium benzoate, potassium gluceptate, potassium gluconate, potassium phosphate, and potassium tartrate. Typical doses for the prevention of hypokalaemia may be up to 50 mmol daily and similar doses may be adequate in mild potassium deficiency. However, higher doses may be needed in more severe deficiency. Patients with renal impairment should receive correspondingly lower doses. *Oral* treatment is used for prophylaxis and is also suitable for treating most cases of hypokalaemia. Oral potassium salts are more irritating than the corresponding sodium salts; they should be taken with or after meals with plenty of fluid; liquid preparations are preferable.

An *intravenous* potassium salt may be required in severe acute hypokalaemia. This normally entails infusing a solution containing 20 mmol of potassium in 500 mL over 2 to 3 hours under ECG control. A recommended maximum dose is 2 to 3 mmol/kg of potassium in 24 hours. Higher concentrations have been given when an infusion pump has been used (see Administration p. 1794.1). Adequate urine flow must be ensured and careful monitoring of plasma-potassium and other electrolyte concentrations is essential. Potassium chloride is the salt most commonly used and solutions intended for intravenous use that are in a concentrated form (such as 1.5 or 2 mmol/mL) *must* be diluted to the appropriate concentration before use. There should be careful and thorough mixing when adding concentrated potassium chloride solutions to infusion fluids. Potassium chloride is also available as premixed infusions with sodium chloride and/or glucose containing 10 to 40 mmol/litre of potassium (but see also Administration, p. 1794.1). Potassium acetate is also given intravenously.

Amongst **other uses**, the sulfate, and tartrate salts of potassium have been given orally as osmotic laxatives (p. 1804.1).

Some potassium salts are used as sodium-free condiments when sodium intake must be restricted.

Potassium chloride is sometimes used as an excipient in pharmaceutical formulations.

Table 3. Some potassium salts and their potassium content.

	Potassium content per g		
Potassium salt	mg	mmol	mEq
Potassium acetate (anhydrous)	398	10.2	10.2
Potassium aspartate	217	5.5	5.5
Potassium bicarbonate	391	10.0	10.0
Potassium chloride	524	13.4	13.4
Potassium citrate (anhydrous)	383	9.8	9.8
Potassium citrate (monohydrate)	361	9.3	9.3
Potassium gluconate (anhydrous)	167	4.3	4.3
Potassium gluconate (monohydrate)	155	4.0	4.0
Potassium sulfate (anhydrous)	449	11.5	11.5
Potassium tartrate (hemihydrate)	332	8.5	8.5

Administration. The standard concentration and rate of administration of potassium chloride for infusion is discussed in Uses and Administration, p. 1793.3. However, higher concentrations (200 or 300 mmol/litre) and faster infusion rates have been used, via an infusion pump, for cases of severe symptomatic hypokalaemia, especially with fluid overload.[1,2]

There has been controversy regarding the preferred route of administration of these higher concentrations of potassium chloride.[1] The central route avoids the problems of pain and phlebitis when potassium is given peripherally. However, it has been suggested that high concentrations of potassium given centrally may carry a greater risk of cardiac toxicity if the infusion is carried directly to the heart. Use of lidocaine has improved tolerability of peripheral administration of potassium chloride.[2]

Intravenous potassium is usually given in sodium chloride and/or glucose infusion. However, it has been pointed out that glucose can reduce serum-potassium concentrations, and that glucose-free solutions should be used for the initial intravenous administration of potassium in hypokalaemia.[3]

Diabetic ketoacidosis. As discussed under Diabetic Emergencies on p. 465.3, potassium replacement is given in diabetic ketoacidosis to restore total body stores of potassium and thereby prevent the hypokalaemia induced by insulin.

Hypertension. A meta-analysis[1] has reported that potassium supplementation reduces both systolic and diastolic blood pressure. The size of the effect in hypertensive patients was great enough to suggest a possible role in the treatment of hypertension (p. 1251.1); effects in normotensive subjects were less marked but consistent with a similar role for preventing hypertension. Most studies have used potassium chloride, but an effect has also been found with the aspartate[2] and the citrate.[3]

Myocardial infarction. A glucose, insulin, and potassium infusion has been investigated in acute myocardial infarction (see p. 482.3).

Termination of pregnancy. Solutions of potassium chloride are used to reduce fetal numbers in multifetal pregnancies[1-3] or for severe fetal malformation by abolishing the fetal cardiac activity. The solution is injected into the thorax of the fetus without affecting the others, which are allowed to continue to term. Alternatively, potassium chloride may be injected into the umbilical vein when access to the fetal heart is difficult. A retrospective comparison[4] found both techniques to be effective. Significantly smaller doses were required for the umbilical route, possibly because a sustained dose is delivered directly to the fetal heart and myocardium, compared with intraventricular injection.

Adverse Effects

Excessive doses of potassium may lead to the development of hyperkalaemia (p. 1777.1), especially in patients with renal impairment. Symptoms include paraesthesia of the extremities, muscle weakness, paralysis, cardiac arrhythmias, heart block, cardiac arrest, and confusion. Cardiac toxicity is of particular concern after intravenous dosage.

Pain or phlebitis may occur when given intravenously via peripheral veins, particularly at higher concentrations.

Nausea, vomiting, diarrhoea, and abdominal cramps may occur with oral potassium salts. There have been numerous reports of gastrointestinal ulceration, sometimes with haemorrhage and perforation or with the late formation of strictures, after the use of enteric-coated tablets of potassium chloride. Ulceration has also occurred after the use of sustained-release tablets.

Treatment of Adverse Effects

The treatment of hyperkalaemia discussed on p. 1777.1 also applies when hyperkalaemia occurs during potassium therapy. However, in mild hyperkalaemia that has developed on long-term treatment, stopping the potassium supplement and other drugs that may increase plasma-potassium concentrations, and avoidance of foods with a high potassium content may be sufficient to correct the hyperkalaemia.

In cases of acute oral overdosage of potassium supplements, the stomach should be emptied by gastric lavage in addition to the measures described on p. 1777.1.

Precautions

Potassium salts should be given with considerable care to patients with cardiac disease or conditions predisposing to hyperkalaemia such as renal or adrenocortical insufficiency, acute dehydration, or extensive tissue destruction as occurs with severe burns. Excessive use of potassium-containing salt substitutes or potassium supplements may lead to accumulation of potassium especially in patients with renal insufficiency. Regular monitoring of clinical status, serum electrolytes, and the ECG is advisable in patients receiving potassium therapy, particularly those with cardiac or renal impairment.

Liquid or effervescent preparations are preferred to solid dosage forms for oral use; use of the former, with or after food, may reduce gastric irritation. Solid oral dosage forms of potassium salts should not be given to patients with gastrointestinal ulceration or obstruction. They should be given with care to patients in whom passage through the gastrointestinal tract may be delayed, as in pregnant patients. Treatment should be stopped if severe nausea, vomiting, or abdominal distress develops.

Potassium chloride should not be used in patients with hyperchloraemia.

Direct injection of potassium chloride concentrates without appropriate dilution may cause instant death. For the view that glucose-containing solutions should not be used for the initial intravenous administration of potassium in hypokalaemia see Administration, above.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies potassium chloride as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/10/11)

Interactions

Potassium supplements should be used with caution, if at all, in patients receiving drugs that increase serum-potassium concentrations. These include potassium-sparing diuretics, ACE inhibitors, ciclosporin, and drugs that contain potassium such as the potassium salts of penicillin. Similarly, the concomitant use of potassium-containing salt substitutes for flavouring food should be avoided. Antimuscarinics delay gastric emptying and consequently may increase the risk of gastrointestinal adverse effects in patients receiving solid oral dosage forms of potassium.

Pharmacokinetics

Potassium salts other than the phosphate, sulfate, and tartrate are generally readily absorbed from the gastrointestinal tract. Potassium is excreted mainly by the kidneys; it is secreted in the distal tubules in exchange for sodium or hydrogen ions. Some potassium is excreted in the faeces and small amounts may also be excreted in sweat.

Human Requirements

Potassium is an essential body electrolyte. However, requirements are difficult to determine and have been estimated from the amount accumulated during growth and reported urinary and faecal excretion.

Over 90% of dietary potassium is absorbed from the gastrointestinal tract. Potassium is particularly abundant in vegetables, potatoes, and fruit.

UK and US recommended dietary intake. In the UK dietary reference values (DRV—see Human Requirements, p. 2046.1)[1] have been estimated for potassium. The reference nutrient intake (RNI) for adults is 3.5 g (90 mmol) daily. In the USA, no recommended dietary allowance (RDA) has been established for potassium. However a daily intake of 1.6 to 2 g (40 to 50 mmol) is considered adequate for adults.

Sodium

Natrium; Sód; Sodio; Натрий.
Na=22.98976928
UNII — 9NEZ333N27 (sodium); LYR4M0NH37 (sodium ion).

Description. Sodium chloride is the principal sodium salt used as a source of sodium ions. Sodium salts used chiefly as sources of bicarbonate ions, such as the acetate, bicarbonate, citrate, and lactate, are covered under Bicarbonate, p. 1780.3. Phosphate salts of sodium are covered under Phosphate, p. 1790.3.

Sodium Chloride

Chlorid sodný; Chlorure de Sodium; Cloreto de Sódio; Cloruro sódico; Natrii Chloridum; Natrio chloridas; Natrium-chlorid; Natriumklorid; Nátrium-klorid; Natriumkloridi; Salt; Sodio, cloruro de; Sodium, chlorure de; Sodu chlorek; Sodyum Klorür; Натрия Хлорид.
NaCl=58.44
CAS — 7647-14-5.
ATC — A12CA01; B05CB01; B05XA03.
ATC Vet — QA12CA01; QB05CB01; QB05XA03.
UNII — 451W47IQ8X.

NOTE. An aqueous solution of sodium chloride 0.9% is often known as physiological saline.

SALINE is a code approved by the BP 2014 for use on single unit doses of eye drops containing sodium chloride 0.9% where the individual container may be too small to bear all the appropriate labelling information. HECL is a similar code approved for hyetellose and sodium chloride eye drops.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 8: (Sodium Chloride). A white or almost white, crystalline powder or colourless crystals or white or almost white pearls. Freely soluble in water; practically insoluble in dehydrated alcohol.

USP 36: (Sodium Chloride). Colourless cubic crystals or white crystalline powder. Soluble 1 in 2.8 of water, 1 in 2.7 of boiling water, and 1 in 10 of glycerol; slightly soluble in alcohol.

Equivalence. Each g of sodium chloride represents about 17.1 mmol of sodium and of chloride. Sodium chloride 2.54 g is equivalent to about 1 g of sodium.

Storage. Solutions of some sodium salts, including sodium chloride, when stored, may cause separation of solid particles from glass containers and solutions containing such particles must not be used.

Uses and Administration

Sodium chloride is used in the management of deficiencies of sodium and chloride ions in salt-losing conditions (see Hyponatraemia, p. 1778.1). Sodium chloride solutions are used as a source of sodium chloride and water for hydration.

A 0.9% solution in water is iso-osmotic, and thus in most cases isotonic with serum and lachrymal secretions. Doses may be expressed in terms of mEq or mmol of sodium, mass (mg) of sodium, or mass of sodium salt (for comparative purposes, see Table 4, below).

A typical oral replacement dose of sodium chloride in **chronic salt-losing conditions** is about 2.4 to 4.8 g (about 40 to 80 mmol of sodium) daily as a modified-release preparation, accompanied by a suitable fluid intake; doses of up to 12 g daily may be necessary in severe cases. Oral supplements are also used for the prevention of muscle cramps during routine haemodialysis (p. 1779.3); a suggested dose is about 6 to 10 g of a modified-release preparation per dialysis session.

Glucose facilitates the absorption of sodium from the gastrointestinal tract, and solutions containing sodium chloride and glucose usually with additional electrolytes (see p. 1780.1) are used for oral rehydration in acute diarrhoea (p. 1805.2).

Table 4. Some sodium salts and their sodium content.

Sodium salt	Sodium content per g		
	mg	mmol	mEq
Sodium acetate (anhydrous)	280	12.2	12.2
Sodium acetate (trihydrate)	169	7.3	7.3
Sodium acid citrate	175	7.6	7.6
Sodium bicarbonate	274	11.9	11.9
Sodium chloride	394	17.1	17.1
Sodium citrate (anhydrous)	267	11.6	11.6
Sodium citrate (dihydrate)	235	10.2	10.2
Sodium lactate	205	8.9	8.9

The concentration and dosage of sodium chloride solutions for intravenous use is determined by several factors including the age, weight, and clinical condition of the patient and in particular the patients' hydration state. Serum-electrolyte concentrations should be carefully monitored. In severe sodium depletion, 2 to 3 litres of sodium chloride 0.9% may be given over 2 to 3 hours and thereafter at a slower rate. If there is combined water and sodium depletion a 1 to 1 mixture of sodium chloride 0.9% and glucose 5% may be appropriate. Although hypertonic sodium chloride solutions may be used in certain patients with severe acute dilutional hyponatraemia, over-rapid correction may have severe neurological adverse effects (see Hyponatraemia, p. 1778.1). Solutions containing 1.8 to 5% are available.

In **hypernatraemia** with volume depletion (p. 1778.1), sodium chloride 0.9% may be used to maintain plasma-sodium concentrations with expanding fluid volume. Sodium chloride 0.9% (or rarely, in marked hypernatraemia, 0.45%) is used for fluid replacement in diabetic ketoacidosis (see Diabetic Emergencies, p. 465.3).

Among its **other uses**, sodium chloride solution 0.9%, being isotonic, is a useful fluid for sterile irrigations, for example, of the eye or bladder, and general skin or wound cleansing. The 0.9% concentration is also widely used as a vehicle or diluent for the parenteral administration of other drugs. Nasal drops of sodium chloride 0.9% are used to relieve nasal congestion. A mouthwash containing sodium chloride is also available for oral hygiene.

Sodium chloride in the form of sea water or sea salt (see p. 2612.1) has been also used for nasal irrigations.

Sodium chloride solutions should *not* be used to induce emesis; this practice is dangerous and deaths from resulting hypernatraemia have been reported.

Sodium chloride is sometimes used as an excipient in capsules and tablets.

Homoeopathy

Sodium chloride has been used in homoeopathic medicines under the following names: Natrium muriaticum; Nat. Mur.; Natrii chloridum; Natricum chloratum; Natrum muriaticum.

NOTE. Do not confuse Natricum chloratum with sodium chlorate (p. 2618.1).

Catheters and cannulas. For reference to sodium chloride 0.9% being used to maintain the patency of catheters and cannulas, and to its equivalent efficacy to heparin, see Catheters and Cannulas under Uses and Administration of Heparin, p. 1398.1.

Cystic fibrosis. Inhalation of 4 mL of a hypertonic solution of sodium chloride (7%) twice daily for 48 weeks in 82 patients with stable cystic fibrosis (p. 177.2) was associated with a moderate but sustained improvement in lung function and a marked reduction in the number of exacerbations and need for antibacterials, when compared with 80 placebo-treated patients.[1] There was, however, no difference in the rate of change of lung function. Each inhalation was preceded by a bronchodilator to minimise airway narrowing; adverse reactions to the active treatment were nonetheless reported in 14 patients and included cough, chest tightness or pharyngitis, sinusitis, haemoptysis, sneezing, and vomiting. As a result, 6 patients withdrew from the study, but the effects resolved in the remainder without the need for dose reduction or interruption. Hypertonic saline was considered to be an inexpensive and safe adjunctive therapy in patients with cystic fibrosis.

1. Elkins MR, *et al.* A controlled trial of long-term inhaled hypertonic saline in patients with cystic fibrosis. *N Engl J Med* 2006; 354: 229–40.

Termination of pregnancy. Trans-abdominal intra-amniotic instillation of sodium chloride 20% (maximum volume 200 to 250 mL) has been used for the termination of second-trimester pregnancy. However, serious adverse effects have occurred (see below), and other methods are generally preferred (p. 2131.3).

Adverse Effects

Adverse effects of sodium salts are attributable to electrolyte imbalances from excess sodium; there may also be effects due to the specific anion.

Retention of excess sodium in the body usually occurs when there is defective renal sodium excretion. This leads to the accumulation of extracellular fluid to maintain normal plasma osmolality, which may result in pulmonary and peripheral oedema and their consequent effects.

Hypernatraemia (a rise in plasma osmolality) is usually associated with inadequate water intake, or excessive water losses (see p. 1778.1). It rarely occurs after therapeutic doses of sodium chloride, but has occurred with the use of hypertonic saline for induction of emesis or for gastric lavage and after errors in the formulation of infant feeds. Hypernatraemia may also occur after inappropriate intravenous use of hypertonic saline.

The most serious effect of hypernatraemia is dehydration of the brain which causes somnolence and confusion progressing to convulsions, coma, respiratory failure, and death. Other symptoms include thirst, reduced salivation and lachrymation, fever, sweating, tachycardia, hypertension or hypotension, headache, dizziness, restlessness, irritability, weakness, and muscular twitching and rigidity.

Gastrointestinal effects associated with acute oral ingestion of hypertonic solutions or excessive amounts of sodium chloride include nausea, vomiting, diarrhoea, and abdominal cramps.

Excessive use of chloride salts may cause a loss of bicarbonate with an acidifying effect.

Intra-amniotic injection of hypertonic solutions of sodium chloride, which has been used for termination of pregnancy, has been associated with serious adverse effects including disseminated intravascular coagulation, renal necrosis, cervical and uterine lesions, haemorrhage, pulmonary embolism, pneumonia, and death.

Treatment of Adverse Effects

In patients with mild sodium excess, drinking water and restricting sodium intake is sufficient. However, in the event of recent acute oral overdose of sodium chloride, gastric lavage should be carried out along with general symptomatic and supportive treatment. Serum-sodium concentrations should be measured, and if severe hypernatraemia is present this should be treated (see p. 1778.1).

Precautions

Sodium salts should be used with caution in patients with hypertension, heart failure, peripheral or pulmonary oedema, renal impairment, pre-eclampsia, or other conditions associated with sodium retention.

When sodium supplements are given orally, adequate water intake should be maintained. Modified-release tablets should not be given to patients with gastrointestinal disorders associated with strictures or diverticula because of the risk of obstruction.

Sodium chloride solutions should *not* be used to induce emesis; this practice is dangerous and deaths from resulting hypernatraemia have been reported.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sodium chloride as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 26/10/11)

Pharmacokinetics

Sodium chloride is well absorbed from the gastrointestinal tract. Excess sodium is mainly excreted by the kidney, and small amounts are lost in the faeces and sweat.

Human Requirements

The body contains about 4 mol (92 g) of sodium of which about one-third is found in the skeleton and about half is present in the extracellular fluid.

The body can adapt to a wide range of intakes by adjustment of renal excretion through physical and hormonal factors. Loss through the skin is significant only if excessive sweating occurs. Sodium requirements may be increased with exercise or exposure to high ambient temperatures in the short term, until the body adjusts.

Sodium is widely available in foods and is also added as salt during processing, cooking, and at the table. Dietary deficiency of sodium is therefore extremely rare and more concern has been expressed that current intakes are excessive. Restriction of sodium intake, by limiting the amount of culinary salt consumed, may be a useful aid in the management of some patients with hypertension (p. 1251.1).

UK and US recommended dietary intake. In the UK dietary reference values (DRV—see Human Requirements, p. 2046.1)[1] have been published for sodium. The reference nutrient intake (RNI) for adults is 1.6 g of sodium (70 mmol) daily, which is about 4 g of sodium chloride. In

the USA, it has been recommended that daily intakes of sodium be limited to 2.4 g (6 g of sodium chloride) or less.[2] Dietary intake is often in excess of these recommendations, and may be a factor in essential hypertension,[3] and osteoporosis.[4] A possible association with cardiovascular disease has also been suggested by the long-term follow-up of two hypertension studies.[5] Results found that reducing sodium intake may also reduce the risk of cardiovascular events.

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Aqua Lent Limpia Cristales; Cutidermin Bebe Gel Nasal†; Hypersol; Larmabak; Muro 128; Oftalook; Relente; Suaviler; Xylisol; Yusin Tears I; *Austral.*: Dimetapp Infants Nasal Relief; Ear Clear Ear Cleanser; Fess; Hypergel; Lens Plus; Mesalt; Narium; Normlgel; Otrivin Saline Baby; Sensitive Eyes Saline; Slow-Sodium; *Austria*: Kochsalz; SmartDose†; *Belg.*: Natriclo; Physiologica; Physiorhine; *Braz.*: Advnasal†; Afrin Natural; Alive; Conidrin Baby; Conidrin Salina; Deltasoro; Descodrin; Fisiorinus; Fluimare; Fluimucil Solucao Nasal; Maresis; Maxidrate; Multisoro; Naridrin Bebe; Naridrin H; Narisoro; Neorino; Neosoro H; Neosoro Infantil; Novo Rino-S; Pratsorin; Rinoben; Rinoflux†; Rinosoft S; Rinosoro; Salsep; Sinustrat Solucao Natural; Snif; Sonarin (INF); Sorine Pediatrico; Sorine; Sorofar; Soroliv; Soroneo; *Canad.*: Hypergel; Mesalt; Muro 128; Nebusal; Normigel; Rhinaris Sinus; Salinex; Sea Clens†; Softwear†; Thalanex†; Thalaris†; *Chile*: Fisiolimp; Larmabak†; Pediasea; Printan; Respirex†; Rinodan; Rinokid; Rinosteryl; Sinus; *China*: Ai Na Duo (艾那多); *Fin.*: Natrosteril†; Selutrio; *Fr.*: Erjean; Hypergel; Jelly-wash; Larmabak; Larmes Artificielles; Multilarm†; Normlgel; Physiologica†; Polyrinse†; Selgine; *Ger.*: Adsorbonac†; Freka-Drainjet†; Hylase; Isogutt akut; Isotone Kochsalz; Isotonische Kochsalzlosung; Olynth salin; Omni-Sorb; Tetrisal; Tussamag Nasenspray Pur†; Urgo sterile; *Gr.*: Babynose; Clinofar; Larmabak; Otrisalin; Phy-O; Rhinodose; Selva N; *Hong Kong*: Ayr Saline†; Earinse; Larmabak; Nasal Physiological Solution; Physiodose; Unison Enema; *Hung.*: Rins-Sal; Salsol A†; *India*: Hold; Hynasal; Hypersol; Hytosol; Izabel; Libna; Nam Cold-NS; Nasalt; Nasivion-S; Nasoclear; Nipit; Nos-Air Saline; Ocutone; Osmogel; Otrivin-S; *Indon.*: Breathy; Infusan-NS; Otsu-NS; Wida NS; Wida NSI; *Irl.*: Diarrest RF†; *Israel*: Af-Kid; Af-Tiponet; Alrin Baby; Baby AF; Baby Saline†; Clean-AF; L'Batzeket; Moviprep; Normasol; Ocean Spray; Otrivini; Tinok AF; Tipotaf; *Ital.*: Adsorbonac†; Hydrabak; Libenar; Narhinel; Otrivin Baby†; Physiodose; Respifree Baby; Rinowash; *Mex.*: Corni Limp; Hiperton; Muro 123; Phylarm; *Mon.*: Unilarm; *NZ*: Narium; *Philipp.*: Hypersalt; Hyperton-Opta; Larmabak†; Muconase; SalinaGel; Salinase; Snif; *Pol.*: Oftarinol; Solnasin†; *Port.*: Extraneal; *Rus.*: Aquamaster (Аквамастер); Rizosin (Ризосин); Salin (Салин); *S.Afr.*: Polyrinse†; Vicks Vapomist†; *Singapore*: Adsorbonac†; Dorama-neo; Larmabak; Normasol; Oftalmolosa Cusi Antiedema†; Otrivin Saline Nasal Spray; Salacyn; *Spain*: Antiedema; Apiroserum Clorurado; Fisiologica†; Fisiologico Bieffe Medital†; Fisiologico Braun; Fisiologico Mein; Fisiologico Serra Pamies†; Fisiologico Vitulia†; Fisiologico†; Flebobag Fisio; Fleboflex Salina Fisiologica†; Fleboplast Fisio; Freeflex Cloruro Sodico; Hidrathea; Meinvenil Fisiologico†; Plast Apyr Fisiologico; Solucion Fisiologica Respitol; Suero Fisiologico; Suero Fisiologico; *Switz.*: Physiologic; Physiosoin†; Serophy; *Thai.*: Patar Enema; Royal-C; U-Enema; Unison Enema; *Turk.*: Berko-Fiz; Droser; Fizyolen; Fizyolik; Fizyosol; Larmabak; Otrisalin; Physiodese; Physiologica Gifrer; Ser Damla†; Serum Fizyolojik; *UAE*: Normaline; *UK*: Askina; Equaleze; Irriclens; Irripod; Miniversol; MucoClear; Nasosal; Nebusal; Normasol; Slow-Sodium; SodiClor; Stericlens; Steripod; Tubilux; Uriflex S; Uro-Tainer M; Versol; *Ukr.*: No-Sol (Но-Соль); *USA*: Adsorbonac†; Ak-NaCl; Ayr Saline; Breathe Free; Broncho Saline; Dristan Saline Spray; Entsol; HuMist Nasal Mist; Marlin Salt System†; Muro 128; Muroptic; Nasal Moist; NaSal; Normaline; Ocean; Pretz; Rhinaris; Salinex; SeaMist; Sochlor; Your Choice†; *Venez.*: Larmabak; Nafavine.

Multi-ingredient Preparations. Numerous preparations are listed in Volume B.

Homoeopathic Preparations. *Austral.*: Allergy Relief; Childrens Runny Nose Relief; Respatona Head Cold; Vitatona Energy†; *Austria*: Globuli gegen Hautausschlage; *Canad.*: Adrisin†; Calms Forte 4 Kids; Cold Sores & Fever Blisters; Combinaison†; Diamite; Eczema; Hives; Homeoknop Bioactiv O Weight Loss Aid†; Homeoknop Ikoplex 13†; Hylands Bioplasma; Hylands Vaginitis†; Hylavir FB†; Ikoplex 11 Digestion Aid†; Ikoplex 14†; Melange†; Nuage Bioplasma†; Sore Throat L39†; Sorinoheel; *Chile*: Anacardio con Fosforo; Bioactiv M; Bioactiv O; Bioactiv P; Ikoplex No 11; Ikoplex No 13; Ikoplex No 14; Ikoplex No 17; Ikoplex No 19; Ikoplex No 6; Ikoplex No 7; Ikoplex No 8; *Fr.*: Billerol; Pulsatilla Complexe No 60†; Soludor; *Ger.*: Derivatio H; Drufusan N†; Drufusan; Herpes-Gastreu R68; Hewelymphon N†; Muco-cyl L Ho-Len-Complex; Nuxal comp; Schleimhaut-Komplex L Ho-Fu-Complex; *Neth.*: Ailgeno spag; Hemorrolite; Urtizon complex; *Rus.*: Diet-Comfort (Диет-Комфорт); *Switz.*: Regenaplex Nr 28b.

Pharmacopoeial Preparations

BP 2014: Compound Glucose, Sodium Chloride and Sodium Citrate Oral Solution; Compound Sodium Chloride Mouthwash; Compound Sodium Lactate Infusion; Oral Rehydration Salts; Potassium Chloride and Sodium Chloride Infusion; Potassium Chloride, Sodium Chloride and Glucose Infusion; Sodium Chloride and Glucose Infusion; Sodium Chloride Eye Drops; Sodium Chloride Eye Lotion; Sodium Chloride Eye Ointment; Sodium Chloride Infusion; Sodium Chloride Irrigation Solution; Sodium Chloride Nebuliser Solution; Sodium Chloride Oral Solution; Sodium Chloride Solution; Soluble Sodium Chloride Tablets;

USP 36: Bacteriostatic Sodium Chloride Injection; Cimetidine in Sodium Chloride Injection; Cisplatin for Injection; Dextran 40 in Sodium Chloride Injection; Dextran 70 in Sodium Chloride Injection; Dextrose and Sodium Chloride Injection; Fructose and Sodium Chloride Injection; Half-strength Lactated Ringer's and Dextrose Injection; Inulin in Sodium Chloride Injection; Lactated Ringer's and Dextrose Injection; Lactated Ringer's Injection; Mannitol in Sodium Chloride Injection; Multiple Electrolytes and Dextrose Injection Type 1; Multiple Electrolytes and Dextrose Injection Type 2; Multiple Electrolytes and Dextrose Injection Type 3; Multiple Electrolytes and Dextrose Injection Type 4; Multiple Electrolytes and Invert Sugar Injection Type 1; Multiple Electrolytes and Invert Sugar Injection Type 2; Multiple Electrolytes and Invert Sugar Injection Type 3; Multiple Electrolytes Injection Type 1; Multiple Electrolytes Injection Type 2; Oral Rehydration Salts; PEG 3350 and Electrolytes for Oral Solution; Potassium Chloride in Dextrose and Sodium Chloride Injection; Potassium Chloride in Lactated Ringer's and Dextrose Injection; Potassium Chloride in Sodium Chloride Injection; Ringer's and Dextrose Injection; Sodium Chloride and Dextrose Tablets; Sodium Chloride Inhalation Solution; Sodium Chloride Injection; Sodium Chloride Irrigation; Sodium Chloride Ophthalmic Ointment; Sodium Chloride Ophthalmic Solution; Sodium Chloride Tablets for Solution; Sodium Chloride Tablets.

Gases

This chapter includes monographs on gases with medical or pharmaceutical uses and applications (such as oxygen, carbon dioxide, helium, and nitrogen) and some whose main medical interest is management of their toxicity or adverse effects (such as carbon monoxide or hydrogen sulfide). Also included are some compressed and liquefied gases used as refrigerants and aerosol propellants. Nitric oxide gas is used in bronchopulmonary disorders and is discussed in Cardiovascular Drugs (p. 1457.1). Other gases with medical uses can be found in Disinfectants and Preservatives (p. 1730.1) and General Anaesthetics (p. 1896.1).

Refrigerants and Aerosol Propellants

Some gases have properties that make them suitable for use as refrigerants and as aerosol propellants; these include nitrogen, nitrous oxide, carbon dioxide, and hydrocarbons such as propane, and the butanes. Chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) have been widely used but are generally being phased out due to their environmental effects, particularly depletion of the ozone layer. Nonchlorinated fluorocarbons (hydrofluorocarbons; HFCs) do not affect the ozone layer (although they may contribute to global warming) and are a possible alternative; however, their physical properties may be less suitable. Ammonia gas (see p. 2441.2) may be used as an industrial refrigerant.

The evaporation of propellants such as halogenated hydrocarbons and dimethyl ether produces an intense cold. Topical application has a numbing effect on tissues and has been used for analgesia (see Rubefacients and Topical Analgesia, p. 6.3), although cold injury, including frostbite, has been reported.

Refrigerants and aerosol propellants have been subject to deliberate abuse. They have similar effects to volatile solvents (see Abuse, under Adverse Effects of Toluene, p. 2216.3), and both acute and chronic toxicity may occur. Inhalation of high concentrations of halogenated hydrocarbons for their euphoriant effect may result in CNS depression, cardiac arrhythmias, respiratory depression, and death, while propane and butane can act as simple asphyxiants. Toxicity may also result from decomposition products, such as hydrogen chloride and phosgene from heating halogenated hydrocarbons.

Toxicity. The toxicity resulting from abuse by deliberate inhalation of propellants has been reviewed.[1-4] Further references relevant to the toxicity of individual agents are given in the monographs.

Argon

Argón; Argonum; E938; Аргон.
CAS — 7440-37-1.
UNII — 67XQY1V3KH.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Argon). A colourless gas. Soluble 1 in about 29 of water by volume at 20 degrees and at a pressure of 101 kPa. Store as a compressed gas or liquid in appropriate containers.

Profile

Argon is an inert gas and is used to replace air in containers containing oxidisable substances.

Bromochlorodifluoromethane

Bromoclorodifluorometano; Halon 1211; R-12B1; Бромхлордифторметан.
$CBrClF_2$=165.4
CAS — 353-59-3.
UNII — 915X8AJX5.

Profile

Bromochlorodifluoromethane is a halogenated hydrocarbon that has been used as a fire-extinguishing agent. Like chlorofluorocarbons it causes ozone depletion and other environmental effects and its use is generally being phased out.

Toxicity has been reported after the misuse or abuse of fire extinguishers containing bromochlorodifluoromethane,[1-3] and in persons exposed in other ways.[4,5]

Butane

n-Butané; Butano; E943a; Бутан.
C_4H_{10}=58.12
CAS — 106-97-8.
UNII — 6LV4FOR43R.

Pharmacopoeias. In *USNF.*

USNF 31: (Butane). A colourless gas. It is highly flammable and explosive. Store in airtight cylinders at a temperature not exceeding 40 degrees.

Profile

Butane is used as an aerosol propellant (above). It is widely used as a fuel.

Abuse. Toxicity has been reported with the abuse of butane.[1-10]

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Arg.*: Frionex.

Carbon Dioxide

Anglies dioksidas; Anhídrido carbónico; Carbone, dioxyde de; Carbonei Dioxidum; Carbonei Dioxydum; Carbonic Acid Gas; Carbonique; Hiilidioksidi; Kohlendioxid; Koldioxid; Oxid uhličitý; Szén-dioxid; Węgla dwutlenek; Диоксид Углерода; Двуокись Углерода; Углекислый Газ.
CO_2=44.01
CAS — 124-38-9.
ATC — V03AN02.
ATC Vet — QV03AN02.
UNII — 142M471B3J.

NOTE. Carbon dioxide is about 1½ times as heavy as air.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US.*

Ph. Eur. 8: (Carbon Dioxide). A colourless gas. Soluble 1 in about 1 of water by volume at 20 degrees and at a pressure of 101 kpA. Store liquefied under pressure in suitable containers.

The BP 2014 directs that carbon dioxide should be kept in approved metal cylinders which are painted grey and carry a label stating 'Carbon Dioxide'. In addition, 'Carbon Dioxide' or the symbol 'CO_2' should be stencilled in paint on the shoulder of the cylinder.

USP 36: (Carbon Dioxide). A colourless, odourless gas. Its solutions are acid to litmus. One volume dissolves in about 1 volume of water. Store in cylinders.

Uses and Administration

Carbon dioxide is a product of respiration and blood concentrations are normally kept within strict physiological limits. Manipulation of carbon dioxide concentrations has been used therapeutically (see below) but hypocapnia is not always desirable and carbon dioxide has been added to the oxygen in pump oxygenators to prevent hypocapnia developing.

Carbon dioxide acts as a respiratory stimulant, but is rarely used therapeutically for this purpose. However, inhalation of low concentrations has been tried in the management of neonatal apnoea (p. 1204.3).

Carbon dioxide may be used as the insufflating gas for laparoscopy, and to flood the surgical field to prevent formation of gas emboli during cardiac surgery. It may also be used as a contrast agent in radiography (p. 1580.1).

Solid carbon dioxide, or 'dry ice' has a temperature of -80 degrees and has been used to treat warts (p. 1689.3) and naevi by cryotherapy.

Pharmaceutically, carbon dioxide is used as an aerosol propellant and as a replacement for air to preserve oxidisable substances. Carbonated vehicles are useful for masking the unpleasant taste of some medicinal preparations.

Manipulation of carbon dioxide concentrations in the blood may be achieved by ventilatory techniques and has been used therapeutically. Examples include the use of hyperventilation in the management of raised intracranial pressure (p. 1271.3) and breath-holding or rebreathing for intractable hiccup (p. 1046.3).

Adverse Effects

Carbon dioxide has direct toxic effects and also acts as an asphyxiant. Above a concentration of about 6%, it causes headache, dizziness, confusion, palpitations, hypertension, dyspnoea, increased depth and rate of respiration, and CNS depression. Concentrations of about 20% and higher produce convulsions and loss of consciousness; inhalation of 50% carbon dioxide is reported to produce central effects similar to anaesthetics. The inhalation of high concentrations may produce respiratory acidosis.

Abrupt withdrawal of carbon dioxide after prolonged inhalation may produce malaise, pallor, headache, and nausea or vomiting.

Skin contact with solid carbon dioxide may cause frostbite.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Canad.*: Carbogen.

Carbon Monoxide *(USAN)*

Anglies monoksidas; Carbone, monoxyde de; Carbonei Monoxidum; Hiilimonoksidi; Karbon Monoksit; Kolmonoxid; Monóxido de carbono; Węgla tlenek; Монооксид Углерода; Окись Углерода; Угарный Газ.
CO=28.01
CAS — 630-08-0.
UNII — 7U1EE4V452.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Carbon Monoxide). A colourless, flammable gas obtained by steam reforming (catalytic oxidation) of hydrocarbons. Soluble 2.266 in 100 of water by volume at 20 degrees and at a pressure of 101 kPa. Store as a compressed gas in appropriate containers.

Uses

Carbon monoxide has been used in low concentrations as a tracer gas in measurements of lung function. It is also reported to have anti-inflammatory properties and is under investigation for various medical uses, including the management of delayed graft function. It appears to have a physiological role as a signalling molecule. Carbon

monoxide labelled with carbon-11 may be used to assess the blood volume.

3. Ghosh S, *et al.* Carbon monoxide: endogenous mediator, potential diagnostic and therapeutic target. *Ann Med* 2010; 42: 1–12.

Adverse Effects

Carbon monoxide is produced by incomplete combustion of organic materials and is highly toxic when inhaled; infants, small children, and elderly people are particularly susceptible. Although the number of cases of poisoning in countries such as the UK has fallen as the availability of coal gas has declined and as changes have been made to motor vehicles to improve their exhaust fumes, carbon monoxide is still a major cause of poisoning. Common sources of carbon monoxide include poorly maintained and ventilated heating systems and improperly burnt fuel in domestic fires.

When inhaled, carbon monoxide combines with haemoglobin in the blood to form carboxyhaemoglobin; this complex is unable to transport oxygen, and cellular hypoxia therefore results. Most of the symptoms of poisoning are due to anoxia, but carbon monoxide also has a direct toxic effect on cells, which may contribute. The skin and tissues may turn a classic cherry red in patients poisoned with carbon monoxide although this is seen most often after death.

The symptoms of carbon monoxide poisoning are varied and depend on the degree and duration of exposure, although there is wide variation between individuals. Unconsciousness may occur suddenly but is commonly preceded by headache, dizziness, weakness, nausea, and vomiting, which may be misdiagnosed as a viral illness or food poisoning. Other symptoms may include skin lesions, excessive sweating, pyrexia, increased respiration, mental dullness and confusion, visual disturbances, convulsions, hypotension, tachycardia or other cardiac arrhythmias, myocardial ischaemia, and possibly myocardial infarction. Death may result from respiratory failure, pulmonary oedema, cardiovascular failure, or cerebral damage. Carboxyhaemoglobin concentrations are a guide to the severity of poisoning, although they are not a reliable measure of toxicity; the lethal concentration of carboxyhaemoglobin in the blood is about 50% or more. Concentrations over 1000 ppm of carbon monoxide in inspired air may be fatal in 1 hour. Neurological and psychiatric sequelae may develop some weeks later in the survivors of severe poisoning and therefore a prolonged follow-up of such patients is advised; symptoms include memory impairment, apathy, mutism, irritability, personality change, gait disturbance, and urinary and faecal incontinence. Chronic carbon monoxide exposure may present as a non-specific illness with headache, nausea, and flu-like symptoms.

Treatment of Adverse Effects

The patient should be removed from the contaminated atmosphere and an effective airway established. Oxygen (100%) should be given until the blood carboxyhaemoglobin concentration has fallen below dangerous levels (usually 5%). Management is then usually symptomatic and supportive with attention being given to the possible need to treat or correct any cardiovascular disorders, metabolic acidosis, or cerebral oedema. Hyperbaric oxygen therapy may be considered in pregnant patients or in severe poisoning (if the patient is, or has been, unconscious, or if there are neurological symptoms or cardiac complications) but is of unproven benefit (see below) and its use is controversial.

Hyperbaric oxygen therapy. The use of hyperbaric oxygen therapy in the management of carbon monoxide poisoning is controversial.[1-3] The rationale for using hyperbaric oxygen is that it increases the rate at which carboxyhaemoglobin dissociates, shortening the half-life from about 2 hours with normobaric 100% oxygen to about 30 minutes with hyperbaric oxygen. Theoretically, this should be of benefit, and retrospective studies have shown improved symptoms in patients given hyperbaric oxygen, particularly in terms of neurological outcomes.[6] However, controlled studies have had conflicting results, and systematic reviews[1-4] have found insufficient evidence to determine the value of hyperbaric oxygen. Although hyperbaric oxygen has been widely recommended, particularly in severe poisoning, availability is limited and it remains unclear which patients should be considered for therapy. There is some evidence that older patients, and those with loss of consciousness, prolonged exposures, or high carboxyhaemoglobin concentrations gain most benefit,[7] but this is not established. It is also unclear whether use in pregnancy should be recommended, since few studies have included pregnant patients. Case reports suggest that hyperbaric oxygen is safe in pregnancy,[8] and there is a theoretical basis for therapy since fetal carboxyhaemoglobin concentrations are higher than maternal concentrations, but evidence is limited and successful outcomes without the use of hyperbaric oxygen have also been reported.[9]

NOTE. Trichlorofluoromethane is a gas above 24 degrees.

Pharmacopoeias. In *USNF.*

USNF 31: (Trichloromonofluoromethane). A clear, colourless gas having a faint ethereal odour. Store in airtight cylinders at a temperature not exceeding 40 degrees.

Profile

Chlorofluorocarbons are halogenated hydrocarbons that contain only chlorine, fluorine, and carbon. They have been widely used as refrigerants and as aerosol propellants (p. 1797.1), but have been phased out in most countries due to their effects on atmospheric ozone. Medicinally, they have been used in metered dose inhalers and in cold sprays for topical anaesthesia, but alternatives are now preferred.

Helium

E939; Helio; Hélium; Гелий.

He=4.002602

CAS — 7440-59-7.

ATC — V03AN03.

ATC Vet — QV03AN03.

UNII — 206GF3GB41.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Helium). A colourless, inert gas. Store as a compressed gas or liquid at cryogenic temperatures, in appropriate containers.

USP 36: (Helium). A colourless, odourless, tasteless gas which is not combustible and does not support combustion. Very slightly soluble in water. Store in cylinders.

Profile

As helium is less dense than nitrogen, breathing a mixture of 80% helium and 20% oxygen requires less effort than breathing air. Thus mixtures containing various concentrations of oxygen ('Heliox') have been used in patients with respiratory disorders. Mixtures of helium and oxygen have also been used as an alternative to compressed air by divers or others working under high pressure, to prevent the development of nitrogen narcosis. Helium has been used in pulmonary function testing.

Breathing helium increases vocal pitch and causes voice distortion. Cerebral artery gas embolism has been reported after inhalation of helium from a pressurised container.

Although individual studies may have shown benefit, systematic reviews of the use of helium and oxygen mixtures (heliox) in various respiratory disorders have generally failed to find convincing evidence of value.

Hydrogen Sulfide

Ácido sulfhídrico; Hydrogen Sulphide; Siarkowodór; Sulfuro de hidrógeno; Sulphuretted Hydrogen; Сульфид Водорода; Сероводород.
H_2S=34.08
CAS — 7783-06-4.
UNII — YY9FVM7NSN.

Description. Hydrogen sulfide is a colourless flammable gas with a characteristic odour.

Uses

Hydrogen sulfide is used in industrial processes as a source of sulfur and in the manufacture of other chemicals, although it is mainly encountered as a byproduct. It appears to have a physiological role as a signalling molecule and has been investigated for therapeutic use.

Adverse Effects

Hydrogen sulfide is a common industrial hazard and is encountered in such places as chemical works, mines, sewage works, and stores of decomposing protein. Concentrations of 0.1 to 0.2% in the atmosphere may be fatal in a few minutes. At concentrations of about 0.005% and above hydrogen sulfide causes anosmia and its unpleasant odour is no longer detectable. Pulmonary irritation, oedema, and respiratory failure usually occur after acute poisoning; prolonged exposure to low concentrations may cause severe conjunctivitis with photophobia and corneal opacity, irritation of the respiratory tract, cough, nausea, vomiting and diarrhoea, pharyngitis, headache, dizziness, and lassitude. There are some similarities to poisoning with cyanides.

General references.

1. WHO. Hydrogen Sulfide. *Environmental Health Criteria 19*. Geneva: WHO, 1981. Available at: http://www.inchem.org/documents/ehc/ehc/ehc019.htm (accessed 05/07/04)

Treatment of Adverse Effects

In poisoning with hydrogen sulfide the patient should be removed from the contaminated atmosphere and an effective airway established. Inhalation of amyl nitrite or parenteral therapy with sodium nitrite have been suggested for severe poisoning; this produces methaemoglobin, which may bind sulfide. Oxygen should be given; hyperbaric oxygen therapy has also been suggested. The conjunctival sacs should be carefully washed out if eye irritation is severe. Management is then usually symptomatic and supportive.

Isobutane

E943b; Isobutano; 2-Methylpropane; 2-Metilpropano; Изобутан.
C_4H_{10}=58.12
CAS — 75-28-5.
UNII — BXR49TP611.

Pharmacopoeias. In *USNF.*

USNF 31: (Isobutane). A colourless gas. It is highly flammable and explosive. Store in airtight cylinders at a temperature not exceeding 40 degrees.

Profile

Isobutane is used as an aerosol propellant (p. 1797.1).

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *UK*: Histofreezer; *USA*: Compound W Freeze Off.

Nitrogen

Azot; Azotas; Azote; Dusík; E941; Kvävgas; Nitrogén; Nitrogenium; Nitrógeno; Nitrogenum; Stickstoff; Typpi; Азот.
N_2=28.014
CAS — 7727-37-9.

ATC Vet — QV03AN04.
UNII — N762921K75.

Pharmacopoeias. In *Eur.* (see p. vii) and *Jpn.* Also in *USNF.*

Ph. Eur. 8: (Nitrogen). The monograph applies to nitrogen for medicinal use. A colourless, odourless gas. Soluble 1 in about 62 of water and 1 in about 10 of alcohol by volume at 20 degrees and at a pressure of 101 kpA. Store as a compressed gas or a liquid in appropriate containers.

The BP 2014 directs that nitrogen should be kept in approved metal cylinders, the shoulders of which are painted black and the remainder grey. The cylinder should carry a label stating 'Nitrogen'.

Ph. Eur. 8: (Nitrogen, Low-oxygen). The monograph applies to nitrogen used in the production of an inert atmosphere for finished medicinal products that are particularly sensitive to degradation by oxygen. A colourless, odourless gas. Soluble 1 in about 62 of water and 1 in about 10 of alcohol by volume at 20 degrees and at a pressure of 101 kpA. Store as a compressed gas or a liquid in appropriate containers.

USNF 31: (Nitrogen). A colourless, odourless, tasteless gas. It is non-flammable and does not support combustion. Soluble 1 in about 65 of water v/v and 1 in about 9 of alcohol v/v at 20 degrees and at a pressure of 760 mmHg. Store in cylinders.

USNF 31: (Nitrogen 97 Percent). It contains not less than 97% v/v of nitrogen. Store in cylinders or in a low-pressure collecting tank.

Uses and Administration

Nitrogen is used as a diluent for pure oxygen or other active gases and as an inert gas to replace air in containers holding oxidisable substances. It is also used as an aerosol propellant. Liquid nitrogen is used as a cryotherapeutic agent for the removal of warts (p. 1689.3) and for preservation of tissues and organisms.

Adverse Effects

Nitrogen narcosis has been reported after use of nitrogen mixtures (such as air) at high pressure, for example in deep-water diving. Under high pressure, nitrogen dissolves in blood and lipid. If decompression is too rapid, nitrogen effervesces from body stores producing gas emboli and leads to the syndrome of decompression sickness. High inhaled concentrations of nitrogen are asphyxiant. Skin contact with liquid nitrogen causes frostbite or burns.

CAS — 7782-44-7.
ATC — V03AN01.
ATC Vet — QV03AN01.
UNII — S88TT14065.

Pharmacopoeias. In *Chin., Eur.* (see p. vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 8: (Oxygen). A colourless gas. Soluble 1 in about 32 of water by volume at 20 degrees and at a pressure of 101 kPa. Store as a compressed gas or liquid in appropriate containers. Oils and grease are not to be used unless oxygen-compatible.

The BP 2014 directs that oxygen should be kept in approved metal cylinders, the shoulders of which are painted white and the remainder black. The cylinder should carry a label stating 'Oxygen'. In addition, 'Oxygen' or the symbol 'O_2' should be stencilled in paint on the shoulder of the cylinder.

Ph. Eur. 8: (Oxygen (93 per cent)). It contains 90.0% v/v to 96.0% v/v of O_2, the remainder mainly consisting of argon and nitrogen. A colourless gas. It is normally used on the site where it is produced. It is fed directly into a medicinal gas pipeline or administration system. Where authorised, it may be stored in suitable containers. Oils and grease are not to be used unless oxygen-compatible.

Ph. Eur. 8: (Air, Medicinal; Aer Medicinalis; Medical Air BP 2014). It is compressed ambient air containing not less than 20.4% and not more than 21.4% of oxygen. A colourless, odourless gas. Soluble 1 in about 50 of water by volume at 20 degrees and at a pressure of 101 kPa. Store as a gas in suitable containers.

Ph. Eur. 8: (Air, Synthetic Medicinal; Aer Medicinalis Artificiosus; Synthetic Air BP 2014). It is a mixture of nitrogen and oxygen containing between 21.0% and 22.5% of oxygen. A colourless, odourless gas. Soluble 1 in about 50 of water by volume at 20 degrees and at a pressure of 101 kPa. Store as a compressed gas in suitable containers.

USP 36: (Oxygen). A colourless, odourless, tasteless gas that supports combustion more energetically than does air. Soluble 1 in about 32 of water v/v and 1 in about 7 of alcohol v/v at 20 degrees and at a pressure of 760 mmHg. Store in cylinders or in a pressurised storage tank.

USP 36: (Medical Air). A natural or synthetic mixture of gases consisting largely of nitrogen and oxygen. It contains not less than 19.5% and not more than 23.5% of oxygen. Store in cylinders or in a low pressure collecting tank.

USP 36: (Oxygen 93 Percent). It contains not less than 90% v/v and not more than 96% v/v of oxygen, the remainder consisting mostly of argon and nitrogen. Store in cylinders or in a low-pressure collecting tank.

Uses and Administration

Oxygen comprises about 21% of ambient air (at sea level) and is essential for human life. Supplementary inhaled oxygen may be necessary to prevent or correct hypoxaemia and increase oxygen delivery to the tissues in situations where the ambient air is unable to meet the body's demands. It is used in respiratory failure (p. 1801.1), as an adjunct to specific treatment of the underlying cause and general measures such as correction of anaemia or repositioning of the patient. It is also used in situations where the oxygen content of the air breathed is inadequate, for example in the management of high-altitude disorders (p. 1276.2).

Oxygen is of value in the treatment of poisoning with several substances, including carbon monoxide (p. 1798.1), cyanides (see under Hydrocyanic Acid, p. 2156.2), and dichloromethane (p. 2181.2). It is also used in inhalation injury and in poisoning with asphyxiant gases. Workers in pressurised spaces and divers may breathe oxygen rather than air to reduce the risk of nitrogen narcosis, although mixtures of oxygen with an inert gas such as helium may be preferred to reduce the risk of oxygen toxicity. Oxygen is also used as a diluent of volatile and gaseous anaesthetics.

Supplementary oxygen is usually provided at a concentration of 100% as a compressed gas in metal cylinders, but is also available as liquid oxygen, supplied at low temperatures in insulated containers. Oxygen concentrators, which extract oxygen from the air, can provide concentrations of 95 to 98% and are useful for domiciliary therapy, especially in patients using large quantities of oxygen. Oxygen is used in varying concentrations, and this is controlled by the flow rate and delivery system. In general, the exact concentration inhaled is not critical, and most delivery systems work by adjusting the flow rate to provide an approximate dose. Nasal cannulae deliver concentrations of 24 to 40% at flow rates of 1 to 4 litres/minute and are widely used, particularly for domiciliary therapy. Standard face masks deliver concentrations of 40 to 60% at flow rates of 5 to 10 litres/minute, while reservoir masks allow flow rates of 10 to 15 litres/minute and oxygen concentrations of 60 to 90%. Where more precise dosage is required Venturi masks may be used; these provide a set oxygen concentration independent of the flow rate and are available for a range of concentrations between 24 and 60%. If very high doses are required, endotracheal tubes or oxygen tents can be used to deliver concentrations of up to 100%.

The concentration of inspired oxygen used has generally been determined by the condition being treated, but for acute therapy it is now considered preferable to adjust the concentration in line with the patient's oxygen saturation. For most patients, the **target oxygen saturation**, measured by pulse oximetry, should be 94 to 98%. However, for patients with hypercapnia or at risk of hypercapnia, a lower target range of 88 to 92% is recommended (see Chronic Lung Disorders under Precautions, p. 1802.1). Suggested initial concentrations and delivery systems are as follows:

- critically ill patients, including those with carbon monoxide poisoning: **high** concentration oxygen (reservoir mask at flow rate of 15 litres/minute)
- patients with acute hypoxaemia due to conditions such as acute asthma, pneumonia, pulmonary embolism, and postoperatively: **moderate** concentration therapy
  - oxygen saturation below 85%: reservoir mask at flow rate of 10 to 15 litres/minute
  - oxygen saturation 85% or higher: nasal cannulae or simple face mask at flow rate of 2 to 10 litres/minute
- patients with chronic obstructive pulmonary disease or otherwise at risk of hypercapnia: low concentration (controlled) oxygen therapy
  - if oxygen saturation unknown: 28% at 4 litres/minute, or 24% at 2 to 4 litres/minute if there is a history of hypercapnia (via Venturi mask)
  - oxygen saturation below 88%: nasal cannulae at 2 to 6 litres/minute or simple face mask at 5 litres/minute

Hyperbaric oxygen therapy, in which oxygen is given at pressures greater than 1 atmosphere, has an established role in the management of decompression sickness and gas emboli. It may also be used in carbon monoxide poisoning, severe anaerobic infection, and several other conditions, although this is more controversial; for further discussion, see below.

Cluster headache. Randomised studies[1,2] and case series[3] have suggested that inhalation of 100% oxygen can provide rapid and effective treatment of cluster headache attacks (p. 670.1), although the evidence is limited.[4] Treatment with 100% oxygen should therefore be considered in all patients,[5] although practical issues may limit its use.

Hyperbaric oxygen therapy. Hyperbaric oxygen therapy[1-3] involves the inhalation of 100% oxygen at a pressure of greater than 1 atmosphere and is given by enclosing the patient in a special high-pressure chamber. The optimum pressure and duration of treatment depend on the indication, but pressures of 2.5 to 3 atmospheres for periods from 45 minutes to 2 hours are commonly used. A single session may be adequate for some indications, but treatment is usually repeated once or twice daily and up to 40 sessions may be required. Hyperbaric oxygen therapy is generally safe, but adverse effects may occur (see p. 1801.3); intermittent replacement of oxygen with air as the inspired gas may reduce the risk of oxygen toxicity.[2]

Hyperbaric oxygen therapy appears to act by 2 main mechanisms. The increased pressure has a physical effect, reducing the size of gas bubbles within the circulation, which is of benefit in decompression sickness and gas embolism. In addition, the amount of oxygen dissolved in the blood increases under pressure, increasing tissue oxygen supply. This hyperoxia has various physiological and biochemical effects, including stimulation of wound healing and tissue repair and improved resistance to infection.

Therapy with hyperbaric oxygen has been tried in many disorders, but for most there have been few controlled studies and evidence of benefit is therefore limited. However, there are several accepted indications, and research continues in many other disorders.

The role of hyperbaric oxygen therapy as a safe and effective primary therapy for *decompression sickness* and *air or gas embolism* is well established. Reduction in bubble size is the main action, although the increase in oxygenation may also be beneficial. Pressures are generally similar to those used for other indications (initially about 2.8 atmospheres), although up to 6 atmospheres may be required. The pressure may then be gradually reduced at a safe rate.

Hyperbaric oxygen therapy has been widely recommended for *carbon monoxide poisoning* but its precise role remains unclear (see p. 1798.1); it may be considered in selected patients. Its mechanism of action is not fully understood; it increases the rate at which carboxyhaemoglobin concentrations decline, increases intracellular delivery of oxygen, and may also reduce lipid peroxidation and thus spare neuronal cell membranes.

In the management of *wounds and infections*, hyperbaric oxygen has various applications.[4] It is used as adjunctive therapy in *clostridial infections (gas gangrene)* (p. 182.2). Early treatment appears to reduce systemic toxic reactions (probably by inhibiting the production of alpha toxin by the anaerobic bacteria, *Clostridium*) thus enabling patients to tolerate surgery more readily; additionally there is a clearer demarcation of viable and nonviable tissue. *Necrotising fasciitis* (p. 193.1) is another infection in which hyperbaric oxygen therapy may be useful, although evidence is limited. Other infections in which hyperbaric oxygen therapy may be used include osteomyelitis, and intracranial abscesses.

There is some evidence that hyperbaric oxygen may be useful in non-infected wounds where hypoxia contributes to poor healing.[5,6] In *problem wounds*, including venous ulcers, therapy may increase the tissue oxygen tension and stimulate angioneogenesis but it is emphasised that it is adjunctive therapy and not a replacement for meticulous local care. Hyperbaric oxygen therapy might also reduce the risk of major amputation in patients with chronic *diabetic foot ulcer*.[7,8] Improved healing of leg ulcers has been reported[9] with use of hyperbaric oxygen therapy in patients with livedoid vasculopathy. Other wounds in which therapy may be beneficial include thermal burns and compromised skin grafts and flaps. The management of burns and wounds is described on p. 1683.1 and p. 1690.1, respectively. Hyperbaric oxygen may also be of benefit in patients with acute trauma and *crush injuries*;[10] it reduces oedema by causing vasoconstriction and may reverse ischaemia by increasing oxygen delivery.

In patients with malignancy, hyperbaric oxygen may have a role in the treatment of *radiation-induced tissue damage*;[11] radiation therapy can damage normal adjacent tissue resulting in tissue hypoxia and eventual cell death but hyperbaric oxygen therapy appears to aid in salvaging such tissue by stimulating angioneogenesis in marginally viable tissue. There is some evidence of benefit in osteoradionecrosis, soft-tissue damage, and radiation-induced haemorrhagic cystitis (p. 2347.3), although a randomised study[12] failed to confirm this in patients with jaw osteoradionecrosis. Hyperbaric oxygen has also been tried as an adjunct to standard treatment for malignant neoplasms but does not yet have an established role.[13]

Evidence to support the use of hyperbaric oxygen in *neurological disorders* is limited. Benefits have been reported in children with *cerebral palsy*, but this has not been established, and there is some evidence that it is no better than pressurised air.[14] Improvement has been reported in neonates with hypoxic-ischaemic encephalopathy,[15] but again further research is needed. A study of hyperbaric 24% oxygen in children with autism has also suggested benefits.[16]

Hyperbaric oxygen may also have a limited role in the management of severe anaemia (p. 1121.2) due to massive blood loss, since it enables sufficient oxygen to be dissolved in the blood to meet tissue demands, independent of haemoglobin. However, practical issues mean that other treatments are generally preferred.

Respiratory failure. Respiratory failure is a clinical condition in which the arterial plasma partial pressure of oxygen (P_aO_2) and of carbon dioxide (P_aCO_2) cannot be maintained within normal physiological limits. It may result from an abnormality in any part of the respiratory system, including airways, alveoli, CNS, respiratory muscles, and circulation, and may be associated with various underlying disorders; it may be acute or chronic. In type I respiratory failure P_aO_2 is low (hypoxaemia) but P_aCO_2 may be normal or low, whereas in type II respiratory failure $P_aO_2$is low but $P_aCO_2$is raised (hypercapnia). Type I respiratory failure is most common and can occur in most acute lung disorders; examples include pulmonary oedema, pneumonia, and pulmonary haemorrhage. Type II respiratory failure (also known as ventilatory failure) is associated with conditions such as drug overdosage, neuromuscular disorders, and chronic obstructive airways disease. Patients with asthma may develop either type of respiratory failure.

The signs and symptoms of respiratory failure are those of the underlying condition plus any associated hypoxaemia or hypercapnia. Dyspnoea (painful or difficult breathing) is common, and patients may also have tachypnoea, tachycardia and other arrhythmias, signs of cyanosis, and neurological symptoms such as confusion and somnolence.

Management of respiratory failure mainly involves giving oxygen to reverse hypoxaemia, and specific therapy for any underlying condition. Invasive or non-invasive ventilatory support may be required in severe cases. Respiratory stimulants have a limited role but may be considered in some situations.

In acute respiratory failure, oxygen is the mainstay of therapy.[1,2] The concentration given should be the minimum required to reverse hypoxaemia and, ideally, should be determined by blood gas measurements or pulse oximetry. Use of oxygen in patients who are not hypoxaemic is not generally recommended,[3] and there is no evidence that it is beneficial for dyspnoea associated with causes such as cancer or heart failure.[4]

In ***type I respiratory failure*** high initial oxygen concentrations are given using nasal cannulae or face masks and target oxygen saturations are 94 to 98%. Ventilatory support may be required if adequate saturations cannot be maintained using reservoir masks.

In ***type II respiratory failure*** initial oxygen concentrations depend on the risk of exacerbating hypercapnia and acidosis:

- In *acute severe asthma* (p. 1195.2), hypercapnia is not a barrier to oxygen therapy and oxygen should be given from a reservoir mask, at a flow rate of 10 to 15 litres/minute (if oxygen saturation is below 85%), or from nasal cannulae or a simple face mask at a flow rate of 2 to 10 litres/minute if oxygen saturation is 85% or higher.[3] (The *BNF* notes that if the P_aCO_2 remains high despite other treatment, intermittent positive-pressure ventilation needs to be considered urgently.)
- In exacerbations of chronic respiratory disorders such as *chronic obstructive pulmonary disease* (COPD, p. 1199.1), cystic fibrosis (p. 177.2), or neuromuscular disorders, high concentrations of oxygen may exacerbate hypercapnia (see Precautions, p. 1802.1), particularly if given for a long period. Controlled delivery of low concentrations (24 to 28%) is therefore recommended for initial therapy,[3,5] although this is based on consensus opinion rather than controlled studies.

Ventilatory support is required in patients with respiratory failure when hypoxaemia persists or if hypercapnia and acidosis worsen. This generally involves endotracheal intubation and invasive ventilation, but the use of non-invasive methods is increasing and may be preferred in many situations, particularly in exacerbations of chronic conditions.[6] Use of gas mixtures that are less dense than air, such as mixtures of helium and oxygen, has been tried in acute respiratory failure to reduce the work of breathing, but is not of established benefit.[7] In extreme cases of respiratory failure, such as acute respiratory distress syndrome, extracorporeal membrane oxygenation (ECMO) may be tried,[8] although evidence for benefit is limited.

Respiratory stimulants such as doxapram have been used in respiratory failure but their role is limited. In patients with exacerbations of chronic ventilatory failure, the central drive to respiratory muscles is already increased and stimulants have little effect, although they may be tried in patients who are unsuitable for mechanical ventilation or where this is unavailable. Respiratory stimulants may also be considered in the management of *postanaesthetic hypoventilation*. Specific antagonists such as naloxone and flumazenil may have a role if respiratory depression is due to drugs such as opioids or benzodiazepines, respectively, although care is needed since therapeutic effects may be reduced.

Severe respiratory failure in *neonates* may result from various disorders. Use of surfactant or inhaled nitric oxide may be of benefit in some cases but ECMO may be required.[9]

In **chronic respiratory failure**, management involves treating the underlying cause and dealing with acute exacerbations, but oxygen therapy may have a role in some patients with stable disease. Long-term oxygen therapy, given by nasal cannulae, may improve survival in patients with severe chronic obstructive pulmonary disease and persistent hypoxaemia, and should be given for at least 15 hours each day.[5,10] Patients may also use intermittent, 'short-burst' oxygen to improve symptoms associated with exercise, although benefit is not established.[5,10] There is also limited evidence to support the use of nocturnal oxygen in patients with nocturnal hypoxaemia.[5]

Wounds. Hyperbaric oxygen therapy may have a role in the management of infected and problem wounds (see p. 1800.2). Supplemental normobaric oxygen has also been tried in the prevention of postoperative wound infections. Although the results of individual studies remain contradictory, a meta-analysis[1] concluded that oxygen, at 80%, provided a beneficial effect. However, a more recent multicentre study[2] found no reduced risk of infection after 80% rather than 30% oxygen, during, and for 2 hours after, surgery.

Oxygen has also been applied topically to wounds.[3]

Adverse Effects

Oxygen is essential for life but inhalation of high concentrations may have adverse effects, particularly with prolonged exposure at higher pressures. Both pulmonary and CNS effects may occur. Pulmonary toxicity usually results from prolonged or repeated exposure. Symptoms include cough, dyspnoea, and substernal discomfort, and there may also be a reduction in vital capacity; alveolar collapse (absorption atelectasis), pulmonary oedema, and pneumonitis have also been reported. CNS toxicity is usually only seen at pressures above 2 atmospheres absolute but generally precedes pulmonary toxicity; the risk is higher in wet conditions and with physical activity. Symptoms include nausea, mood changes, vertigo, twitching, convulsions, and loss of consciousness. Toxic effects on the eyes may also occur (see Hyperbaric Oxygen Therapy, and Retinopathy of Prematurity, below).

The mechanism of oxygen toxicity is not clear, but may involve an increase in oxygen free radicals. Hyperoxaemia may also have adverse physiological effects related to cerebral and coronary vasoconstriction. It is also increasingly recognised that high inhaled concentrations of oxygen may be detrimental in patients with chronic lung disorders due to the effects of oxygen on ventilation (see Precautions, p. 1802.1).

Hyperbaric oxygen therapy. CNS toxicity is an important and unpredictable adverse effect with inhalation of oxygen at pressures higher than atmospheric, both during hyperbaric oxygen therapy and when used by divers.[1] Hyperbaric oxygen is also associated with pulmonary toxicity, particularly after repeated treatments. Complications related to the increased pressure also occur.[2-5] Barotrauma affecting the middle ear and sinuses is relatively common, and tympanic membrane rupture may result. Pulmonary barotrauma and pneumothorax have been reported, and dental barotrauma may rarely cause pain under a dental filling. Visual changes including myopia may occur, but are reversible once treatment is stopped; cataracts have been reported but there is no evidence that hyperbaric oxygen is the cause. Psychological adverse effects such as claustrophobia may also occur.

Retinopathy of prematurity. The role of oxygen in the development of retinopathy of prematurity has been controversial.[1,2] In the 1940s and 1950s an epidemic of retinopathy of prematurity, affecting perhaps 10 000 babies, was attributed to excessive use of oxygen in neonates. This resulted in the use of oxygen being reduced or curtailed and the incidence of the condition fell dramatically. However, other complications increased and use of oxygen was later liberalised, possibly contributing to a resurgence of cases in the 1970s, although other factors such as the improved survival of very preterm neonates were probably more important. It is now generally accepted that very low birth-weight and extreme prematurity are the major risk factors for retinopathy of prematurity, but that excessive oxygen use also has an important role.[3] Retinal development occurs late in gestation and depends to some extent on the relative hypoxia of the uterine environment. Supplementary oxygen inhibits production of vascular endothelial growth factor, thereby inhibiting retinal vascularisation. The lack of retinal blood vessels then leads to hypoxia, which stimulates excessive neovascularisation, leading to retinal fibrosis and detachment in severe cases. Generation of reactive oxygen species may also play a role.

The optimum approach to oxygen supplementation in infants and neonates remains unclear (see under Precautions, p. 1802.2). Studies[4,5] have suggested that policies in which oxygen use is adjusted for the individual neonate to maintain oxygen saturation (measured by pulse oximetry) within specific limits, avoiding both hyperoxia and hypoxia, can reduce the incidence of retinopathy, and one study[6] found that this had no deleterious effect on development at 18 months. The most appropriate oxygen saturation has not been determined, but may depend on the age of the infant: target saturations of 85 to 92% for gestational age less than 34 weeks and 92 to 97% for gestational age 34 weeks and above have been suggested.[7] For infants who develop signs of retinopathy, higher saturations may also be appropriate; a study[8] of supplemental oxygen for treating pre-threshold retinopathy suggested that therapy was safe, but a beneficial effect could not be confirmed.

Precautions

Any fire or spark is highly dangerous in the presence of increased oxygen concentrations especially when oxygen is used under pressure.

Metal cylinders containing oxygen should be fitted with a reducing valve by which the rate of flow can be controlled. It is important that the reducing valve should be free from all traces of oil or grease (unless it is oxygen-compatible) as otherwise a violent explosion may occur. Combustible material soaked in liquid oxygen is potentially explosive and the low temperature of liquid oxygen may cause unsuitable equipment to become brittle and crack. Liquid oxygen should not be allowed to come into contact with the skin as it produces severe 'cold burns'.

Oxygen intended for aviation or mountain rescue must have a sufficiently low moisture content to avoid blocking of valves by ice at low temperatures.

Excessive oxygen may be detrimental in some patients with chronic lung disorders and in neonates, and high initial concentrations should generally be avoided until oxygen saturations are known (see below). Prophylactic oxygen is given in many acute situations but there is some evidence that it may be detrimental in non-hypoxic patients and routine use may not be advisable (see Myocardial Infarction and Pregnancy, below).

Oxygen should be avoided in the initial management of paraquat poisoning since it may increase pulmonary damage. Pulmonary toxicity associated with bleomycin toxicity may also be exacerbated by oxygen use.

Chronic lung disease. Breathless patients are frequently treated with 100% oxygen but, paradoxically, this may be detrimental in those with chronic lung disorders.[1-3] In chronic obstructive pulmonary disease and in patients with chest wall deformities or musculoskeletal disorders, high concentrations of inhaled oxygen may lead to carbon dioxide retention (hypercapnia) and acidosis, which may in turn lead to organ dysfunction. The mechanism by which this occurs is complex but probably involves a reduction in hypoxic drive and an increased mismatching of blood flow and gas flow to the lungs. A lower target oxygen saturation of 88 to 92% is recommended in such patients[3] and initial oxygen concentrations of 24 to 28% should be used until oxygen saturation is known.

Myocardial infarction. Oxygen is routinely recommended for patients with acute myocardial infarction (see p. 1257.1). However, a systematic review[1] found that studies were lacking, and the very limited evidence available indicated that the use of high-flow oxygen in myocardial infarction might increase infarct size and raise the risk of mortality, possibly due to a reduction in coronary blood flow. The authors concluded that there was insufficient evidence to support the practice, and that further study was urgently needed.

1. Wijesinghe M, *et al.* Routine use of oxygen in the treatment of myocardial infarction: systematic review. *Heart* 2009; 95: 198–202.

Neonates and infants. The use of supplemental oxygen in neonates and infants is controversial.[1-3] For the *resuscitation* of asphyxiated term neonates, use of 100% oxygen has been standard, but there is some evidence that the use of room air (21% oxygen) is equally effective and possibly safer. However, a systematic review[4] concluded that there was insufficient evidence for recommendations to be made. Guidelines[5,6] for neonatal resuscitation recommend the use of either air or blended oxygen to achieve target oxygen saturations,[5,6] although increasing to 100% oxygen might be suitable for those who remain bradycardic after 90 seconds of resuscitation at lower concentrations.[6] Pulse oximetry should be used to guide treatment, with care taken to avoid both hypoxia and hyperoxia.[5,6] A study[7] in preterm neonates found that room air (21% oxygen) was insufficient to maintain adequate oxygen saturations and the authors suggested that an initial oxygen concentration of 30 to 40% might be more appropriate.

For *respiratory support* in preterm neonates and infants, oxygen use should be closely monitored. Excessive use of supplementary oxygen has been associated with retinopathy of prematurity and chronic lung disease,[8] and there is some evidence for a link between neonatal oxygen supplementation and childhood cancer,[9] although this remains to be confirmed. However, untreated hypoxia may result in permanent brain injury or death,[3] and it has been suggested that oxygen supplementation improves sleep and respiratory patterns in healthy preterm infants.[10] Unrestricted use of inhaled oxygen is therefore not advised, and the concentration given should be adjusted individually based on arterial-oxygen saturation measured by pulse oximetry. The optimum saturation range is not entirely clear,[11] but target saturations of between 85 and 93 to 94% have been suggested[2,3] for preterm neonates.

Pregnancy. Oxygen has commonly been given to women during labour as a treatment for fetal distress; however, a systematic review[1] found little evidence to support its use. Furthermore, prophylactic oxygen given during labour may be harmful to the fetus,[2] and guidelines[3] therefore do not recommend this practice.

Propane

Dimethylmethane; E944; Propano; Propyl Hydride; Пропан.

C_3H_8=44.10

CAS — 74-98-6.

UNII — T75W9911L6.

Pharmacopoeias. In *USNF*.

USNF 31: (Propane). A colourless gas. It is highly flammable and explosive. Store in airtight cylinders at a temperature not exceeding 40 degrees.

Profile

Propane is used as a refrigerant and as an aerosol propellant (p. 1797.1). It is also widely used as a fuel.

Toxicity has been reported[1-8] with the abuse or misuse of propane.

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Ger.*: Olbas; Wartner; *Irl.*: Wartner; *Israel*: Wartner†; *NZ*: Wartner; *Singapore*: Wartner; *Switz.*: Wartner; *UK*: Histofreezer; Wartner; *USA*: Compound W Freeze Off.

Gastrointestinal Drugs

Gastrointestinal Drug Groups, p. 1803
Antacids, p. 1803
Antidiarrhoeals, p. 1803
Antiemetics, p. 1803
Antisecretory drugs, p. 1803
Antispasmodics, p. 1803
Laxatives, p. 1804
Mucosal protectants, p. 1804
Prokinetic drugs, p. 1804
Management of Gastrointestinal Disorders, p. 1804
Aspiration syndromes, p. 1804
Constipation, p. 1804
Decreased gastrointestinal motility, p. 1805
Diarrhoea, p. 1805
Diverticular disease, p. 1806
Dumping syndrome, p. 1806
Dyspepsia, p. 1806
Eosinophilic oesophagitis, p. 1807
Gastrointestinal spasm, p. 1807
Gastro-oesophageal reflux disease, p. 1807
Haemorrhoids, p. 1808
Hepatic encephalopathy, p. 1808
Inflammatory bowel disease, p. 1808
Irritable bowel syndrome, p. 1810
Microscopic colitis, p. 1811
Mouth ulceration, p. 1811
Nausea and vomiting, p. 1811
Oesophageal motility disorders, p. 1813
Peptic ulcer disease, p. 1813
Zollinger-Ellison syndrome, p. 1814

This chapter describes the principal drugs used in the treatment of gastrointestinal disorders, and the choice of treatment for some of the main disorders.

Gastrointestinal Drug Groups

Antacids

Antacids are basic compounds that neutralise hydrochloric acid in the gastric secretions. They are used in the symptomatic management of gastrointestinal disorders associated with gastric hyperacidity such as dyspepsia (p. 1806.3), gastro-oesophageal reflux disease (p. 1807.2), and peptic ulcer disease (see p. 1813.2).

Antacids do not reduce the volume of hydrochloric acid secreted and elevation of the gastric pH may actually promote an increase in acid secretion. However, this is usually minor and short-lived except after large doses of calcium carbonate. Antacids are normally given between meals and at bedtime when symptoms of gastric hyperacidity usually occur; the presence of food in the stomach can prolong the neutralising activity. Some calculate doses as mEq or mmol of acid-neutralising capacity, but the relationship between neutralising capacity and beneficial effect is not straightforward. Other factors, including formulation (liquid preparations are more effective than solids) and duration of action (relatively insoluble antacids are longer acting) are also important.

Aluminium salts tend to produce constipation and to delay gastric emptying, while magnesium salts have the reverse effect; a combination of the two may reduce adverse gastrointestinal effects. Another advantage of combined antacid formulations is that a slow-acting antacid such as aluminium hydroxide may be combined with a more rapidly acting drug such as magnesium hydroxide to improve the onset and duration of effect. Alternatively, complexes containing both aluminium and magnesium may be used, such as almasilate, hydrotalcite, and magaldrate. Other drugs that may be combined with antacid formulations include simeticone, which acts as a defoaming agent to reduce excess gas in the stomach, and alginates, which form a gel or foam on the surface of the stomach contents thereby impeding reflux and protecting the oesophageal mucosa from acid attack.

Calcium carbonate and sodium bicarbonate are both rapidly acting but have disadvantages: calcium carbonate is usually reserved for short-term treatment because of the risks of rebound acid secretion and metabolic alkalosis, while sodium bicarbonate is absorbed and is contra-indicated in patients who must control sodium intake (e.g. in heart failure, hypertension, renal failure, cirrhosis, or pregnancy).

Antacids may interact with numerous other drugs, affecting the rate and extent of their absorption, and in some cases their renal elimination. Changes in gastric pH affect the dissolution of other drugs, and together with altered gastric emptying can markedly influence absorption. Aluminium compounds in particular are noted for their propensity to adsorb other drugs and to form insoluble complexes that are not absorbed. Antacids that alter urinary pH will affect renal clearance of drugs that are weak acids or bases. Several mechanisms may play a part in any particular interaction. Interactions can be minimised by giving antacids and other medication 2 to 3 hours apart.

Antacids in this chapter include aluminium salts, magnesium salts, and calcium carbonate. For sodium bicarbonate, see p. 1781.1.

Described in this chapter are

- Aceglutamide Aluminium, p. 1814.3
- Alexitol Sodium, p. 1815.1
- Almagate, p. 1815.3
- Almasilate, p. 1815.3
- Aloglutamol, p. 1816.2
- Aluminium Glycinate, p. 1817.2
- Aluminium Hydroxide, p. 1817.2
- Aluminium Hydroxide-Magnesium Carbonate Co-dried Gel, p. 1818.2
- Aluminium Phosphate, p. 1818.3
- Aluminium Sodium Silicate, p. 1818.3
- Basic Aluminium Carbonate, p. 1817.1
- Bismuth Compounds, p. 1821.3
- Calcium Carbonate, p. 1824.3
- Dihydroxyaluminum Sodium Carbonate, p. 1835.2
- Hydrotalcite, p. 1845.2
- Magaldrate, p. 1856.1
- Magnesium Carbonate, p. 1856.2
- Magnesium Hydroxide, p. 1857.2
- Magnesium Oxide, p. 1857.3
- Magnesium Trisilicate, p. 1858.1

Antidiarrhoeals

Antidiarrhoeals are used as adjuncts in the symptomatic treatment of diarrhoea (see p. 1805.2), although the main aim in the management of *acute* diarrhoea is the correction of fluid and electrolyte depletion with rehydration therapy; this is especially important in infants and young children and antidiarrhoeals are not generally recommended for this age group. Their use is also limited in *chronic* diarrhoea since treatment aimed at the underlying disorder will often alleviate the diarrhoea.

Described in this chapter are drugs that reduce intestinal motility such as the opioid analogues diphenoxylate and loperamide, and adsorbents such as attapulgite and kaolin. Bulking agents (which include bran and ispaghula) have also been used for diarrhoea and for adjusting faecal consistency in patients with colostomies.

Described in this chapter are

- Albumin Tannate, p. 1815.1
- Attapulgite, p. 1820.1
- Bismuth Compounds, p. 1821.3
- Bran, p. 1823.3
- Chalk, p. 1826.3
- Crofelemer, p. 1833.3
- Difenoxin, p. 1835.2
- Diphenoxylate, p. 1835.3
- Ispaghula, p. 1849.1
- Kaolin, p. 1850.1
- Lidamidine, p. 1853.1
- Loperamide, p. 1854.2
- Racecadotril, p. 1881.3
- Smectites, p. 1887.1
- Zaldaride, p. 1895.3

Antiemetics

Antiemetics are a diverse group of drugs used to treat or prevent nausea and vomiting, including that associated with cancer therapy, anaesthesia, and motion sickness (see p. 1811.3).

The choice of drug depends partly on the cause of nausea and vomiting. For example, hyoscine or an antihistamine are used in motion sickness whereas dopamine antagonists (such as metoclopramide and domperidone) and serotonin 5-HT_3-receptor antagonists (5-HT_3 antagonists), such as ondansetron, are ineffective. Conversely, nausea and vomiting associated with cancer chemotherapy is often hard to control and special regimens have been devised including the use of the 5-HT_3 antagonists, dexamethasone, and, more recently, the neurokinin-1 receptor antagonists aprepitant and casopitant.

Described in this chapter are

- Alizapride, p. 1815.2
- Aprepitant, p. 1819.2
- Azasetron, p. 1820.2
- Bromopride, p. 1824.2
- Casopitant, p. 1826.2
- Cerium Oxalate, p. 1826.2
- Clebopride, p. 1833.1
- Difenidol, p. 1835.1
- Dolasetron, p. 1837.2
- Domperidone, p. 1838.1
- Dronabinol, p. 1840.1
- Fosaprepitant, p. 1843.2
- Ginger, p. 1844.1
- Granisetron, p. 1844.3
- Hyoscine, p. 1845.3
- Indisetron, p. 1848.3
- Itopride, p. 1850.1
- Mecloxamine Citrate, p. 1859.1
- Metoclopramide, p. 1862.2
- Metopimazine, p. 1865.1
- Nabilone, p. 1865.2
- Ondansetron, p. 1872.1
- Palonosetron, p. 1875.1
- Ramosetron, p. 1881.3
- Tropisetron, p. 1894.1

Antisecretory drugs

Antisecretory drugs are used in the treatment and prophylaxis of peptic ulcer disease (p. 1813.2); some are also employed in other disorders associated with gastric hyperacidity such as gastro-oesophageal reflux disease (p. 1807.2) and dyspepsia (p. 1806.3). They may generally be divided into:

- *Histamine H_2-receptor antagonists* (H_2-antagonists), which act by blocking histamine H_2-receptors on gastric parietal cells, thereby antagonising the normal stimulatory effect of endogenous histamine on gastric acid production. Those described in this chapter include cimetidine, famotidine, nizatidine, and ranitidine.
- *Proton pump inhibitors*, which act by blocking the enzyme system responsible for active transport of protons into the gastrointestinal lumen, namely the hydrogen/potassium adenosine triphosphatase (H^+/K^+ ATPase) of the gastric parietal cell, also known as the 'proton pump'. Those described in this chapter include lansoprazole, omeprazole, pantoprazole, and rabeprazole.
- *Selective antimuscarinics*, which block cholinergic stimulation of gastric acid production with fewer adverse effects than less selective antimuscarinics (see Action of Antimuscarinics, p. 1310.3), but have largely been superseded. Pirenzepine is an example.
- *Prostaglandin analogues*, which inhibit gastric acid secretion by a direct action on the parietal cell and may also inhibit gastrin release and possess cytoprotective properties. Misoprostol (p. 2140.3) is an example.

Described in this chapter are

- Cimetidine, p. 1827.1
- Dexlansoprazole, p. 1834.2
- Eseridine Salicylate, p. 1840.3
- Esomeprazole, p. 1841.1
- Famotidine, p. 1842.1
- Ilaprazole, p. 1848.2
- Lafutidine, p. 1851.3
- Lansoprazole, p. 1851.3
- Nizatidine, p. 1866.1
- Omeprazole, p. 1867.2
- Pantoprazole, p. 1875.3
- Pirenzepine, p. 1878.2
- Proglumide, p. 1880.1
- Rabeprazole, p. 1881.1
- Ranitidine, p. 1882.1
- Ranitidine Bismuth Citrate, p. 1883.3
- Revaprazan, p. 1884.2
- Roxatidine, p. 1884.3
- Tenatoprazole, p. 1893.3
- Urogastrone, p. 1894.3

Antispasmodics

Antispasmodics are drugs used for their relaxant action on smooth muscle, either direct or through an antimuscarinic action on the parasympathetic innervation. They play a role in the management of gastrointestinal spasm (p. 1807.1) and irritable bowel syndrome (p. 1810.3) as well as other disorders associated with smooth muscle spasm. Those described in this chapter are mainly antimuscarinics; drugs in other chapters that may be used for relaxation of smooth muscle include calcium-channel blockers (p. 1244.2) and nitrates (p. 1245.2), as well as drugs with less well defined mechanisms of action such as papaverine (p. 2362.2).

Described in this chapter are

- Alverine Citrate, p. 1819.1
- Butropium Bromide, p. 1824.3
- Cidonium Bromide, p. 1827.1
- Cimetropium Bromide, p. 1831.3
- Clidinium Bromide, p. 1833.2
- Dicycloverine Hydrochloride, p. 1834.2
- Difemerine Hydrochloride, p. 1835.1
- Dihexyverine Hydrochloride, p. 1835.2
- Diisopromine Hydrochloride, p. 1835.3
- Drofenine Hydrochloride, p. 1839.3
- Hyoscine, p. 1845.3
- Hyoscine Butylbromide, p. 1845.3
- Hyoscine Hydrobromide, p. 1845.3
- Hyoscine Methobromide, p. 1846.1
- Hyoscine Methonitrate, p. 1846.1
- Hyoscyamine, p. 1848.1
- Hyoscyamine Hydrobromide, p. 1848.1
- Hyoscyamine Sulfate, p. 1848.1
- Isopropamide Iodide, p. 1848.3
- Mebeverine Hydrochloride, p. 1858.3
- Mepenzolate Bromide, p. 1859.1
- Methanthelinium Bromide, p. 1861.3
- Methylbenactyzium Bromide, p. 1861.3
- Octatropine Methylbromide, p. 1866.2
- Oxapium Iodide, p. 1874.3
- Oxyphencyclimine Hydrochloride, p. 1875.1
- Oxyphenonium Bromide, p. 1875.1
- Pargeverine Hydrochloride, p. 1877.1
- Peppermint Leaf, p. 1877.1
- Peppermint Oil, p. 1877.1
- Pipenzolate Bromide, p. 1878.1

Piperidolate Hydrochloride, p. 1878.1
Pipethanate Ethobromide, p. 1878.2
Platyphylline Acid Tartrate, p. 1878.3
Poldine Metilsulfate, p. 1879.1
Prifinium Bromide, p. 1879.3
Propantheline Bromide, p. 1880.1
Tiemonium, p. 1893.3
Timepidium Bromide, p. 1894.1
Tiquizium Bromide, p. 1894.1
Valethamate Bromide, p. 1895.2

Laxatives

Laxatives (purgatives or cathartics) promote defaecation and are used in the treatment of constipation (see below) and for bowel evacuation before investigational procedures, such as endoscopy or radiological examination, or before surgery.

Laxatives are frequently used for self-medication. Abuse of laxatives is a well-known phenomenon that may occasionally lead to toxicity.

Laxatives may be classified according to their mode of action. There is, however, a degree of overlap between the various groups and in some cases the precise mechanisms of action are not fully understood. Many traditionally used laxatives have fallen from use owing to the violence of their action or their adverse effect profile.

- *Bulk laxatives* (bulk-forming laxatives or bulking agents) cause retention of fluid and an increase in faecal mass resulting in stimulation of peristalsis. Owing to their hydrophilic nature, bulk laxatives may also be used to control diarrhoea and to regulate the consistency of effluent in colostomy patients. Those described in this chapter include bran, ispaghula, and sterculia.
- *Stimulant laxatives* (contact laxatives) act by directly stimulating nerve endings in the colonic mucosa, thereby increasing intestinal motility. It is this group of laxatives which is most commonly associated with abuse. Those described in this chapter include bisacodyl, cascara, phenolphthalein, senna, and sodium picosulfate.
- *Osmotic laxatives* act by increasing intestinal osmotic pressure thereby promoting retention of fluid within the bowel. Those described in this chapter include saline laxatives such as magnesium citrate, magnesium hydroxide, and sodium sulfate (for magnesium sulfate and sodium phosphate see p. 1787.3 and p. 1791.1 respectively). Lactulose may also be classified as an osmotic laxative because its breakdown products exert a similar effect. Also included in this group are the hyperosmotic laxatives such as glycerol (p. 2517.2) and sorbitol (p. 2092.1), and the macrogols (p. 2547.3).
- *Faecal softeners* (emollient laxatives) are claimed to act by decreasing surface tension and increasing penetration of intestinal fluid into the faecal mass. Those described in this chapter include docusate (which is also believed to have a stimulant action).

For the lubricant laxative liquid paraffin see p. 2191.2.

Described in this chapter are

Aloes, p. 1816.1
Aloin, p. 1816.2
Bisacodyl, p. 1821.1
Bisoxatin, p. 1823.2
Bran, p. 1823.3
Buckthorn, p. 1824.2
Casanthranol, p. 1826.1
Cascara, p. 1826.1
Cassia Pulp, p. 1826.2
Colocynth, p. 1833.3
Dantron, p. 1833.3
Docusates, p. 1836.2
Euonymus, p. 1842.1
Fig, p. 1843.2
Frangula, p. 1843.3
Ispaghula, p. 1849.1
Jalap, p. 1850.1
Lactitol, p. 1850.3
Lactulose, p. 1850.3
Liquorice, p. 1853.2
Magnesium Citrate, p. 1857.1
Magnesium Hydroxide, p. 1857.2
Magnesium Oxide, p. 1857.3
Manna, p. 1858.2
Pentaerythritol, p. 1877.1
Phenolphthalein, p. 1877.3
Polycarbophil, p. 1879.1
Potassium Acid Tartrate, p. 1879.2
Potassium Sodium Tartrate, p. 1879.3
Prune, p. 1881.1
Psyllium Seed, p. 1849.1
Rhubarb, p. 1884.2
Senna, p. 1885.1
Sodium Picosulfate, p. 1887.2
Sodium Sulfate, p. 1888.1
Sodium Tartrate, p. 1888.2
Sterculia, p. 1888.3
Tamarind, p. 1892.2

Mucosal protectants

Cytoprotective drugs (mucosal protectants) play a role in the management of peptic ulcer disease (p. 1813.2). They may be divided into:

- *Chelates or complexes*, which coat the gastric mucosa preferentially at sites of ulceration by forming an adherent complex with proteins. Those described in this chapter include sucralfate and tripotassium dicitratobismuthate (which also has an antibacterial role in regimens aimed at eradicating *Helicobacter pylori*)
- *Miscellaneous drugs* include liquorice and its derivatives, such as carbenoxolone, which may act by stimulating the synthesis of protective mucus

Described in this chapter are

Benexate, p. 1821.1
Carbenoxolone, p. 1825.3
Cetraxate, p. 1826.3
Dosmalfate, p. 1839.3
Ecabet, p. 1840.2
Enoxolone Aluminium, p. 1840.3
Gefarnate, p. 1844.1
Irsogladine, p. 1848.3
Liquorice, p. 1853.2
Plaunotol, p. 1879.1
Polaprezinc, p. 1879.1
Rebamipide, p. 1884.1
Sofalcone, p. 1888.2
Sucralfate, p. 1889.1
Sulglicotide, p. 1892.2
Teprenone, p. 1893.3
Tripotassium Dicitratobismuthate, p. 1822.2
Troxipide, p. 1894.3

Prokinetic drugs

Prokinetic drugs stimulate the motility of the gastrointestinal tract. Gastrointestinal smooth muscle exhibits intrinsic motor activity which is modified by autonomic innervation, local reflexes, and gastrointestinal hormones. This activity produces peristaltic waves, which move the gut contents from stomach to anus, and segmentations, which encourage digestion. Prokinetic drugs may act at various points within this complex system to enhance gastrointestinal movement. Those described in this chapter include metoclopramide, cisapride, and domperidone. Other drugs with prokinetic properties include parasympathomimetics such as bethanechol (p. 2456.2) or neostigmine (p. 687.1), and the macrolide antibacterial erythromycin (p. 291.2).

Described in this chapter are

Aclatonium Napadisilate, p. 1815.1
Acotiamide Hydrochloride, p. 1815.1
Bromopride, p. 1824.2
Cinitapride, p. 1831.3
Cisapride, p. 1831.3
Clebopride, p. 1833.1
Domperidone, p. 1838.1
Itopride, p. 1850.1
Linaclotide, p. 1853.1
Lubiprostone, p. 1856.1
Metoclopramide, p. 1862.2
Mosapride, p. 1865.2
Prucalopride, p. 1880.2
Renzapride, p. 1884.1
Tegaserod, p. 1893.1

Management of Gastrointestinal Disorders

The management of some gastrointestinal disorders is discussed below.

Aspiration syndromes

Regurgitation and aspiration of gastric contents (Mendelson's syndrome) is a potential cause of morbidity and mortality associated with anaesthesia, especially in obstetrics and in emergency surgery. Chemical pneumonitis and respiratory distress result from the acid aspiration, the risk of which is increased by the drugs given as adjuncts to anaesthesia such as opioid analgesics and atropine.

Apart from good anaesthetic technique, including a prohibition on oral intake before elective procedures, efforts to prevent or reduce the problem have focussed mainly on increasing the pH of gastric contents to above 2.5, and in reducing gastric volume. However, there is little evidence to show that reduced gastric acidity or volume is associated with decreased morbidity or mortality in patients who have aspirated gastric contents,[1] and some do not recommend the routine pre-operative use of pharmacological prophylaxis in patients undergoing elective surgery with no apparent increased risk for pulmonary aspiration.[1] Similarly there is little evidence to support the routine use of prophylactic drugs in women undergoing normal labour (particularly with the increased use of regional anaesthetic techniques).[2]

The *H_2-antagonists* decrease gastric acid secretion and may decrease gastric fluid volume. However, they do not affect the pH of fluid already in the stomach; they must therefore be given some time before anaesthesia, which limits their value in emergency procedures. Cimetidine is considered effective in most patients, although where more prolonged reduction of acidity is required H_2-antagonists with a longer duration of action such as ranitidine or famotidine may be preferred. Nizatidine has the advantage of a relatively rapid onset of action.[3] The *proton pump inhibitors* (PPIs) have also been tried, but results have been variable. A meta-analysis[4] suggested that ranitidine was more effective than a PPI in reducing the volume of gastric secretions and increasing their pH. Combination of a PPI with a prokinetic drug may produce better results.[3]

Because of the lack of effect of antisecretory drugs on the pH of existing gastric fluid H_2-antagonists may be combined with *antacids* to neutralise gastric acidity. Although magnesium trisilicate has been extensively used[6] without apparent problems particulate antacids are potentially toxic to the lung, which is why soluble antacids such as sodium citrate have been widely favoured. An effervescent formulation of sodium citrate with cimetidine has been reported to raise gastric pH above 2.5 in more than 98% of patients undergoing caesarean section.[7]

A third component of prophylactic regimens for acid aspiration may be use of a *prokinetic drug* such as metoclopramide. These increase gastric emptying and thereby decrease the volume of stomach contents, and also increase pressure at the lower oesophageal sphincter. The ability of metoclopramide to reverse the effects of opioids on gastric emptying appears to depend on the route: 10 mg given intravenously after opioid analgesia is reported to be effective in promoting gastric emptying, whereas the same dose intramuscularly is not.[8]

If aspiration occurs, pulmonary damage may result within seconds; treatment has included removal of any particulate matter, and measures to maintain the airway and ensure adequate oxygenation. Corticosteroids have been used but are no longer considered helpful.[9]

Constipation

The pattern of normal defaecation is extremely variable, which makes constipation hard to define, and to some extent subjective. However, expert consensus considers that it occurs if 2 or more of the following features are present for at least 12 weeks in the previous year: less than 3 defaecations in a week, or hard or lumpy stool, straining, feeling of incomplete evacuation or anorectal blockage, or need for manual assistance, on at least a quarter of occasions.[1,2] New onset constipation, especially in patients over 50 years of age, or accompanying symptoms such as anaemia, abdominal pain, weight loss, or overt or occult blood in the stool should provoke urgent investigation because of the risk of malignancy or other serious bowel disorder.[3-5] Constipation can be a symptom of a range of disorders or of drug toxicity[2,3,6] and appropriate management of any underlying cause is required. It tends to be more common in the elderly, in women, and in late pregnancy.[1,2]

Certain subtypes of constipation have been identified: patients may be subdivided according to whether intestinal transit time is slow or normal, or whether there is pelvic floor dysfunction (dyssynergia; outlet obstruction; anismus).[2,3,5,7]

There is relatively little evidence to guide management. In general, stepped or graded management is favoured, beginning with advice on lifestyle (including exercise and adequate hydration), and dietary modification if appropriate.[2,4-6,8] An increase in fibre intake, preferably through a high-fibre diet, is useful in patients with normal transit times although it is less beneficial in slow-transit constipation.[5,7] In patients with pelvic floor dysfunction, biofeedback training may be instituted.[3,5,7]

Where lifestyle changes and dietary modification are insufficient, a laxative may be considered. Because of the lack of clear evidence to guide the choice of laxative, practice varies considerably. Many favour the use of either a bulk laxative or an osmotic laxative as a first choice option,[2-4,7] with stimulant laxatives tending to be reserved as a second-line option, and diphenylmethane derivatives being preferred to anthraquinones.[3,6] For the treatment of opioid-induced constipation unresponsive to usual laxative therapy opioid antagonists such as *methylnaltrexone* have been tried.

- *Bulk laxatives* include bran, ispaghula, methylcellulose and related compounds, psyllium, or sterculia. Bulk laxatives are of particular value in those with small hard stools. However, they have a delayed onset of action (up to 72 hours) and they may exacerbate symptoms of flatulence, bloating, and cramping;[6] use should be avoided where these are severe. A gradual increase in dose may help reduce such effects.[7] They may not be the first choice for elderly patients who are frail or immobile since the resulting soft faeces may result in faecal incontinence,[9] and should only be given where fluid intake is adequate, because of the risk of obstruction.[7]
- *Osmotic laxatives* include saline laxatives such as magnesium hydroxide and magnesium sulfate, poorly absorbed sugars such as lactulose or sorbitol, and macrogols (often formulated with electrolytes). Some favour the use of macrogol 3350 or 4000, for which there is reasonable evidence of benefit in chronic constipation,[5,6,10] However, in practice lactulose is widely used,[6] although it is less effective in the elderly than a combination of bulking and stimulant laxatives (see below). In the USA, a saline laxative such as magnesium hydroxide has been

recommended,[3,4,7] although saline laxatives may not be acceptable to some patients because they can cause watery stool and urgency.

- *Stimulant laxatives* in current use include diphenylmethane derivatives such as bisacodyl or sodium picosulfate, and anthraquinone-containing drugs such as senna. They have a more rapid onset of action than bulk laxatives or lactulose, and are usually given at night to help produce a bowel motion the following morning. Many traditional stimulant laxatives have fallen from use because of adverse effects, and it has been widely thought that their prolonged use or abuse may irreversibly damage colonic nerves and muscles; however, the evidence for this is poor, and appropriate stimulant laxatives used at licensed doses are unlikely to cause significant harm.[11,12] Tolerance can occur but seems to be uncommon in the majority of users.[11,12] Combined preparations are also available, and a combination of senna and fibre has been found to be more effective than the osmotic laxative lactulose in elderly patients with chronic constipation.[13]
- *Other laxatives* include the docusates, surfactants that are used as stool softeners,[7] but their efficacy used alone for constipation is not well established;[4] perhaps for this reason, they are often formulated with a stimulant or osmotic laxative. Stool softeners would have potential value for patients with haemorrhoids or anal fissures, or those in whom straining is potentially hazardous (such as the elderly or those with existing cardiovascular disease). Liquid paraffin has also been used as a lubricant for the passage of stool,[7] but should be used with caution because of its adverse effects, which include anal seepage and the risks of granulomatous disease of the gastrointestinal tract or of lipoid pneumonia on aspiration. Although it has been recommended in some countries for constipation in children,[14,15] the *UK CSM* considers it should not be used in those under 3 years of age. Prokinetic drugs have theoretical advantages in patients with slow-transit constipation, but few suitable drugs are available,[5] although the selective 5-HT_4 agonist prucalopride may be tried in chronic constipation, and tegaserod has been used in constipation-predominant irritable bowel syndrome (p. 1810.3) and in chronic constipation. The chloride-channel activator lubiprostone and the guanylate cyclase-C agonist linaclotide are also used in chronic constipation and constipation-predominant irritable bowel syndrome.

Rectal administration of laxatives using enemas or suppositories is appropriate in patients requiring rapid relief from constipation. Phosphate enemas should be used with caution because of the risks of absorption of significant amounts of phosphate.[4] Glycerol and bisacodyl may be given as suppositories to promote faecal evacuation; they should not be used regularly, as changes in the rectal epithelium have been seen with bisacodyl, and the effect of glycerol on rectal mucosa is unclear.[4]

During *pregnancy* the preferred options for management are increased fluid intake, exercise, and dietary fibre;[2] bulking agents may be given as fibre supplements, and stimulant laxatives such as senna reserved for cases where these are ineffective.[2,16]

Faecal impaction is the inability to pass a hard collection of stool, and may result in overflow diarrhoea. Faecal impaction should be treated with a laxative enema and/or a lubricant and manual disimpaction.[4,5,9] Oral laxatives should not be used because of the risk of colonic perforation.[9] When all stool has been cleared, it is important to institute measures, often including regular laxatives, to prevent constipation and recurrent impaction.[5,7,9]

Decreased gastrointestinal motility

Decreased gastrointestinal motility may occur in any part of the gastrointestinal tract, with symptoms depending on the site. It is of varying aetiology and often secondary to some other disorder, such as infection, metabolic or electrolyte disturbance (for example in gastroparesis due to diabetic neuropathy—see also p. 465.2), or insult to the gastrointestinal tract (for example, paralytic or adynamic ileus is frequently a consequence of abdominal surgery and is a serious adverse effect of some drugs).

Acute loss of gastrointestinal motility is often self-limiting once the underlying cause has been treated. Provided the ability of gastrointestinal smooth muscle to contract has not been lost, however, prokinetic drugs such as metoclopramide or domperidone, or erythromycin, or drugs capable of stimulating functional contraction including parasympathomimetics such as neostigmine or bethanechol, may be used. The opioid μ-receptor antagonist alvimopan has recently been introduced for the treatment of postoperative ileus. Injection of botulinum toxin into the pyloric sphincter may produce temporary symptomatic improvement in patients with refractory gastroparesis. Gastric electrical stimulation may also be an option.

Drugs are less successful in chronic conditions such as chronic intestinal pseudo-obstruction where neuromuscular function of the gastrointestinal tract has some intrinsic abnormality.

Diarrhoea

Diarrhoea is characterised by liquid stools and increased stool weight and frequency of defaecation. Although diarrhoea is commonly associated with infection (see Gastro-enteritis, p. 182.2), it may also result from the accumulation of nonabsorbed osmotically active solutes in the gastrointestinal lumen, as in lactase deficiency, or from the gastrointestinal effects of secretory stimuli other than the enterotoxins from an infection. It may also occur when intestinal motility or morphology is altered.

Acute diarrhoea may lead to excessive water and electrolyte loss and dehydration, and is potentially life-threatening in infants; frail and elderly patients are also at risk. Severe dehydration associated with acute diarrhoea (greater than 10% loss of body-weight), requires *intravenous rehydration therapy* with Ringer's lactate solution or normal saline.[1–4] Intravenous therapy is also needed for patients who are unable to drink. Otherwise, *oral rehydration therapy* to correct fluid and electrolyte depletion should form the basis of treatment for acute diarrhoea[1–6] and an oral rehydration solution containing essential electrolytes (sodium, potassium, chloride, and bicarbonate or citrate) and glucose is indicated regardless of the age of the patient or the cause of the diarrhoea. A rehydration phase, which involves the replenishment of fluid and electrolytes lost through the diarrhoea, is followed by a maintenance phase to replace continuing losses. Oral rehydration therapy does not stop diarrhoea, which usually continues for a limited period, although it can reduce stool output and vomiting. Oral rehydration therapy may need to be modified if the diarrhoea is associated with malnutrition.[7] The rationale for the composition of oral rehydration solutions is that glucose absorption is coupled to the active transport of electrolytes,[8] the absorption of which theoretically increases in efficiency as the ratio of carbohydrate to sodium approaches 1:1.

WHO originally recommended a solution containing 90 mmol/litre of sodium and 111 mmol/litre of glucose; this type of preparation has been used effectively in developing countries where diarrhoeas are commonly bacterial in origin. There is now evidence from studies and meta-analyses to suggest that solutions of reduced sodium content and osmolarity are safe and effective and may be preferable to the original standard WHO solution, even in developing countries,[9–12] and WHO and UNICEF now recommend a solution containing 75 mmol/litre of sodium and 75 mmol/litre of glucose, with a reduced total osmolarity of 245 mmol/litre.[13] Despite concerns about the possible increased risk of hyponatraemia with the use of the reduced osmolarity solutions in patients with cholera,[14–16] WHO and UNICEF have stated that hyponatraemia may also occur with the standard WHO formulation, and that there is no evidence to suggest that this transient hyponatraemia has had significant adverse clinical consequences for cholera patients.[13]

In developed countries viral diarrhoeas, which are associated with less electrolyte loss, are more common, and reduced osmolarity solutions are favoured.[2] Commercial preparations available in the UK, for example, usually provide 50 to 60 mmol/litre of sodium and 90 to 111 mmol/litre of glucose; the total osmolarity is slightly hypotonic (about 250 mmol/litre) to prevent possible induction of osmotic diarrhoea.[17] Similar preparations are available in other developed countries.[18]

Areas of debate have included the necessity for inclusion of citrate or bicarbonate,[17] and whether cereal-based rather than glucose-based rehydration solutions would be preferable. There is considerable evidence that cereal-based solutions tend to produce more rapid resolution of diarrhoea, although one study has suggested that the reduction in stool output is temporary,[19] and another found that a glucose-based solution was equally effective when combined with early re-introduction of feeding.[20] In 1994, a review of clinical studies concluded that a rice-based rehydration solution should be recommended for patients with cholera, but that there was no reason to change from WHO's glucose-based formulation for children with non-cholera diarrhoea.[21] A study in 48 patients with cholera compared the use of standard glucose-based oral rehydration therapy, standard therapy plus rice flour, and standard therapy plus amylase-resistant starch.[22] The addition of amylase-resistant starch to standard oral rehydration solution was shown to reduce stool output and to reduce the duration of diarrhoea,[22] although the methodology of this study was questioned[23] and further investigation of such solutions is required.

Home remedies[1] that have been used to prevent dehydration include coconut water, rice water, soups, unsweetened fresh fruit juice, and unsweetened weak tea; these may be of value when more conventional oral rehydration solutions are unavailable. The use of cordials and soft drinks with low pH and high osmolality, however, may exacerbate diarrhoea and dehydration.[1,18]

Oral rehydration therapy should be combined with *dietary measures*, particularly in children, to avoid malnutrition owing to low food intake during the illness, and as mentioned above, may need to be modified if the diarrhoea is associated with malnutrition. Breast feeding should be continued throughout rehydration therapy,[2,4,6,17] as such feeding may decrease stool output and shorten the duration of diarrhoea.[2] Dilution of formula feeds does not seem to be of clinical benefit and may even prolong symptoms.[4,8] Generally food should not be withheld in adults or children with diarrhoea, but for those with some signs of dehydration, food is not normally given during the initial rehydration period.[1]

To reduce the duration and severity of diarrhoea, and to prevent recurrence, zinc supplements are recommended by WHO as adjunctive therapy to oral rehydration salts for acute diarrhoea, see p. 2127.2. Children with persistent diarrhoea, lasting at least 14 days, should receive zinc as part of a multivitamin and mineral supplement.[1] Vitamin A may be important in reducing mortality, see p. 2100.1.

There is considerable interest in the potential use of *probiotic bacteria*, or *prebiotic foods* intended to stimulate the growth of beneficial species in the gastrointestinal tract, in the management of diarrhoea. Although meta-analyses have suggested that treatment with lactic-acid producing organisms may reduce stool frequency and disease duration in children with acute infectious diarrhoea,[24] and may reduce the risk of antibacterial-associated diarrhoea in children,[25] the role of probiotics and prebiotics remains to be established,[4,8] particularly since many commercial products are poorly characterised.

Oral rehydration therapy prevents dehydration, but does not necessarily shorten the duration of the diarrhoea, and patients therefore frequently desire the symptomatic relief provided by *drug therapy*. Use of such therapy should be

balanced against the risk that it may distract from the need for oral rehydration therapy and may have undesirable adverse effects. WHO considers that antidiarrhoeal drug therapy is of limited value for acute infectious diarrhoea, does not reduce fluid and electrolyte loss, may delay the expulsion of causative micro-organisms, and should never be used in children.[26] However, it has been pointed out that extrapolating results in children to adult treatment is unwarranted; there is no good evidence that antidiarrhoeal drugs prolong illness or retard expulsion of pathogens, and no reason to withhold medication in otherwise healthy adults.[27] Short courses of antidiarrhoeals are often used in practice (frequently as self medication) if symptoms are causing discomfort.[3,27,28]

The main groups of antidiarrhoeal drugs are adsorbents such as attapulgite, kaolin, and pectin, and drugs that reduce intestinal motility such as diphenoxylate, loperamide, and codeine. Oral loperamide has been recommended as the treatment of choice, particularly for self-medication,[3,27] although bismuth salicylate, which has antisecretory properties, is probably equally effective,[3] and may be preferred in some countries such as the USA.[28] Other drugs with antisecretory properties are under investigation; they include the enkephalinase inhibitor racecadotril, which unlike other antidiarrhoeal drugs is of interest as a potential adjunct in children.[4] Bulk laxatives such as methylcellulose have also been used for symptomatic treatment because of their absorptive capacity.

Antibacterial and antiprotozoal drugs have been used for infective diarrhoeas, including the prophylaxis and treatment of travellers' diarrhoea (see Gastro-enteritis, p. 182.2 and p. 921.2), but their overuse encourages the development of resistance and prophylaxis is not recommended. Vaccines are being developed for the prevention of rotaviral diarrhoeas (p. 2416.1).

Chronic diarrhoea may be associated with underlying disease and therefore symptomatic relief is less appropriate than treatment of the disease itself. For example, colestyramine will reduce the diarrhoea associated with bile acid malabsorption. Where the disease process responsible for chronic diarrhoea cannot be satisfactorily suppressed, however, symptomatic relief may be appropriate,[29] for example in diabetic diarrhoea (see p. 464.1).

Diverticular disease

Diverticula are small hernias or pouches of mucosa that develop through the muscular wall of the gut (especially the colon) or other hollow organs; they increase in prevalence with increasing age. Diverticular disease (the presence of colonic diverticula) is usually asymptomatic, but may be associated with symptoms of abdominal pain and altered bowel habit (diverticulosis). Occasionally there may be severe life-threatening complications such as inflammation and necrosis of diverticula (diverticulitis), perforation, fistula formation, obstruction, or haemorrhage. There is some evidence that the use of NSAIDs may be associated with an increase in diverticular complications such as perforation.

In uncomplicated diverticular disease, treatment is with a high-fibre diet, gradually supplemented if necessary with a bulk laxative such as bran or ispaghula, to ease constipation, although the evidence to support such management is limited. Supplements may not relieve the other symptoms of diverticular disease. The antibacterial rifaximin may be of benefit in improving symptoms; giving rifaximin and fibre supplementation has been shown to be more effective than fibre supplementation alone. Rifaximin has also been combined with 5-aminosalicylates, chiefly mesalazine; the latter may be of benefit in maintaining remission. Use of probiotics, in the form of lactic-acid-producing organisms, after a non-absorbed antibacterial such as rifaximin has also produced some evidence of additional benefit. Antispasmodics such as antimuscarinics or mebeverine may be useful in relieving pain due to muscle spasm.

Diverticulitis requires treatment with broad-spectrum antibacterials and fluid support; analgesia may be needed for severe pain. If peritonitis or abscess develops, surgical intervention may be necessary. Surgical resection is usually considered when fistula, perforation, or obstruction are present.

Dumping syndrome

The word dumping in this context is used to describe the unnaturally rapid transport of gastric contents to the small intestine. The dumping syndrome is an important cause of morbidity after gastrointestinal surgery, and is thought to be due to the destruction of normal regulatory mechanisms in the upper gastrointestinal tract.[1-3] Early dumping begins within 10 to 30 minutes of the ingestion of a meal (typically, symptoms are triggered by hyperosmolar, carbohydrate-rich food) and has gastrointestinal symptoms (fullness, abdominal pain, nausea and vomiting, explosive diarrhoea) and vasomotor symptoms (sweating, weakness, dizziness, flushing, and palpitations). The effects are thought to be due to fluid shifts from the intravascular space to the bowel lumen. Some patients have late dumping, 1 to 4 hours after a meal, with only the vasomotor symptoms; it appears to be due to reactive hypoglycaemia caused by high carbohydrate concentrations in the small intestine.

The mainstays of therapy are dietary modifications, taking small frequent meals low in carbohydrate, followed by liquids 30 minutes later. Attempts to slow or reduce carbohydrate absorption have involved the use of dietary fibre (guar gum or pectin) or α-glucosidase inhibitors such as acarbose; acarbose and pectin have also been tried in combination.[4] However, such agents may themselves cause gastrointestinal disturbances and they do not seem to be helpful in most patients.[2] However, beneficial results with somatostatin have led to the use of its longer-acting analogue, octreotide.[2,5] Octreotide substantially reduces the symptoms of both early and late dumping, probably by slowing gastric emptying and by inhibiting the release of gastrointestinal mediators (peptide hormones such as neurotensin), and prevents hyperinsulinaemia and subsequent reactive hypoglycaemia. It may be given up to 2 hours before a meal, or as long-acting formulation.[3]

In the minority of patients who do not respond to medical therapy surgery may be required.[1-3]

Dyspepsia

Dyspepsia, also commonly known as indigestion or heartburn, is a frequent but ill-defined disorder primarily associated with epigastric discomfort or pain. It may be a symptom of specific diseases such as peptic ulcer disease, gastro-oesophageal reflux disease, gastric carcinoma, chronic pancreatitis, or gallstones. However, in many patients there is no identifiable systemic disease, in which case it is known as non-ulcer dyspepsia or functional dyspepsia.

Many reviews and recommendations have addressed the subject of dyspepsia,[1-7] and, in the UK, various authoritative guidelines have been issued.[8,9] The initial management of non-ulcer dyspepsia usually includes advice to avoid alcohol, caffeine, smoking, and aggravating foods, and to eat small regular meals to aid digestion. Results of studies of drugs for non-ulcer dyspepsia have been variable and difficult to evaluate since the condition tends to be self-limiting, and there is often a large placebo response.[10]

Drugs that *suppress gastric acid* such as *antacids* or antisecretory drugs are often used. Antacids may give some symptomatic relief, and are widely used for self-medication.[9] However, long-term use is inappropriate. Similarly, H_2-antagonists are often tried, especially for symptoms of reflux, and a systematic review[10] has suggested benefit, at least in a proportion of patients. Proton pump inhibitors (PPIs) are also widely used; although a systematic review had considered their relative efficacy in non-ulcer dyspepsia versus H_2-antagonists to be unclear,[11] others[5-7,12] consider them superior to H_2-antagonists. They may be useful for on-demand therapy to manage symptoms long-term.[9]

It is not clear what role *Helicobacter pylori* plays in the pathology of non-ulcer dyspepsia. One meta-analysis found eradication to be of no benefit in non-ulcer dyspepsia,[13] but another, incorporating more patients, found that a small benefit existed,[14] although it noted that most patients positive for *H. pylori* will continue to have symptoms after eradication. As a result there has been much debate about the appropriateness of so-called 'test and treat' strategies, but UK[9] and US[4,5] guidelines consider them a valid alternative to a trial of a PPI in the initial management of uninvestigated dyspepsia.

Initial management of dyspepsia in patients under 55 years of age who do not have so-called 'alarm symptoms' (such as chronic gastrointestinal bleeding, unintentional weight loss, difficulty swallowing, persistent vomiting, iron deficiency anaemia, or epigastric mass) should therefore consist of either:[4,9]

- an empirical one-month course of a PPI, *or*
- testing for *Helicobacter pylori* and appropriate eradication therapy. Those who are *H. pylori*-negative should be prescribed an empirical trial of acid suppression with a PPI for 1 to 2 months

Patients over 55 years of age, or those with alarm symptoms, should be referred for endoscopy. After endoscopy, treatment should be targeted at the underlying diagnosis.[4]

Prokinetic drugs may be given, particularly if an underlying gastrointestinal motility disorder is suspected. Meta-analysis has suggested that prokinetic therapy may be more effective than an H_2-antagonist in non-ulcer dyspepsia,[10,15] but this may be due to publication bias.[10] In addition, cisapride is no longer available in many countries and evidence for domperidone or metoclopramide is limited. Results with motilin agonists (derivatives of erythromycin) and 5-HT_3 antagonists have been disappointing to date.[3] Other approaches to drug therapy include the use of an insoluble bismuth salt, and the use of antispasmodics. Antidepressants may have a limited role in some patients,[5,7] and various herbal medications have been tried, though the quality of any studies is generally poor.[7]

Eosinophilic oesophagitis

Eosinophilic oesophagitis is a disease of the oesophagus characterised by a marked accumulation of eosinophils in the oesophageal mucosa. Severe squamous epithelial hyperplasia generally occurs, resulting in complications such as oesophageal strictures and a narrow oesophagus. Symptoms include heartburn, chest pain, dysphagia, pain on swallowing, vomiting, food impaction, and feeding intolerance in children.

Although data on treatments are sparse, corticosteroids are considered appropriate. Systemic and topical corticosteroids are effective at relieving acute symptoms, although symptoms usually recur when treatment is stopped. Gastro-oesophageal reflux disease may coexist with eosinophilic oesophagitis; however, the symptoms and pathological features of eosinophilic oesophagitis do not respond to acid suppression treatment. Allergy has been implicated in eosinophilic oesophagitis, with many patients being atopic. Dietary therapy based on eliminating exposure to food allergens is considered an effective treatment option for children, in whom most of the research has been carried out.[1]

Gastrointestinal spasm

Pain or discomfort of the gastrointestinal tract may be due to spasm of the smooth muscle of the gut; such pain and spasm may be associated with the irritable bowel syndrome (see p. 1810.3), dyspepsia (see p. 1806.3), or diverticular disease (see p. 1806.2). Antispasmodic drugs have traditionally been used in patients thought to have gastrointestinal spasm, and have mainly been of two types: antimuscarinics such as dicycloverine, and direct smooth muscle relaxants such as mebeverine; use of antimuscarinics, in particular, has tended to be limited by concern about their adverse effects.

Colic is a general term used to describe spasmodic or griping pain, usually of the viscera, and when not otherwise qualified is often understood to refer to pain in the gastrointestinal tract. Infant colic is common in the first few months of childhood,[1,2] and tends to be managed by nonpharmacological measures and assessment of the feeding technique. Elimination of cow's milk protein appears to be of benefit, but use of a low-lactose formula is not.[1] Tilactase has been added to feeds to aid lactose digestion but the extent of any benefit is unclear. Traditional remedies such as gripe water, which contains essential oils of dill or fennel and is mildly carminative, are of dubious efficacy. Antimuscarinic antispasmodics, although effective[1,2] may be associated with adverse effects, and are no longer considered appropriate.[3] Simeticone suspension, given before feeds, is commonly used but has been found to be no better than placebo.[3,4] It has been reported that sucrose, given as a 12% solution, improves infant colic.[5] Glucose solution may also have some benefit.[2]

Gastro-oesophageal reflux disease

Gastro-oesophageal reflux disease results from the reflux of gastric or duodenal contents into the oesophagus. Symptoms include heartburn, acid regurgitation, and dysphagia (difficulty in swallowing); oesophageal inflammation and ulceration (reflux oesophagitis), and stricture formation may occur. Extra-oesophageal symptoms may include cough, horseness, and asthma. Some patients develop Barrett's oesophagus (below), which is a risk factor for oesophageal cancer (p. 705.3).

Lifestyle advice on weight loss, raising the head of the bed, stopping smoking, and avoidance of alcohol and aggravating foods such as chocolate and coffee is often given as part of initial **management**,[1-6] although the evidence for most of these interventions other than weight loss and bed position is lacking.[3]

Patients often manage initial mild symptoms with over-the-counter therapies, including *antacids* and antisecretory drugs. Although the placebo response is often high, meta-analysis has shown some additional symptomatic benefit from antacids, *histamine H_2-antagonists*, and in particular for combinations of an antacid with an alginate;[7] such combinations are believed to form an alkaline 'raft' above the stomach contents that impedes reflux and protects the oesophageal mucosa.

The symptoms and management of gastro-oesophageal reflux disease may overlap with those of dyspepsia (see p. 1806.3), and initial symptomatic management is likely to be similar.[4] Patients who do not have alarm symptoms that would indicate a need for prompt endoscopy should be treated with an appropriate dose of a *proton pump inhibitor* (PPI) for 1 to 2 months.[4,5] Such treatment is more effective for empirical management than an H_2-antagonist,[8] and is appropriate therapy for endoscopy-negative disease[8] as well as for patients with reflux oesophagitis.[9] There is no evidence for the superiority of any particular PPI, nor for greater benefit from doubling doses in patients with reflux oesophagitis.[8]

A significant minority of patients do not, however, respond to PPIs; reasons may include poor compliance, nocturnal acid breakthrough, non-acid reflux, and hypersensitivity to acid.[4,5] Trying an alternative PPI, increasing the dose, or adding a H_2-antagonist to PPI treatment have been suggested for patients with persistent symptoms,[4,10] although evidence of improved efficacy is generally lacking.[6,9,11] Some benefit has been reported in extensive metabolisers of rabeprazole when famotidine was added to treatment compared with an increased rabeprazole dose.[12]

Alternatively, a *prokinetic drug* such as metoclopramide may improve gastro-oesophageal sphincter function and accelerate gastric emptying. These appear to be as effective as H_2-antagonists,[1] although they are probably less effective than PPIs.[8] An H_2-antagonist used with cisapride may be more effective than either drug alone.[1] However, concern over the risk of cardiotoxicity and potential for serious interactions with cisapride has led to severe restrictions on its use.

In patients with mild disease, a trial of withdrawal of drug therapy is appropriate after successful initial treatment.[1] Short courses of therapy as and when symptoms demand (intermittent treatment) may be effective in uncomplicated disease.[13] However, most patients with oesophagitis relapse when treatment is withdrawn, and long-term **maintenance** therapy is likely to be required.[1,4,5] As in acute management, PPIs appear to be the most effective maintenance treatment, although the 'step-down' approach of reduced maintenance doses, which is widely favoured,[4,5] may produce less benefit than continuing to give full dose PPIs.[14] H_2 antagonists were found to be of marginal benefit for maintenance, although they did give some symptomatic relief, and although prokinetic drugs (cisapride) and sucralfate were also reported to be more effective than placebo their value was considered dubious.[14] Another approach is to use a combination for maintenance, and in one study omeprazole with cisapride provided more effective maintenance than ranitidine or cisapride alone or together.[15] Again, however, cisapride is now unlikely to be used in practice because of the risks.

Helicobacter pylori **eradication** does not heal or prevent relapse of gastro-oesophageal reflux disease,[1] and some epidemiological evidence has appeared to suggest that *H. pylori* infection protects against gastro-oesophageal reflux disease.[16] However, there is no clinical evidence that eradication of *H. pylori* exacerbates gastro-oesophageal reflux disease or significantly increases the risk of its development.[17,18]

In patients who have a poor response to drug therapy, or in those with complications such as oesophageal stricture or ulceration, **surgery** to re-establish gastro-oesophageal competence may be considered.[1,4,5] Submucosal implants and various other endoscopic techniques have also been investigated.[4] Although surgery is as effective as drug treatment, it carries greater associated risks, and many patients continue to require antisecretory drugs.[4]

Investigational approaches to drug therapy include the development of drugs with GABAergic actions similar to those of baclofen (but without its CNS effects), cholecystokinin antagonists such as loxiglumide, and cannabinoid CB_1 agonists; motilin receptor agonists such as alemcinal and mitemcinal do not appear to be of much benefit.[19]

A minority of patients with gastro-oesophageal reflux disease develop **Barrett's oesophagus** (columnar lined oesophagus, CLO), in which the normal oesophageal squamous lining is replaced with a metaplastic columnar epithelium. This is most common in patients with long-standing disease but may represent part of a spectrum of possible responses to acid reflux rather than a progression from less severe to more severe disease.[4] The abnormal epithelium in Barrett's oesophagus shows dysplastic changes that may progress to oesophageal adenocarcinoma. However, not all patients go on to develop cancer, and many aspects of management are controversial.

Management of acid reflux, as for other forms of gastro-oesophageal reflux disease, is the mainstay of management.[20-23] Long-term treatment with PPIs appears to be effective;[22] the use of maximal doses, perhaps with an H_2-antagonist at night, is advocated by some[23] but evidence to support twice daily (double) dosing is lacking.[22] As the altered epithelium is relatively less sensitive to acid, symptom control does not necessarily equate to suppression of reflux.[23] There is a lack of good evidence that control of acid reflux produces anything other than limited regression of the abnormal epithelium, or alters the risk of progression to malignancy,[22,23] although there are some results that suggest benefit.[24,25] Some evidence suggests that additional chemoprevention with aspirin or another NSAID might offer benefits in reducing cancer risk,[22,26] but this remains investigational. The roles of screening, surveillance, and endoscopic ablation therapy or photodynamic therapy (5-aminolaevulinic acid or porfimer) remain matters of debate.[20,22,23]

In **infants**, gastro-oesophageal reflux is common but usually resolves spontaneously with increasing age and requires no treatment. Occasionally, it may be associated with complications such as failure to thrive, oesophagitis, and pulmonary symptoms of acid regurgitation, but can be managed by upright positioning and the use of thickened foods; drug therapy is controversial,[27] and the evidence base is poor.[28] It has been suggested that where drug therapy is needed, an alginate-antacid combination may be appropriate initially;[27] PPIs are probably safe but are not well studied in infants.[28] Cisapride has been given[27,28] but the risk of cardiotoxicity makes the use of cisapride in infants extremely problematic (see p. 1832.2). Metoclopramide may have some benefit but again this must be weighed against the risk of adverse effects.[29] Evidence of benefit with domperidone is poor,[30] and it too has the potential for serious adverse effects, but restrictions on cisapride have led to its over-use.[28] Erythromycin has been investigated in infants with food intolerance, though not in gastro-oesophageal reflux itself; there is a risk of promoting bacterial resistance from such use.[28]

Gastro-oesophageal reflux is commonly encountered during normal **pregnancy**, and is generally managed by lifestyle and dietary modifications.[31] If drug therapy is required, nonsystemically absorbed antacids or sucralfate should be tried first. If these are ineffective, ranitidine may be tried. Proton pump inhibitors are reserved for women with severe or complicated reflux disease,[31] due to concerns about their safety in pregnancy, although the relative risk associated with exposure seems to be quite low (see under Precautions of Omeprazole, p. 1870.3).

Haemorrhoids

Haemorrhoids ('piles') are venous swellings of the tissues around the anus: those above the dentate line (the point where the modified skin of the outer anal canal becomes gut epithelium), which usually protrude into the anal canal, are termed internal haemorrhoids, while those below this point are called external haemorrhoids. Due to internal pressure, internal haemorrhoids tend to congest, bleed, and eventually prolapse; with external haemorrhoids painful thrombosis may develop.[1-3]

Initial treatment of internal haemorrhoids involves a high-fibre diet and avoidance of straining at stool,[2-4] so bulk laxatives and faecal softeners may be indicated.[2] The prime objective of drug therapy is to control the acute bleeding phase so that definitive therapy can be scheduled.[1] Small bleeding haemorrhoids may be injected with a sclerosing agent such as oily phenol injection, but rubber band ligation, or perhaps a technique such as infra-red coagulation, is more effective and associated with fewer complications.[3,5,6] More severe and prolonged prolapse generally requires surgery.[2-4,7] Surgical excision to remove the clot is used for thrombosed external haemorrhoids.[8]

An enormous range of mainly topical drug treatments is available for symptomatic relief, but in many cases their value is at best unproven.

Topical preparations are usually made up in a lubricating or emollient base. Local anaesthetics may be included to relieve pain, and corticosteroids may be used where infection is not present: preparations containing either group of drugs are intended only for short-term use. Inclusion of antibacterials is thought to be of little value and may encourage the development of resistant organisms. Some preparations include heparinoids. Other agents frequently included for their soothing properties include various bismuth salts, zinc oxide, hamamelis, resorcinol, and peru balsam.[2,3] Topical nitrates have also been used.[1]

Bioflavonoids and various derivatives of aesculus may also be included in topical preparations; they have also been given systemically in some countries as have some other compounds such as calcium dobesilate and tribenoside, presumably for their supposed action on venous capillary walls. Oral micronised bioflavonoid preparations may reduce symptoms as an adjunct to surgery.[1,7,9]

Other agents that have been used in the treatment of haemorrhoids include pilewort (ficaria) and combinations of yeast extract with shark-liver oil.

Hepatic encephalopathy

Hepatic encephalopathy (portal systemic encephalopathy) is a metabolically related dysfunction of the brain associated with abnormalities of liver function. It may be acute, as in patients with fulminant hepatic failure, or chronic, with acute episodes precipitated by some triggering factor, as in patients with cirrhosis or other chronic liver disease.

Treatment is aimed at identifying and correcting any precipitating factor, decreasing the production and absorption of ammonia in the gut, and increasing metabolism of ammonia in the tissues. Precipitating factors include infection, increased protein load due to gastrointestinal haemorrhage or high protein intake, alcohol abuse, electrolyte imbalance, and certain drugs (notably anxiolytics, hypnotics, and diuretics).

Restriction of dietary protein intake is a mainstay of short-term treatment, but in the long-term, care must be taken to provide adequate protein to avoid malnutrition. A daily protein intake of 0.5 to 1.5 g/kg has been recommended.[1-3] There is some evidence that vegetable protein is better tolerated than animal protein.[4,5] Giving branched-chain amino acids (valine, isoleucine, and leucine) by infusion or as dietary supplements may facilitate adequate protein intake in some patients.[1,3-5] Supplementation with ornithine aspartate has been used to increase metabolic conversion of ammonia to urea and glutamine.[2,4,5] Sodium benzoate has also been tried.[4,5]

Active drug treatment may begin with bowel cleansing by means of a magnesium sulfate enema, especially if the patient is constipated. Lactulose is then the treatment of choice in many cases, particularly in the elderly, the constipated, and those with renal impairment. It is usually given orally although it may be used rectally[2,5] or by nasogastric tube[2] when oral use is not feasible.[5] It reduces colonic pH and absorption of ammonia and aromatic amino acids. The lactulose analogue lactitol is also used.[6] However, a recent meta-analysis[7] was unable to find sufficient evidence to support or refute the use of nonabsorbable disaccharides, such as lactulose and lactitol, for hepatic encephalopathy. The disaccharidase inhibitor voglibose has been tried to reduce intestinal uptake of disaccharides and promote fermentation, with effects similar to lactulose.[5]

Alternatively, locally active antibacterials have been given to reduce the urease-producing bacteria.[2] Neomycin is the traditional drug but adverse effects such as ototoxicity and nephrotoxicity may be a problem, particularly if used long-term. Metronidazole[4] and rifaximin[4,8,9] are also used. A combination of lactulose and neomycin[4] or metronidazole has been tried in patients who fail to respond to single-drug therapy.

In low grade chronic recurrent encephalopathy *Lactobacillus acidophilus* or *Enterococcus faecium* SF68 have been tried orally in an attempt to produce a more favourable bowel flora. Results have been inconsistent.[3,10] *Helicobacter pylori* is a urease-producing organism, but the relevance of *H. pylori* infection to hepatic encephalopathy is unclear.[11]

Investigational therapy has also attempted to affect cerebral function directly. Flumazenil, a benzodiazepine antagonist, has been tried, on the basis of the suspected role of endogenous benzodiazepine-like agonists.[2,12] A systematic review[13] concluded that flumazenil did produce short-term improvement of hepatic encephalopathy but had no effect on recovery or survival; it might be considered for patients with chronic liver disease and hepatic encephalopathy but routine clinical use was not recommended. Similarly, although dopaminergics such as levodopa or bromocriptine have been given, on the grounds that impaired dopaminergic neurotransmission may play a role in the syndrome,[2] evidence to support their use was not forthcoming from a systematic review.[14]

Liver transplantation (p. 1936.3) is the ultimate therapy for end-stage cirrhosis, acute liver failure, or patients with severe refractory hepatic encephalopathy.[4]

Inflammatory bowel disease

Inflammatory bowel disease (IBD) covers chronic non-specific inflammatory conditions of the gastrointestinal tract, of which the two major forms are *Crohn's disease* and *ulcerative colitis*.

Crohn's disease is characterised by thickened areas of the gastrointestinal wall, with inflammation extending through all layers, deep ulceration and fissuring of the mucosa, and the presence of granulomas; affected areas may occur in any part of the gastrointestinal tract, interspersed with areas of relatively normal tissue; the terminal ileum is frequently involved. Symptoms depend on the site of disease but may include abdominal pain, diarrhoea, fever, weight loss, and rectal bleeding. Extra-intestinal manifestations may include joint inflammation, skin lesions, mouth ulcers, and liver disorders.

In **ulcerative colitis**, disease is confined to the colon and rectum, inflammation is superficial but continuous over the affected area, and granulomas are rare. In mild disease, the rectum alone may be affected (proctitis); in severe disease, ulceration is extensive and much of the mucosa may be lost, with an increased risk of toxic dilatation of the colon, a potentially life-threatening complication. Symptoms include diarrhoea and rectal bleeding. The extra-intestinal manifestations are similar to those of Crohn's disease.

Drug treatments.

Although there are important differences between Crohn's disease and ulcerative colitis which affect their management, the broad principles of treatment, and the drugs used, are similar.[1-6] The aminosalicylate derivatives are generally the first choice in mild to moderate active disease, and are of particular value for maintenance treatment of ulcerative colitis; the role of maintenance treatment in Crohn's disease is less well established. Corticosteroids are also used in the initial treatment of active disease, dosage and route varying with disease site and severity. Immunosuppressant or biological therapy may be helpful in severe or chronic active disease. For Crohn's disease an elemental diet (see Inflammatory Bowel Disease, p. 2043.2) may have some value in active disease, but diet plays a lesser role in ulcerative colitis.

- Oral **sulfasalazine**, a **5-aminosalicylate** derivative (5-aminosalicylic acid linked to sulfapyridine), is of value in producing remission of mild ulcerative colitis;[7] results in Crohn's disease have been more equivocal.[4,8]

The discovery that 5-aminosalicylate was the active component of sulfasalazine led to the development of numerous derivatives, including mesalazine (5-amino-

salicylic acid itself, either used rectally, or orally in slow-release or enteric-coated form), olsalazine (2 molecules of 5-aminosalicylic acid joined by an azo bond), and a variety of forms, such as balsalazide, in which the active moiety was joined to inert carriers. All the above have been shown to be effective in active ulcerative colitis, and may be better tolerated than sulfasalazine, since many of the latter's adverse effects are due to its sulfonamide portion. In patients who can tolerate sulfasalazine, the newer drugs have no clinical advantage for remission induction.[7] Nevertheless, the risk of adverse effects on starting sulfasalazine therapy has led to increasing use of the newer derivatives. The 5-aminosalicylates are also recommended for the maintenance of remission in ulcerative colitis;[3,6,9] in contrast, although they are often used in practice it is unclear that they are of value for maintenance in patients with Crohn's disease.[3-5,10]

- The other major group of drugs used in the treatment of IBD is the **corticosteroids**, particularly for more severe ulcerative colitis, and in Crohn's disease. Rectal use may be appropriate in some patients with distal ulcerative colitis or proctitis; oral prednisone or prednisolone is often used in more severe and extensive disease, and in the most severe cases intravenous corticosteroids (usually hydrocortisone or methylprednisolone) may be given. Unfortunately, treatment of IBD is often prolonged, and adverse effects remain a problem, hence the interest in poorly absorbed or rapidly metabolised corticosteroids such as beclometasone, budesonide, or tixocortol. Oral budesonide is more effective than mesalazine in inducing remission in Crohn's disease and although it may be slightly less effective than conventional corticosteroids, adverse effects are reduced.[11] Corticosteroids are not suitable for maintenance of remission in IBD,[3,12] and inability to withdraw corticosteroid treatment without precipitating relapse (corticosteroid dependence) is a therapeutic challenge.
- Other drugs used in active IBD include **immunosuppressants**. The majority of studies have been with azathioprine, or its metabolite mercaptopurine. Because they have a slow onset of action (months) their use in acute disease is limited, but they are of benefit in remission induction in patients with chronically active disease, particularly corticosteroid-resistant or corticosteroid-dependent disease; they may also be used for maintenance in both ulcerative colitis and Crohn's disease, often with other drugs.[3-6,13,14] Low-dose intramuscular methotrexate also appears to be useful for induction[15] and maintenance[16] of remission in Crohn's disease, although it is often given subcutaneously in practice. Evidence for the oral route is lacking,[15,16] and it does not appear to be of value in ulcerative colitis.[5,6] Conversely, ciclosporin has not generally proved useful in chronically active inflammatory bowel disease but may have some value in the short-term treatment of acute severe ulcerative colitis.[5,17] Tacrolimus also appears to be of benefit in severe ulcerative colitis,[5] and possibly in Crohn's disease;[18] mycophenolate mofetil has been tried, although the limited evidence is equivocal.[18]
- Of increasing importance in the management of severe or refractory forms of IBD are the so-called '**biological therapies**', comprising in particular anti-tumour-necrosis factor antibodies such as infliximab, adalimumab, and certolizumab pegol. These have been shown to be effective for induction therapy and maintenance in Crohn's disease;[5,19,20] infliximab[5,20] and adalimumab[21,22] are also used for induction and maintenance of remission in ulcerative colitis.[5,20] Golimumab is another drug in this group that may be used for ulcerative colitis. The anti-integrin antibody natalizumab is effective in inducing remission in Crohn's disease.[23] Thalidomide, a tumour necrosis factor inhibitor, has also been tried in Crohn's disease with some benefit,[18,24] but another such inhibitor, pentoxifylline, was ineffective.[25]
- **Metronidazole** is useful in fistulising perineal Crohn's disease and may be used in colonic Crohn's disease. It is usually given for 3 months. Ciprofloxacin is an alternative, and has also been given with metronidazole,[26,27] although the combination may not be very well tolerated. There has been interest in the possible causal role of *Mycobacterium paratuberculosis* in Crohn's disease,[28] but a study of 2 years of antituberculous therapy with clarithromycin, rifabutin, and clofazimine in patients with Crohn's disease found no evidence of sustained benefit, suggesting that the organism probably did not play a significant role.[29] In contrast, a meta-analysis[30] of several mostly small studies suggested that long-term treatment with a nitroimidazole such as metronidazole, or with clofazimine, might have benefits in patients with Crohn's disease. Antibacterials do not have a role in ulcerative colitis, except for infection prophylaxis in severe attacks.
- **Many other drugs** are being or have been tried in IBD, including immunoglobulins, some interleukins, interferons, short-chain fatty acids, heparin, factor XIII, rosiglitazone, and aminosalicylic acid (4-aminosalicylic acid as opposed to 5-aminosalicylic acid). There have been some short-term responses to the anti-integrin antibody, vedolizumab,[31] and to the anti-interleukin-12 antibody, briakinumab.[32] There is limited evidence of improvement in disease severity from the use of the granulocyte-macrophage colony-stimulating factor sargramostim,[33] which is thought able to stimulate intestinal innate immune defence processes that may be impaired in Crohn's disease. Other biological therapies which are being investigated include the ICAM-antisense oligonucleotide alicaforsen, the T-cell costimulation blocker abatacept, the anti-CD3 antibody visilizumab, and the CCR9 chemokine receptor inhibitor CCX-282.[34] Nicotine has been tried in ulcerative colitis, based on the observation that the disease is rare in smokers. Studies have suggested that nicotine, supplied via transdermal patch, may have benefit in active disease,[35] although it is ineffective for maintenance.[36] Rectal and oral formulations of nicotine are under investigation.

Nutritional and dietary therapies.

Correction of nutritional deficiencies may be necessary in severe IBD, but dietary modification may also have therapeutic effects. In Crohn's disease, enteral feeding, often with an elemental diet is effective in inducing remission (see Inflammatory Bowel Disease, p. 2043.2), although corticosteroids are more effective;[37] there is also some evidence of benefit in maintaining remission.[38] Elemental diets are useful in children and those unable to tolerate corticosteroids. The role of omega-3 fatty acids has been investigated, but systematic reviews have concluded that they are ineffective for maintenance of remission in Crohn's[39] and ulcerative colitis.[40]

There has been some interest in manipulation of the bowel flora through use of lactobacilli and other probiotic bacteria.[41] There have been some reports of benefit in ulcerative colitis,[42,43] and probiotics may be useful in the management of pouchitis,[3,6] but there is no good evidence to date of benefit in Crohn's disease.[44] The observation that inflammatory bowel disease is uncommon in developing countries where most people carry helminths has led to preliminary studies of bowel colonisation using *Trichuris suis* ova (porcine whipworm) in active Crohn's disease[45] and ulcerative colitis.[46]

Surgery.

In patients with ulcerative colitis surgical colectomy is curative, and may avoid the risks of long-term corticosteroid therapy and the increased risk of bowel cancer to which patients with inflammatory bowel disease are subject. Formation of an ileoanal pouch, which acts as a reservoir for the ileal contents, avoids the necessity for a standard ileostomy and maintains a degree of continence in suitable patients. Curative surgery is not possible in Crohn's disease, since recurrence elsewhere in the gut is almost inevitable, but resection of the affected area becomes necessary in many patients during the course of their illness.

CHOICE OF THERAPY

Ulcerative colitis.

- ACTIVE DISEASE:
  - ***mild to moderate***

    In mild to moderate *distal* disease topical mesalazine, preferably with an oral aminosalicylate (balsalazide, mesalazine, or olsalazine), is the treatment of choice.[3,6] Selected patients may benefit from oral sulfasalazine. Patients intolerant of topical mesalazine may be given a topical corticosteroid instead, though they are less effective.[47] Suppositories are suitable for *proctitis* but foam or liquid enemas are required for more proximal disease (*proctocolitis*).[3] Patients who fail to improve on a combination of oral aminosalicylate with topical mesalazine or corticosteroid may require an oral corticosteroid (e.g. prednisone or prednisolone 40 mg daily).[3,5,48] Infliximab is an alternative.[6]

    In *left-sided* or more *extensive* ulcerative colitis the preferred therapy is an oral aminosalicylate;[3,5,6] olsalazine is best avoided in patients with *pancolitis* as it may be more likely to produce diarrhoea than mesalazine or balsalazide.[3] There is some evidence that the benefits of aminosalicylates are dose related,[5,6] and some controversy exists as to the optimum induction dose: use of higher doses initially may produce better responses,[5,6] but there is an increased risk of toxicity. Some recommend the addition of topical aminosalicylates as the combination is considered more effective than oral treatment alone.[48]

    Patients who fail to respond to aminosalicylates should be given an oral corticosteroid (as above).[3,6,48] The corticosteroid should be reduced gradually (tapered) over several weeks once response is achieved.[3,6] Since long-term treatment with corticosteroids is undesirable, patients with *chronic active disease* who are at high risk of relapse when the corticosteroid is withdrawn (corticosteroid-dependent disease) should be treated with a thiopurine (azathioprine or mercaptopurine) as a corticosteroid-sparing drug.[3,6,48] Thiopurines may also be effective in inducing remission in some patients who do not respond to oral corticosteroids, although their slow onset of action is problematic.[6] In patients with more extensive, moderate to severe disease, infliximab may be an option.[5,6] Adalimumab and golimumab are also licensed for use in such patients.
  - ***severe***

    Patients who present with severe colitis or who fail to respond to maximal oral treatment should be admitted to hospital for treatment with intravenous corticosteroids.[3,5,6,48] Patients should be given appropriate supportive therapy (including nutritional support if the patient is malnourished, intravenous antibacterials for infection, and blood transfusion if markedly anaemic).[3,6] Intravenous ciclosporin may be a useful option in patients with severe disease who cannot tolerate corticosteroids.[48] Ciclosporin should also be considered as a second-line treatment for those who fail to respond to intravenous corticosteroids within a few days.[3,5,6,48] Infliximab or tacrolimus are also options.[5,6,48] Patients who respond to intravenous ciclosporin may be given oral continuation treatment for 3 to 6 months.[3] Drug therapy is ineffective in up to 40% of patients with severe colitis,[6] and colectomy is an alternative.[3,6]
- MAINTENANCE:

  Lifelong maintenance therapy is generally recommended for patients with ulcerative colitis once remission is achieved, particularly in those with left-sided or more extensive disease, or those with distal disease who relapse more than once a year.[3] The treatment of choice is an oral aminosalicylate,[3,5,6,48] most often mesalazine,[5] although in those that can tolerate it sulfasalazine is possibly more effective.[9] A combination of oral and topical aminosalicylates has been recommended as a second-line maintenance treatment.[48] Topical aminosalicylates alone have been used for maintenance in patients with proctitis, left-sided,[48] or distal disease;[3,5] a combination of oral and rectal aminosalicylates can be used second line.[48] Corticosteroids are ineffective in maintaining remission and associated with severe adverse effects on prolonged use. Azathioprine may be used for maintenance therapy, but is best reserved for patients who relapse frequently despite aminosalicylate maintenance, or who are unable to tolerate such therapy.[3,6,48] Patients with gastrointestinal intolerance of azathioprine may be tried cautiously with mercaptopurine; alternatively, surgery may be considered.[3] Infliximab is also effective for maintenance of remission,[6] especially in patients who remain corticosteroid dependent despite alternative therapies.[5] Golimumab is also used.
- POUCHITIS.

  Ileoanal pouch anastomosis allows for surgical removal of the colon without loss of continence or the need for an ostomy, but subsequent inflammation of the pouch (pouchitis) occurs in about half of all patients.[6] On the basis of limited evidence it is considered to be best treated by a short course of antibacterials (metronidazole or ciprofloxacin).[3,6] If these are ineffective, mesalazine or corticosteroids may be considered.[3] Use of a probiotic formulation, VSL 3, containing a mixture of bacteria, may also be of benefit.[3,6]

Crohn's disease.

- ACTIVE DISEASE:
  - ***mild to moderate***

    First-line therapy in mild to moderate Crohn's disease is a matter of some debate. Oral mesalazine is of limited benefit in *ileal* or *ileocaecal* disease,[4,5] and some consider that it should not be used at all,[5] although others recommend high doses as an appropriate initial therapy.[3] Aminosalicylates may be of more benefit in *colonic* disease, particularly sulfasalazine if it can be tolerated.[3-5] Others favour the use of oral budesonide as first-line therapy for mild to moderate ileocaecal disease;[4,5] although it is somewhat less effective than conventional oral corticosteroids, which are an option in more active disease,[3,4] it produces fewer adverse effects.[11] Opinion also varies on the use of topical mesalazine in colonic disease,[3,4] although it is widely used.[4] Nutritional support (enteral feeding or the use of elemental diets) may be considered as an alternative to drug therapy or surgery in selected patients.[3]
  - ***moderate to severe***

    In outpatients with moderate to severe disease, and those who fail to respond to initial therapy with budesonide or aminosalicylates, conventional oral corticosteroids, typically in a dose corresponding to

40 mg of prednisolone daily (or up to 1 mg/kg daily), are recommended.[3-5] Once response has been achieved, dosage should be gradually tapered off.[3,4]
In patients who have relapsed, azathioprine or mercaptopurine may be added,[4] but they are not best suited to induction of remission because of the delay in onset.[3] Methotrexate may be an alternative in selected patients.[4]
In patients with severe extensive or *fulminant* disease intravenous corticosteroids should be given.[3-5] Adding intravenous metronidazole may be advisable, because of the difficulty of distinguishing active disease from a septic complication.[3] Infliximab should be considered in patients with disease *refractory* to corticosteroids;[3-5] adalimumab or certolizumab pegol may be alternatives.[5]

- ***fistulising disease***
  Simple perianal fistulae can be treated with metronidazole or ciprofloxacin.[3,5] Azathioprine or mercaptopurine are also potentially effective,[3] while infliximab is recommended in patients who do not respond to other treatment.[3,5] An alternative to infliximab is adalimumab.[5] Surgery is appropriate for complex or persistent fistulae.[3,5]
- ***chronic active and corticosteroid dependent disease***
  Azathioprine or mercaptopurine are the drugs of choice in corticosteroid dependent disease.[3] If they are ineffective or not tolerated, intramuscular methotrexate may be considered;[4] it is also considered appropriate for the management of chronic active disease.[3] Infliximab is generally reserved for patients who fail first-line therapy, as an alternative to surgical resection.[3]

- MAINTENANCE:
  The most important intervention in maintaining remission in patients with Crohn's disease is probably to persuade those who smoke to stop smoking.[3] Mesalazine appears to be of limited benefit at best for the maintenance of remission,[3,4,10,49] although it is widely used,[5] and the other aminosalicylates are considered inappropriate.[3,4] Corticosteroids are also not effective for maintenance,[3,4,12] although budesonide may delay relapse for a limited period.[4,5] In patients who required corticosteroids to achieve remission, the usual drug treatment for maintenance is a thiopurine (azathioprine or mercaptopurine).[3-5] In patients who achieved remission with intramuscular methotrexate, it may be continued for maintenance;[3] it is also an option in patients intolerant of thiopurines.[4] Thiopurine maintenance may need to be continued for several years,[4] or even indefinitely.[5] Infliximab is also an option for maintenance, particularly in patients brought to remission with the same drug,[3,4] or those who cannot maintain remission or who remain corticosteroid dependent despite the use of maintenance immunosuppression.[5] Alternatives may be adalimumab or certolizumab pegol.[5] To prevent recurrence following surgery, short-term antibacterial therapy with nitroimidazoles has been recommended in those with risk factors for early recurrence, although adverse effects limit longer-term use. Mesalazine has also shown benefit in maintaining a surgically-induced remission, as have azathioprine and mercaptopurine, although the risk of adverse effects is higher with the immunosuppressants. Promising results have been reported from early studies using postoperative infliximab.[50]

Patients with inflammatory bowel disease have an increased risk of developing colorectal cancer and chemoprevention has been investigated. The aminosalicylates have shown a preventive effect in most studies, and there is strong evidence that ursodeoxycholic acid reduces colorectal cancer in patients with ulcerative colitis who also have primary sclerosing cholangitis.[51]

Irritable bowel syndrome

Irritable bowel syndrome is a functional gastrointestinal disorder of abdominal pain and altered bowel habit; pain is characteristically relieved by defaecation and may be associated with increase or decrease in stool frequency. There may be abdominal bloating. Women are more often affected than men. Most patients have symptoms intermittently, with flares lasting several days followed by periods of remission.[1] Patients may be classified as having different subtypes of the syndrome, depending on the nature of the main symptoms.

Given the heterogeneity of the condition, only a minority of patients will respond to any given treatment, and this together with a high placebo response rate limits the evidence base for treatment.[1-3] The mainstay of treatment is explanation and reassurance, coupled with sensible advice about lifestyle.[1,4] Dietary modification should involve increasing the amount of vegetable fibre in the diet initially (but see below); some patients respond to exclusion of particular foods but this is probably best reserved for more refractory cases, and should not be allowed to compromise proper nutrition.[1]

Formal psychological therapies may be appropriate in some patients, especially if they have other psychological problems such as marked anxiety or depression, or are unwilling to consider symptomatic drug therapy.[1] Hypnotherapy may have a role in refractory patients,[1] but a systematic review, although noting promising results, was unable to confirm benefit.[5]

Many drug treatments have been tried in irritable bowel syndrome. Short-term drug therapy may be useful in managing symptoms,[1-4,6-8] and should be directed according to which predominate:

- in patients in whom *diarrhoea* is predominant, loperamide may be considered; it is preferred to other opioid antidiarrhoeal drugs because it does not pass the blood-brain barrier. Alternatively, colestyramine may be of benefit. The 5-HT_3 antagonist alosetron is also available in some countries for use in women with severe symptoms unresponsive to conventional therapy; it was previously withdrawn due to gastrointestinal toxicity
- in *constipation-predominant* forms of the syndrome fibre supplementation is often advocated. However, insoluble fibre, such as bran, may exacerbate pain and bloating in some patients, and if fibre supplements are to be given, soluble fibre, such as ispaghula, is preferable.[1] The benefits of bulking agents in general have been questioned.[9] An osmotic laxative or stool softener may be added in patients who fail to respond to fibre, but stimulant laxatives should be avoided or used only occasionally.[1] The synthetic peptide linaclotide acts locally to activate guanylate cyclase-C receptors and reduce constipation.[10] Tegaserod, a partial agonist at 5-HT_4 receptors, has also been effective in this group of patients, although it has been withdrawn from the market in many countries due to cardiovascular ischaemic events
- in patients with *abdominal pain*, 'as-needed' antispasmodics may be tried. These should be taken before meals if abdominal pain occurs principally after eating. Examples include alverine, dicycloverine, hyoscine, mebeverine, peppermint oil, and pinaverium. Systematic reviews considered the evidence of benefit to be greatest for hyoscine and its derivatives[11] cimetropium, dicycloverine, trimebutine, and pinaverium;[9] peppermint oil was also considered effective.[9,11] Low-dose tricyclics have been suggested for second-line use in patients unresponsive to antispasmodics.[1] Reviews[9,12] found antidepressants more beneficial than placebo for treating symptoms of irritable bowel syndrome. Tricyclic antidepressants and SSRIs were considered equally effective
- patients whose symptoms are associated with mild or masked *depression* may also obtain benefit from antidepressant therapy; a depressed patient with increased bowel frequency and abdominal pain may benefit from a tricyclic antidepressant, which slows intestinal transit. It has been suggested that patients with constipation may be better treated with an SSRI

Many other drugs have been tried in irritable bowel syndrome, but results have mostly been variable.[2,3] Interest in new pharmacological approaches has included investigation of cholecystokinin antagonists (loxiglumide and dexloxiglumide); 5-HT_4-agonists such as ATI-7505 as well as compounds with mixed actions such as renzapride; κ-opioid agonists such as asimadoline and possibly μ-opioid antagonists such as alvimopan; the 2,3-benzodiazepine receptor modulator dextofisopam; chloride channel activators such as lubiprostone; melatonin; non-absorbed antibacterials such as neomycin or rifaximin, or more promisingly the use of probiotic mixtures of lactic acid-producing organisms; and recombinant human nerve growth factors.[13-15] Many herbal medicines have also been tried: a systematic review found the studies mostly to be small and of poor quality, but suggested that there was evidence of benefit for some herbal combinations including Chinese traditional medicines such as tongxie yaofang.[16]

Microscopic colitis

Microscopic colitis covers the diseases collagenous colitis and lymphocytic colitis, which are characterised by chronic, watery, non-bloody diarrhoea with intra-epithelial lymphocytic infiltration; in collagenous colitis this is accompanied by a thickened band of collagen immediately below the surface epithelium of the colonic mucosa.[1-4] Although originally considered to be rare, more recent studies have suggested an increased incidence;[2-4] differentiating from the diarrhoea-predominant form of irritable bowel syndrome (p. 1810.3) may be difficult. It has been suggested that the disease is more common in middle-aged women,[2] but others dispute this.[3]

The evidence base for management is limited, and is complicated by the fact that the disease may remit spontaneously.[2-4] Initial measures may include dietary modification, with avoidance of caffeine[2,3] or lactose-containing foods.[2] A possible association with NSAIDs has been suggested; such drugs should be withdrawn, or their use minimised, if possible.[2,3] Drug treatment has been largely empirical, and relapse is quite common once treatment stops. Antidiarrhoeal treatment with loperamide or fibre supplements has been proposed initially.[1-3,5] Systematic review[6] has suggested that budesonide (see also p. 1626.1), and probably bismuth salicylate, are of benefit in collagenous colitis, and they may be considered for second-line therapy.[3] Data from a small study suggested that bismuth salicylate might also be beneficial for lymphocytic colitis, although no firm conclusions could be drawn.[7] In unresponsive patients, sulfasalazine or another 5-aminosalicylate may be considered;[1-3] it has been suggested that mesalazine or olsalazine may be less effective (though better tolerated) than sulfasalazine.[1,2] Other drugs that may be tried in resistant cases include colestyramine, antibacterials such as metronidazole or erythromycin, oral prednisolone, or immunosuppressants such as azathioprine, mercaptopurine, or methotrexate.[1-3,5] Octreotide and verapamil have also been reported to relieve symptoms.[3]

Mouth ulceration

Recurrent ulceration of the oral mucosa is usually idiopathic and self-limiting and is known as recurrent aphthous stomatitis or recurrent aphthous ulceration. However, oral ulcers (canker sores) may also be caused by mechanical trauma, nutritional deficiencies (particularly iron, folic acid, or vitamin B_{12}), drug reactions, or underlying disease such as Behçet's syndrome (p. 1601.1).

Management includes identifying any underlying disease or nutritional deficiency and treating these as appropriate. Usually no underlying cause can be found, and treatment is purely symptomatic; it may include topical anti-inflammatories, local anaesthetics, antiseptics, astringents, or antihistamines. The value of many of these drugs in reducing symptoms remains anecdotal, and no treatments have yet been proven to reduce the incidence of recurrences.

Where ulceration is due to minor trauma frequent use of a warm saline or compound thymol glycerin mouthwash may be all that is required to relieve discomfort and swelling. Alternatively, pain relief may be obtained with local anaesthetics or analgesics, but their efficacy in oral ulceration is limited by their relatively short duration of action when applied topically. Salicylates are widely used, mainly as choline salicylate gel, although they themselves have the potential for local irritation and ulceration. Benzydamine spray or mouthwash may also be helpful. Lidocaine, as a gel or lozenges, may be of value in pain that has not responded to other measures. Topical corticosteroids are probably the most effective symptomatic treatment for recurrent aphthous stomatitis. Pellets or lozenges of hydrocortisone are allowed to dissolve next to an ulcer, or triamcinolone in an oral paste formulation may be used, although the paste may sometimes be difficult to apply. Mouthwashes have been employed particularly when ulceration is widespread in the mouth and a dexamethasone mouthwash has been used effectively. The healing properties of carbenoxolone have also been employed as a gel or mouthwash, and the mast-cell stabilising agent amlexanox is also used as an oral paste.

Mechanical protection may be provided by a paste or powder of carmellose sodium, although application may be difficult.

Use of an antiseptic mouthwash such as chlorhexidine or povidone-iodine may be helpful, since secondary bacterial infection can delay healing. Chlorhexidine is also available as a gel. Tetracyclines, used as mouthwashes, reportedly reduce ulcer pain and duration, but their potential for adverse effects if swallowed must be borne in mind. Use of hydrogen peroxide 3% is inadvisable, as it can cause ulceration, but application of a 1.5% solution to individual ulcers, with a topical corticosteroid, may be helpful in producing resolution.

Many other drugs have been tried in aphthous ulceration. Sucralfate may be of benefit. Drugs such as levamisole and thalidomide, although possibly beneficial, are unlikely to be suitable in most cases because of their adverse effects, although thalidomide is used, for example, for aphthous stomatitis in patients with AIDS. Pentoxifylline, which, like thalidomide, inhibits tumour necrosis factor production, has been used in patients with minor recurrent aphthous ulceration. Systemic corticosteroids are generally reserved for cases with severe underlying disease.

Nausea and vomiting

Vomiting follows stimulation of the vomiting centre in the medulla of the brain. This may be via the chemoreceptor trigger zone, which is sensitive to many drugs and to certain metabolic disturbances, or from actions on other areas such as the vestibular apparatus of the ear (in motion sickness), the cerebral cortex (in psychogenic vomiting), and multiple peripheral receptors. In adults vomiting is almost invariably preceded by a sensation of nausea.

In situations where it can be anticipated, such as motion sickness, surgery, and cancer therapy, antiemetic drugs are given prophylactically, but if this fails they may need to be given therapeutically. Vomiting of unknown origin should ideally not be treated until the underlying cause has been found. If vomiting is prolonged, dehydration, hypokalaemia, and alkalosis may occur and replacement of fluid and electrolytes may be necessary, especially in young children and the elderly.

Cancer chemotherapy. Nausea and vomiting are common adverse effects of cancer chemotherapy and for many patients represent a major drawback to treatment. Once experienced, anticipatory vomiting may occur at the sight of medical staff or a needle and this problem may be severe enough in some cases to hinder or prevent further treatment.

Antineoplastic or cytotoxic drugs may induce vomiting by both a central action on the chemoreceptor trigger zone and a peripheral action on the gastrointestinal tract. The cerebral cortex is probably responsible for anticipatory vomiting. Mechanisms involving 5-HT_3-receptors are important in the pathogenesis of *acute cisplatin-associated vomiting*, whereas different mechanisms are probably involved in *delayed emesis*.

The emetic potential of antineoplastics varies in terms of severity and incidence. A risk classification system, based on the proportion of patients who have emesis in the absence of effective antiemetic prophylaxis, has been developed. Although there are slight variations in published lists,[1-3] examples of risk for some common drugs include:

- *high (more than 90% frequency of emesis)* and can be very severe with chlormethine, cisplatin, high-dose cyclophosphamide, dacarbazine, dactinomycin, oral procarbazine, and streptozocin
- *moderate (30 to 90% frequency of emesis)* with carboplatin, more modest doses of cyclophosphamide, daunorubicin, doxorubicin, epirubicin, oral etoposide, idarubicin, oral imatinib, irinotecan, high-dose methotrexate, oxaliplatin, oral temozolomide, and oral vinorelbine
- *low (10 to 30% frequency of emesis)* with oral capecitabine, etoposide, oral fludarabine, fluorouracil, gemcitabine, lower doses of methotrexate, mitomycin, mitoxantrone, pemetrexed, and taxanes
- *minimal (less than 10% frequency of emesis)* with bleomycin, busulfan, oral chlorambucil, cladribine, oral erlotinib, fludarabine, oral gefitinib, oral hydroxycarbamide, oral methotrexate, rituximab, oral tioguanine, and vinca alkaloids

Emetogenicity may depend to some extent on the dose, route, and schedule of chemotherapy. Some combination therapy has resulted in a higher incidence of vomiting than would be expected from the constituents.

The *onset and duration* of vomiting also varies from drug to drug. For cisplatin the onset may be between 4 and 8 hours after a dose, while the duration may be up to 48 hours or occasionally even longer; a persistent feeling of nausea, and sometimes vomiting, lasting for several days may also occur. After chlormethine, vomiting may begin within a half to 2 hours, whereas after cyclophosphamide there may be a latent interval of 9 to 18 hours, but in both cases vomiting is generally less prolonged than with cisplatin. *Acute emesis* (that occurring within 24 hours of chemotherapy) has generally been easier to control than *delayed emesis* (that occurring more than 24 hours after chemotherapy) or *anticipatory emesis*. In patients whose regimens are given over several days delayed emesis from the initial doses may overlap with acute emesis from later doses.

MANAGEMENT. Guidelines for the management of nausea and vomiting associated with chemotherapy have been produced.[1-3] It is important that effective antiemetic prophylaxis is given from the first course of chemotherapy, to avoid subsequent problems with anticipatory vomiting. With the antiemetic drugs now available it should be possible to control acute emesis; delayed emesis has proved more resistant but new treatments are becoming available. Drugs used in antiemetic regimens have included:

- dopamine antagonists such as metoclopramide, domperidone, and some phenothiazines such as prochlorperazine
- corticosteroids such as dexamethasone
- 5-HT_3 antagonists such as ondansetron

- neurokinin-1 (NK-1) receptor antagonists such as aprepitant
- cannabinoids such as nabilone
- benzodiazepines such as lorazepam
- antihistamines such as diphenhydramine

The choice depends on the emetogenicity of the cancer chemotherapy regimen, as well as factors such as the age of the patient.

- For prophylaxis of *acute emesis* associated with *highly emetogenic chemotherapy*, a 5-HT_3 antagonist with dexamethasone and aprepitant (or fosaprepitant) is recommended.[1-3] At equipotent doses, dolasetron, granisetron, ondansetron, and tropisetron are effective and equally safe.[1,2] Palonosetron, which has a prolonged action, may also be used.[2] High-dose metoclopramide was formerly used, but frequently caused extrapyramidal adverse effects, particularly in patients under 30 years of age; diphenhydramine was used to reduce these effects
- For prophylaxis of *acute emesis* associated with *moderately emetogenic chemotherapy*, dexamethasone with a 5-HT_3 antagonist is suggested.[1-3] Aprepitant (or fosaprepitant) may be added for patients given an anthracycline and cyclophosphamide or other chemotherapy drugs of moderate emetic risk
- Dexamethasone alone may be used for prophylaxis with chemotherapy of *low emetic risk*;[1-3] alternatives include prochlorperazine or metoclopramide.[2] No routine prophylactic antiemetic needs to be given for chemotherapy of *minimal emetic risk*;[1-3] however, as-needed or prophylactic use of dexamethasone, a phenothiazine, or metoclopramide is common, particularly for patients with poor emetic control during previous therapy[1]
- Lorazepam may be used for its amnestic, sedative, and anxiolytic effects as an adjunct to antiemetics when *anticipatory emesis* is a problem
- Good control of acute emesis is important in preventing *delayed emesis*. In addition, for prophylaxis of delayed emesis from highly emetogenic chemotherapy, a combination of dexamethasone with aprepitant may be used. After moderately emetogenic chemotherapy, prophylaxis with a single drug such as dexamethasone or a 5-HT_3 antagonist may be sufficient.[1,3] Aprepitant or dexamethasone alone has been suggested for patients given an anthracycline with cyclophosphamide[1,3]

Cannabinoids such as dronabinol and nabilone have been used for chemotherapy-induced nausea and vomiting, usually as second-line drugs. Although they have some advantages because of their effects on mood, their use is limited by adverse effects.[4]

If *breakthrough emesis* occurs, management is often difficult. The general principle of treatment is to add an additional antiemetic from a different class; multiple concurrent drugs, perhaps in alternating schedules or by alternating routes may need to be considered. Since oral dosage may not be feasible because of ongoing vomiting, treatment is often given by the rectal or intravenous routes.[2] More intensive prophylactic treatment should be considered in subsequent courses.

Motion sickness has been described as a normal reaction to stimuli that occur during passive transportation and to which the individual is not adapted. The term embraces all forms of travel sickness including sea sickness, car sickness, train sickness, and air sickness. It is a type of vertigo in which autonomic symptoms predominate, therefore signs and symptoms include pallor, sweating, increased salivation, yawning, malaise, and hyperventilation.

MANAGEMENT. The aim is to *prevent* motion sickness and antiemetics are more effective if given prophylactically before nausea and vomiting has developed. The principal drugs used are the antimuscarinic hyoscine and some of the centrally acting antihistamines.[5,6] In some countries dexamfetamine has been tried,[6] although its adverse effects and the risk of abuse make it an unlikely choice. Antiemetic drugs *not* effective against motion sickness include metoclopramide, domperidone, chlorpromazine, and 5-HT_3 antagonists. Ginger has been tried. Evidence for the value of wrist acupressure is equivocal.[6]

For short-term protection against motion sickness hyoscine hydrobromide has been shown to be effective.[7] It can be taken orally about 30 minutes before a journey followed by further doses every 6 hours if necessary. Transdermal hyoscine has a longer duration of action, but the patches need to be applied to the skin several hours before travelling.

There is little good evidence comparing the efficacy of antihistamines with hyoscine against motion sickness,[7] but they are often better tolerated. They are usually given orally and include cinnarizine, cyclizine, dimenhydrinate, meclozine, and promethazine; all have similar efficacy, but differ in onset and duration of action and in the extent of adverse effects such as drowsiness. Their antimuscarinic properties may contribute to their effects. Non-sedating antihistamines (e.g. astemizole and terfenadine) penetrate poorly into the CNS and do not appear to be effective against motion sickness.

Once motion sickness has developed, gastric motility is inhibited and oral antiemetics are unlikely to be effective. Where intramuscular injection is feasible, promethazine appears to be the most effective treatment. If exposure is likely to be prolonged, transdermal hyoscine may be useful, but will not provide benefit for some hours.[6]

Palliative care. Nausea and vomiting are common in terminal illness, and may be prolonged. Causes may include gastric irritation or stasis, bowel obstruction, renal failure, hypercalcaemia, raised intracranial pressure, infection, or the effects of drugs or radiation; anxiety, cough, and pain may exacerbate the condition.[8-11]

MANAGEMENT. Management will depend on the cause of the nausea and vomiting.[9,10] The evidence base for many antiemetics in terminal care is poor; it is perhaps best for metoclopramide, but evidence for many common and apparently effective interventions, such as haloperidol, cyclizine, and levomepromazine, is conflicting.[12] However, guidelines have been developed, either empirically or based on considerations of the likely causes. Recommendations include:[9]

- any correctable causes should be managed appropriately, and treatment for exacerbating conditions (such as anxiety) given
- an appropriate antiemetic should be given immediately, and repeated as often as necessary. If nausea is continuous or vomiting frequent, subcutaneous injection or continuous subcutaneous infusion may be preferred to the oral route. The usual initial choice for palliative care in the UK is between metoclopramide (preferred if the cause is gastric stasis, gastritis, or functional bowel obstruction), haloperidol (favoured in drug-induced vomiting, hypercalcaemia, and renal failure), and cyclizine (raised intracranial pressure, motion sickness, organic bowel obstruction)
- if treatment fails an alternative drug may be considered, or combination therapy may be necessary (prokinetics such as metoclopramide should not be combined with antimuscarinic drugs as their actions are antagonistic). Dexamethasone (usually added to the regimen), or levomepromazine or olanzapine (broad-spectrum antiemetics; these are usually substituted for the previous regimen) are useful where first-line drugs fail. Olanzapine is usually used if levomepromazine is too sedative. Other phenothiazines, notably prochlorperazine, and the phenothiazine antihistamine promethazine, are sometimes still used, but chlorpromazine is less effective than levomepromazine where a broad-spectrum drug is required. The role of 5-HT_3 antagonists is limited but they may be useful in nausea and vomiting secondary to chemotherapy (above) or radiotherapy (below), or sometimes in bowel obstruction or renal failure
- if there is colic or a need to reduce secretions, hyoscine butylbromide should be given, alone or with cyclizine. If this is inadequate in patients with obstruction, octreotide may be helpful

Non-drug measures may include appropriate diet and avoidance of unpleasant odours, adequate hydration, and regular mouth care.[8,10] Acupressure and acupuncture may provide some benefit.[10,13]

Postoperative nausea and vomiting (PONV) is a common and distressing adverse effect of anaesthesia and surgery;[14-18] it is seen in some 20 to 30% of patients undergoing surgery under general anaesthesia,[15,16,19] and is perceived by patients as a problem comparable to postoperative pain.[20]

Risk factors for PONV include a history of motion sickness or previous PONV, female sex, not smoking, use of opioids during or after surgery, use of volatile inhaled anaesthetics or nitrous oxide, and prolonged surgery.[15-19,21,22] It is widely considered that certain types of surgery carry an increased risk, but it is unclear whether the increase is due to the type of surgery or independent risk factors.[15,16] A study comparing various predictive models found that none was perfect, but that a simplified model based on history, sex, smoking status, and opioid use was as effective as more complex methods.[21]

MANAGEMENT. Prediction of risk is of value since much of the management of PONV focuses on prevention. It is generally agreed that prophylaxis should be reserved for patients at moderate to high risk. In these, various strategies may be adopted to *reduce risk* where possible, including the use of regional anaesthesia or total intravenous anaesthesia with propofol (but see also p. 1910.2), avoidance of nitrous oxide, minimal use of opioids, adequate hydration (especially with colloids), and possibly the use of intraoperative supplemental oxygen (although not all studies found this of benefit).[15,16] Avoidance of high-dose neostigmine (limiting the dose to a maximum of 2.5 mg in adults) has also been suggested.[16] There is evidence that some nonpharmacological interventions, such as acupuncture of the P6 point, may also be effective, especially for nausea.[23]

Many types of drugs have been tried as *prophylactic antiemetics*. These include the 5-HT_3 antagonists, phenothiazines such as prochlorperazine, butyrophenones such as droperidol, antihistamines such as promethazine, cyclizine, or dimenhydrinate, and some other drugs such as dexamethasone and hyoscine.[18,22] A large and well-designed multicentre study (IMPACT) has shown that ondansetron, droperidol, and dexamethasone are of similar efficacy;[24] it also confirmed that avoidance of volatile anaesthetics and nitrous oxide was of as much benefit in preventing PONV as use of a prophylactic antiemetic. The evidence suggests that other 5-HT_3 antagonists are of similar efficacy to ondansetron.[16] Evidence for some of the older drugs is less extensive, although benefit has often been shown in individual studies.[16] Systematic reviews have confirmed the benefit of prophylaxis with dimenhydrinate[25] and transdermal hyoscine[26] but have suggested that metoclopramide, which has been widely used, is in fact of little value in preventing PONV,[27,28] perhaps because the doses used are too low.[28] However, another systematic review[29] included metoclopramide in a list of drugs that reliably prevented PONV compared with placebo; other drugs listed were cyclizine, dexamethasone, dolasetron, droperidol, granisetron, ondansetron, and tropisetron. Ginger root has also been suggested, but again does not seem to be effective in this context,[30] although there is some evidence of benefit for intramuscular ephedrine.[31] Clonidine has also been reported to produce benefit,[32,33] possibly secondary to reduced sympathetic tone and lower use of inhalation anaesthetics and opioids. Neurokinin-1 antagonists such as aprepitant may also be effective.[22]

In patients at moderate risk of PONV, therefore, in addition to risk reduction, use of 1 or 2 prophylactic antiemetics may be considered,[15,16] such as a 5-HT_3 antagonist, droperidol (although concerns about effects on QT interval have restricted its availability), or dexamethasone; or perhaps transdermal hyoscine, dimenhydrinate, or another drug such as promethazine or a heterocyclic phenothiazine (prochlorperazine or perphenazine). In patients at higher risk, or in whom nausea and vomiting would be particularly problematic, a combination of antiemetics from different classes should be given,[15,16] since the IMPACT study has shown that the effects of such interventions are additive.[24]

If PONV develops, *treatment* will depend on whether prophylaxis was given. In patients who have received no prophylaxis, or only dexamethasone, a small dose of a 5-HT_3 antagonist has been recommended.[15,16] If PONV occurs within 6 hours of surgery despite antiemetic prophylaxis, additional doses of the same drug convey no further benefit, and treatment with drugs from another class is recommended.[15,16,18,22] Beyond this time any suitable drug may be used, but dexamethasone and transdermal hyoscine are not recommended for treatment because of their slow onset of action.[16]

Pregnancy. Nausea and vomiting or 'morning sickness' is common in the first trimester of pregnancy, but is generally mild and does not require drug therapy. Dietary modification such as eating small frequent carbohydrate meals is widely thought to be helpful.[34] A systematic review has suggested that pyridoxine, which has been shown to be of benefit, should be tried first if drug therapy is required.[34] Benefit has also been reported with ginger root,[34,35] but evidence of benefit from stimulation of the P6 acupuncture point is ambiguous.[34] Antihistamines such as buclizine, dimenhydrinate, hydroxyzine, meclozine, promethazine, and thiethylperazine have also been tried, and appear to be more effective than placebo,[34] but there are obvious concerns about potential effects on the fetus (see Pregnancy, under Precautions for Antihistamines, p. 614.2). Although no real evidence of a teratogenic effect exists,[36] therapy has tended to be reserved for severe cases, and short-term use. In some countries metoclopramide has been widely used; there is evidence for a lack of adverse effects on the fetus,[37] but younger mothers may be at increased risk of extrapyramidal effects.

Persistent vomiting and severe nausea may progress to *hyperemesis gravidarum* if adequate hydration cannot be maintained; the condition occurs in up to 1% of pregnancies.[38] Management of hyperemesis includes hospitalisation for intravenous fluid and electrolyte replacement, and this is usually sufficient. Routine thiamine supplementation, orally if tolerated, otherwise parenterally, has been recommended to reduce the risk of Wernicke's encephalopathy[38,39] (see Wernicke-Korsakoff Syndrome, p. 2103.3), although there is some dissent from this view.[40] If hyperemesis fails to respond to rehydration, antiemetics should be used; options include domperidone, phenothiazines, and antihistamines.[38] It has been suggested that hyperemesis unresponsive to conventional therapy may respond to oral prednisolone or intravenous hydrocortisone.[38] There have also been anecdotal reports of ondansetron being used successfully in life-threatening

hyperemesis gravidarum unresponsive to conventional treatment,[41] although a double-blind pilot study found it to be no more effective than promethazine.[42] A systematic review found no evidence of benefit for any intervention in hyperemesis gravidarum.[34]

After a review[43] of the data the American Gastroenterological Association Institute considered[44] that metoclopramide, prochlorperazine, promethazine, trimethobenzamide, and ondansetron were of low risk in pregnant women and could be used for nausea and vomiting and for hyperemesis gravidarum.

Radiotherapy. The risk of emesis with radiotherapy varies with the treatment given, particularly the area of the body irradiated. However, emetic risk, and recommendations for use of antiemetics, are less clearly defined than in the situation of chemotherapy-induced nausea and vomiting.[1] Use of a prophylactic 5-HT_3 antagonist with or without dexamethasone is usually recommended in patients receiving radiation to the upper abdomen or total body irradiation.[1,2] For radiotherapy of minimal emetogenic potential, treatment on an as-needed only basis has been suggested.[1]

Oesophageal motility disorders

Oesophageal disorders, many due to disturbances in oesophageal motility, may produce non-cardiac chest pain, similar to that of angina pectoris, from which they must be differentiated.

Achalasia is obstruction caused by failure of the lower oesophageal sphincter to relax and permit passage of food into the stomach. It is accompanied by dilatation and abnormal peristalsis in the oesophagus, which becomes a reservoir for the unassimilated matter; symptoms include dysphagia and sometimes pain. The treatment of choice is mechanical dilatation of the sphincter or surgery. Laparoscopic techniques have reduced the risks associated with surgery, and this may become the preferred treatment. Taking isosorbide dinitrate or nifedipine before eating results in some improvement in achalasia, but these drugs have a role only as a temporary measure, or when other options are not suitable. Sildenafil is under investigation. More recently, injection of botulinum toxin into the lower oesophageal sphincter has been found to be effective, but remission in the long-term is better with mechanical dilatation than botulinum toxin. Therefore, it has been recommended that botulinum toxin be reserved for patients thought to be at risk from mechanical dilatation or surgery.

Oesophageal spasm, although frequently asymptomatic, can produce dysphagia and pain. Drug treatment of diffuse oesophageal spasm, or its variant 'nutcracker oesophagus' which is characterised by high amplitude peristalsis in the oesophagus, is often ineffective. Antimuscarinic antispasmodics, nitrates, and calcium-channel blockers have been tried in an attempt to relax the smooth muscle, but results are often disappointing; experience with nifedipine in patients with nutcracker oesophagus suggests that decrease in oesophageal pressure may not correlate with reduction in pain. As with achalasia, minimally invasive surgery is effective for these conditions. Sildenafil is also under investigation.

Peptic ulcer disease

Peptic ulceration is a common condition consisting of a distinct break in the gastrointestinal mucosa, usually of the stomach or duodenum. Duodenal ulcers are rarely malignant but gastric ulcers are more commonly associated with malignancy.

The aetiology of peptic ulcer disease is probably multifactorial but the bacterium *Helicobacter pylori* plays an important role. Abnormalities of normal mucosal defence mechanisms, and, in the case of gastric ulcer, reflux of duodenal contents into the stomach or delayed gastric emptying may also be involved. Other factors include emotional stress, smoking, alcohol, and drugs such as NSAIDs or corticosteroids.

Peptic ulcer disease usually presents as dyspeptic pain, sometimes associated with nausea, vomiting, anorexia, heartburn, or bloating. Patients may develop complications such as bleeding, obstruction, or perforation.

Certain simple measures such as bed rest, dietary modification, and cessation of smoking, may accelerate ulcer healing, but these play an adjuvant role, and the basis of treatment is pharmacological. Treatment is aimed at eradicating *H. pylori* with antibacterials and neutralising or inhibiting acid activity with antisecretory drugs. Surgical treatment is used in patients with acute complications such as perforation, haemorrhage, obstruction, or pyloric stenosis, or in patients with recurrent or intractable ulcer disease, or where there is suspicion of malignancy.

Anti-Helicobacter therapy. The presence of *H. pylori* should usually be confirmed before therapy to eradicate the infection is started. The urea breath test is the most widely used method to test for *H. pylori*, but may produce false-negatives if used during or too soon after treatment with proton pump inhibitors (see Helicobacter Infection under Precautions for Omeprazole, p. 1870.2) or antibacterials. There is good evidence that eradication therapy has benefits both in healing ulcers and preventing recurrence, especially for duodenal ulcer.[1] Many different regimens have been tried, using various combinations of oral antibacterials with antisecretory drugs. Expert consensus is that any treatment regimen should achieve at least 80% eradication of *H. pylori*,[2] and the most appropriate regimen may therefore depend to some extent on local patterns of resistance.

The following recommendations have been made by an international expert group:[2]

- ***where clarithromycin resistance is below 15 to 20%***
  - **triple therapy** with a proton pump inhibitor (PPI), clarithromycin, and metronidazole (provided the prevalence of metronidazole resistance is less than 40%), for 14 days
    or
    PPI, clarithromycin, and amoxicillin, for 14 days
    or
  - **quadruple therapy** with a bismuth compound, a PPI, and two antibacterials, for 14 days. Such a regimen as used in the UK (usually for rescue therapy, see below) comprises a proton pump inhibitor with tripotassium dicitratobismuthate, tetracycline, and metronidazole.
  - Treatment for 7 days rather than 14 may be acceptable where local studies show it to be effective (in the UK, the *BNF* considers that adverse effects and poor compliance are likely to offset any therapeutic gain from 14-day regimens)
- ***in areas of high clarithromycin resistance*** it may be appropriate to consider antibacterial susceptibility testing before beginning treatment; regimens that may be considered include:
  bismuth-containing quadruple therapy as above
  or
  PPI, amoxicillin, and metronidazole (provided metronidazole resistance is low)
  or
  PPI, tetracycline, and metronidazole
- testing to confirm eradication, at least 4 weeks after treatment, is recommended; a urea breath test is the preferred method
- rescue treatments in patients with refractory disease should be based on antibacterial susceptibility testing. In the UK, the *BNF* considers that the bismuth-based quadruple therapy regimen referred to above may be effective.
- other antibacterials that have been investigated in eradication regimens (mainly as rescue treatments) include rifabutin and levofloxacin, although there might be concerns about selecting for mycobacterial resistance if the former were to be used widely, and increasing fluoroquinolone resistance may limit the value of the other

There is some evidence that a **sequential regimen** of a PPI with amoxicillin for 5 days, followed by the PPI with a nitroimidazole antibacterial (tinidazole) and clarithromycin for a further 5 days, is more effective than a standard 7- or 10-day triple therapy regimen in treatment-naive patients.[3] The potential value of such regimens remains to be more widely proven.[2,4]

The use of **dual therapy** regimens comprising a PPI and an antibacterial is no longer recommended. Similarly, although acid suppressive therapy has sometimes been continued after completing eradication therapy, the *BNF* considers this unnecessary, unless the ulcer is large or complicated by bleeding or perforation.

Before the advent of *H. pylori* eradication therapy, drug treatment of gastric and duodenal ulcers relied mainly on antisecretory therapy. Four to 8 weeks of H_2-antagonist or proton pump inhibitor therapy was required for ulcer

healing. Because of the high incidence of relapse, these drugs were then often given as maintenance therapy. Numerous other drugs were formerly used in peptic ulcer disease before the development of H_2-antagonists and proton pump inhibitors, including antacids, antimuscarinics such as pirenzepine, and mucosal protectants such as sucralfate.

NSAID-induced ulceration. The ulcerogenic effects of NSAIDs have been attributed to inhibition of prostaglandin synthesis and mucosal cell proliferation, and the ulcers they cause may differ from non-iatrogenic ulcers in their pathology and prognosis.[5,6] As many as 25% of chronic NSAID users will develop ulcers, and 2 to 4% will bleed or perforate.[7] Although considered to be independent risk factors for peptic ulcer disease, *H. pylori* infection and NSAID use may act synergistically in peptic ulceration and ulcer bleeding.[8,9] If peptic ulceration develops during treatment with an NSAID the drug should be withdrawn if possible. If this can be done, the ulcer may be treated with an antisecretory drug such as an H_2-antagonist or PPI given for 4 to 8 weeks. If NSAIDS have to be continued, *treatment* is with antisecretory drugs or the prostaglandin analogue misoprostol.[5,6] Ulcers tend to heal more slowly with H_2-antagonists if NSAIDs are continued, whereas the rate of ulcer healing with PPIs appears not to be affected. There is also some evidence that omeprazole is more effective at healing NSAID-associated ulceration than misoprostol.[10] Patients at high risk of NSAID-associated gastrointestinal complications, including those with a history of these events, should receive *prophylactic therapy* if NSAID treatment is absolutely necessary.[5-7] A systematic review[11] concluded that misoprostol, PPIs, and double-dose H_2 antagonists are effective at preventing chronic NSAID-associated gastric and duodenal ulcers. Standard doses of H_2-antagonists prevent NSAID-associated duodenal ulceration, but appear to be less effective in preventing gastric ulceration. Another systematic review also found that misoprostol, and probably PPIs, were effective in reducing the risk of symptomatic NSAID-associated ulceration, as was the use of specific inhibitors of cyclo-oxygenase-2 such as celecoxib;[12] use of a cyclo-oxygenase-2 inhibitor with a PPI may be appropriate in very high risk patients.[13] After healing of NSAID-associated ulceration, prophylaxis with a proton pump inhibitor was more effective at preventing recurrence than an H_2 antagonist,[14,15] and omeprazole was more effective and better tolerated than misoprostol.[10] Whether *H. pylori* eradication is appropriate in patients receiving long-term NSAIDs remains debatable. There is some evidence that eradication reduces the risk of bleeding in patients who have not previously taken NSAIDs,[2,16] and testing and eradication in patients taking PPIs long-term for prevention of NSAID-induced ulceration has been advocated by an expert consensus, since there is evidence that combination of *H. pylori* infection and long-term acid suppression may accelerate the development of pre-malignant changes in the stomach.[2] However, PPI maintenance is more effective than *H. pylori* eradication in preventing ulcer recurrence or bleeding in patients taking NSAIDs,[2] and there is no convincing evidence that eradication speeds ulcer healing.[16]

Stress ulceration may occur in the stomach or the duodenum after major physical trauma such as burns or surgery, or after severe sepsis or illness. H_2-antagonists and sucralfate are widely used for the prevention of stress ulceration in high-risk patients in intensive care units,[17-19] and prophylactic therapy is increasingly used, though with little evidence, in less severely ill patients.[20] Pirenzepine is used in a few countries, and some[17] prefer it in neurosurgical patients and those with head trauma. H_2-antagonists may be given orally, by nasogastric tube, or by the intravenous route (intermittent or continuous). Meta-analysis has indicated that sucralfate may be as effective as an H_2-antagonist in reducing bleeding, and is associated with lower rates of mortality and pneumonia.[21] For discussion of the possible increased risk of infections with acid suppressing drugs, see Infection, under Omeprazole, p. 1870.1. The findings of a subsequent large randomised study[22] by the same authors were at odds with those of this meta-analysis, suggesting that intravenous ranitidine was more effective than sucralfate given orally or via nasogastric tube in reducing clinically significant gastrointestinal bleeding. Moreover, there was no difference in rate of ventilator-associated mortality between ranitidine and sucralfate recipients. A further meta-analysis[23] has in turn raised doubts about the efficacy of ranitidine; no significant benefit was found for ranitidine, compared with placebo, in the prevention of bleeding. One clinical guideline suggests that, given the conflicting evidence, the choice between antacids, H_2-antagonists, and sucralfate be made on an institutional basis.[18] PPIs are also used for stress ulcer prophylaxis, although evidence for such use is lacking.[19]

Bleeding ulcer. Peptic ulceration is responsible for about 50% of all cases of upper gastrointestinal bleeding: the condition is potentially life-threatening and in severe cases prompt resuscitation with intravenous fluids and blood may be required. About 80% of patients will stop bleeding spontaneously without recurrence, but the remaining 20% are at risk of severe morbidity or death,[24] and early stratification into low- and high-risk categories on the basis of clinical and endoscopic criteria is important for proper management.[24,25] No treatment may be needed for low-risk patients, but those with a clot in an ulcer bed should undergo irrigation and appropriate treatment of the underlying lesion, and high-risk patients should be given immediate endoscopic injection therapy for haemostasis.[24]

Many different solutions have been used for endoscopic injection, including adrenaline (alone or with sclerosants such as monoethanolamine or lauromacrogol), alcohol, fibrin glue, sodium tetradecyl sulfate, thrombin, or saline (normal or hypertonic). None has been clearly shown to be superior,[24] but sclerosants and alcohol increase the risk of complications such as perforation and necrosis compared with adrenaline.[25] Adrenaline injection 1 in 10 000 is commonly used; a large volume (over 13 mL) is considered more effective at achieving sustained haemostasis than smaller volumes.[25] Thermal, laser, or multipolar (coaptive) or plasma electrocoagulative endoscopic techniques are also of benefit, and again there is no clear evidence to prefer one over another.[24] The use of mechanical clips may also be effective.[24,25] A combination of endoscopic therapies may be of greater benefit than monotherapy.[24,25] If endoscopic treatments fail to stop bleeding, or rebleeding occurs, further endoscopic therapy may be considered, but otherwise patients require surgery,[24,25] or selective arterial embolisation.[25]

There is good evidence from systematic review[26] that treatment with PPIs reduces rebleeding and surgery in patients with acute bleeding peptic ulcers; one such review did not show reduced mortality,[26] although others consider it to have been proven.[24] An intravenous bolus of a PPI followed by continuous infusion for 72 hours is recommended in patients who have undergone successful endoscopic therapy.[24,25] There is no evidence that any PPI is superior to others.[24,27] Some suggest that high-dose PPI therapy (oral or intravenous, depending on the degree of risk) should also be considered in patients awaiting endoscopy.[24]

In contrast, there is no evidence that H_2-antagonists are of benefit in the treatment of acute nonvariceal bleeding, and somatostatin, octreotide, or tranexamic acid are not recommended.[24,25,28]

Eradication of *H. pylori* is recommended in those patients positive for the organism;[24,25] eradication therapy is superior to antisecretory drugs alone in preventing rebleeding.[29]

Zollinger-Ellison syndrome

Zollinger-Ellison syndrome is a rare disorder characterised by the presence of a gastrin-producing tumour (gastrinoma), which leads to hypersecretion of gastric acid and consequent peptic ulcer disease (often with complications such as perforation or bleeding), diarrhoea, or malabsorption. Gastrinomas usually occur in the non-beta islet cells of the pancreas or in the duodenal wall. Up to two-thirds are malignant. About 20 to 25% of cases are seen in patients with multiple endocrine neoplasia type 1 (MEN-1) syndrome.

Initial treatment is aimed at controlling the hypersecretion of gastric acid with an antisecretory drug. Giving enough medication just to control symptoms is not considered adequate, and it is important that acid secretion is reduced below 10 mmol/hour. Intravenous H_2-antagonists or proton pump inhibitors may be required initially. Once the symptoms have been controlled the tumour can be investigated for surgical removal. When complete removal is not possible then antisecretory therapy is continued indefinitely. A proton pump inhibitor is the drug of choice; it profoundly reduces acid secretion with once- or twice-daily use, although relatively high doses are required compared with those used in other conditions. An H_2-antagonist such as cimetidine or ranitidine may be used as an alternative to omeprazole, and, as with omeprazole, daily doses are higher than those used for other conditions; they are given in 3 or 4 divided doses. The somatostatin analogue octreotide can be used to reduce serum gastrin, but has to be given subcutaneously, and is not well tolerated.

Parietal cell vagotomy may be performed to reduce acid secretion if the tumour is not found, to allow lower doses of antisecretory drugs to be used.

Aceglutamide Aluminium *(rINNM)*

Aceglutamida de aluminio; Aceglutamide Aluminum (USAN); Acéglutamide d'Aluminium; Aluminii Aceglutamidum; KW-110; Алюминий Ацеглутамид.

Pentakis (N^2-acetyl-L-glutaminato)tetrahydroxytrialuminium.

$C_{35}H_{59}Al_3N_{10}O_{24}$=1084.8

CAS — 12607-92-0.

UNII — R7QTG0PMPX.

Pharmacopoeias. In *Jpn.*

Profile

Aceglutamide aluminium, a complex of aceglutamide with aluminium hydroxide, is an antacid with general properties similar to those of aluminium hydroxide (p. 1817.2). It is given orally in a usual dose of 700 mg three times daily.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Glumal.

Aclatonium Napadisilate (BAN, rINN)

Aclatonii Napadisilas; Aclatonium Napadisylate; Celatonium Napadisilate; Choline Naphthalene-1,5-Disulphonate (2:1) Dilactate Diacetate; Napadisilate d'Aclatonium; Napadisilato de aclatonio; SKF-100916-J; TM-723; Аклатония Нападизилат.

2-(2-Acetoxypropionyloxy)ethyltrimethylammonium naphthalene-1,5-disulphonate (2:1).

$2C_{10}H_{20}NO_4.C_{10}H_6O_6S_2$=722.8

CAS — 55077-30-0.

UNII — YX23434YHQ.

Profile

Aclatonium napadisilate is a cholinergic agonist given orally for its prokinetic properties in the management of decreased gastrointestinal motility (p. 1805.2) after gastrointestinal surgery, and to relieve symptoms of biliary dyskinesia and chronic gastritis.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Abovis.

Acotiamide Hydrochloride (USAN, rINNM)

Acotiamide, Chlorhydrate d'; Acotiamidi Hydrochloridum; Hidrocloruro de acotiamida; YM-443; Z-338; Акотиамида Гидрохлорид.

N-(2-[bis(1-Methylethyl)amino]ethyl)-2-[(2-hydroxy-4,5-dimethoxybenzoyl)amino]thiazole-4-carboxamide monohydrochloride trihydrate.

$C_{21}H_{30}N_4O_5S.HCl.3H_2O$=541.1

CAS — 773092-05-0.

UNII — NMW7447A9A.

Profile

Acotiamide hydrochloride inhibits peripheral anticholinesterase activity which improves gastrointestinal motility and gastric emptying; it is used orally in the symptomatic relief of functional dyspepsia. Adverse effects have included constipation, diarrhoea, and nasopharyngitis; raised triglyceride, liver enzymes, and prolactin levels have also been reported.

CAS — 331257-52-4.

UNII — 4TWN6SZB8W.

Profile

Alicaforsen is an antisense oligonucleotide that inhibits the production of the cellular adhesion molecule ICAM-1, which plays a role in the inflammatory response involved in inflammatory bowel disease. It has been tried in ulcerative colitis and pouchitis, and with less success in Crohn's disease.

Alizapride Hydrochloride (rINNM)

Alizaprida, hidrocloruro de; Alizapride, Chlorhydrate d'; Alizapridi Hydrochloridum; Hidrocloruro de alizaprida; Ализаприда Гидрохлорид.

N-(1-Allyl-2-pyrrolidinylmethyl)-6-methoxy-1*H*-benzotriazole-5-carboxamide hydrochloride.

$C_{16}H_{21}N_5O_2.HCl$=351.8

CAS — 59338-93-1 (alizapride); 59338-87-3 (alizapride hydrochloride).

ATC — A03FA05.

ATC Vet — QA03FA05.

UNII — 41BT72BOQ7.

Uses and Administration

Alizapride is a substituted benzamide similar to metoclopramide (p. 1862.2), which is used to control nausea and vomiting (p. 1811.3) associated with a variety of disorders. It is given as the hydrochloride but doses are expressed in terms of the base. Alizapride 50 mg is equivalent to about 55.8 mg of alizapride hydrochloride.

Alizapride hydrochloride is given in usual oral doses equivalent to 75 to 300 mg of alizapride daily in divided doses. For children's doses, see below. It is also given by intravenous or intramuscular injection in doses equivalent to 50 to 200 mg of alizapride daily.

For patients receiving cancer chemotherapy usual daily doses equivalent to alizapride 2 to 5 mg/kg have been given intravenously or intramuscularly in 2 divided doses, one 30 minutes before and one 4 to 8 hours after the cytotoxic regimen. For highly emetic regimens requiring doses above 5 mg/kg it may be given by intravenous infusion over 15 minutes every 2 hours for 5 doses, starting 30 minutes before the cytotoxic. It has been recommended that the total dose given with a course of chemotherapy does not exceed 4.5 g.

Administration in children. Alizapride hydrochloride has been given to children for the symptomatic treatment of nausea and vomiting in oral doses equivalent to 5 mg/kg of alizapride daily.

Adverse Effects and Precautions

As for Metoclopramide, (see p. 1863.2).

Pharmacokinetics

Alizapride is well absorbed from the gastrointestinal tract. It is mainly excreted unchanged in the urine and has an elimination half-life of about 3 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Gastriveran; *Belg.*: Litican; *Braz.*: Superan; *Fr.*: Plitican; *Ger.*: Vergentan; *Gr.*: Lyostene; *Ital.*: Limican; *Neth.*: Litican.

Almagate (BAN, USAN, rINN)

Almagaatti; Almagat; Almagát; Almagatas; Almagato; Almagatum; LAS-3876; Альмагат.

Aluminium trimagnesium carbonate heptahydroxide dihydrate.

$AlMg_3(CO_3)(OH)_7.2H_2O$=315.0

CAS — 66827-12-1 (almagate); 72526-11-5 (anhydrous almagate).

ATC — A02AD03.

ATC Vet — QA02AD03.

UNII — 568Z59H7ZJ.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Almagate). A white or almost white, fine crystalline powder. It contains 15.0 to 17.0% aluminium calculated as aluminium oxide, 36.0 to 40.0% magnesium calculated as magnesium oxide, and 12.5 to 14.5% carbonic acid calculated as carbon dioxide. Practically insoluble in water, in alcohol, and in dichloromethane. It dissolves with effervescence and heating in dilute mineral acids. The filtrate of a 4% suspension in water has a pH of 9.1 to 9.7. Store in airtight containers.

Profile

Almagate is a hydrated aluminium-magnesium hydroxycarbonate. It is an antacid with general properties similar to those of aluminium hydroxide (p. 1817.2) and magnesium carbonate (p. 1856.2). It has been given orally in doses of 1 to 1.5 g.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Mex.*: Almax; *Spain*: Almax.

Almasilate (BAN, rINN)

Almasilato; Almasilatum; Aluminium Magnesium Silicate Hydrate; Magnesium Aluminosilicate Hydrate; Magnesium Aluminum Silicate Hydrate; Алмазилат.

$Al_2O_3.MgO.2SiO_2.xH_2O$=262.4 (anhydrous)

CAS — 71205-22-6; 50958-44-6.

ATC — A02AD05.

ATC Vet — QA02AD05.

UNII — 7TO1453R7L (anhydrous almasilate); OZQ8O62H53 (almasilate monohydrate).

Profile

Almasilate is an artificial form of aluminium magnesium silicate hydrate. It is an antacid (p. 1803.1) that is given orally in doses of up to about 1 g.

A hydrated native aluminium magnesium silicate (p. 2168.2) is used as a suspending, thickening, and stabilising agent in pharmaceutical preparations. Attapulgite (p. 1820.1) is another native form.

Preparations

Proprietary Preparations (details are given in Volume B)

CAS — 8001-97-6; 67479-27-0 (aloe gum).

ATC Herb — HA06AB5001 (Aloe ferox: dry leaf juice).

UNII — 0D145J8EME (Aloe ferox leaf); VSVD430YW9 (socotrine aloe).

NOTE. Do not confuse with Aloe vera (p. 1693.2).

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Aloes, Barbados; Aloe barbadensis). The concentrated and dried juice of the leaves of *Aloe barbadensis*. It contains not less than 28% of hydroxyanthracene derivatives expressed as barbaloin and calculated with reference to the dried drug. Dark brown masses, slightly shiny or opaque with a conchoidal fracture, or a brown powder. Partly soluble in boiling water; soluble in hot alcohol. Store in airtight containers. Protect from light.

The BP 2014 lists Curaçao Aloes as an approved synonym.

Ph. Eur. 8: (Aloes, Cape; Aloe capensis). The concentrated and dried juice of the leaves of various species of *Aloe*, mainly *Aloe ferox* and its hybrids. It contains not less than 18% of hydroxyanthracene derivatives expressed as barbaloin and calculated with reference to the dried drug. Dark brown masses tinged with green and having a shiny conchoidal fracture, or a greenish-brown powder. Partly soluble in boiling water; soluble in hot alcohol; practically insoluble in ether. Store in airtight containers. Protect from light.

USP 36: (Aloe). The dried latex of the leaves of *Aloe barbadensis* (*A. vera*) known in commerce as Curaçao Aloe, or of *A. ferox* and its hybrids, known in commerce as Cape Aloe (Liliaceae). It yields not less than 50% of water-soluble extractive. It has a characteristic, somewhat sour and disagreeable, odour. Curaçao Aloe is brownish-black, opaque masses with a fractured, uneven, waxy, and somewhat resinous surface. Cape Aloe is dusty to dark brown irregular masses, the surfaces of which are often covered with a yellowish powder. Its fracture is smooth and glassy.

Uses and Administration

Aloes is an anthraquinone stimulant laxative (p. 1804.1) but other less toxic drugs are generally preferred.

Homoeopathy

Aloes have been used in homoeopathic medicines under the following names: Aloe; Cape aloes; Aloe capensis; Aloe socotrina; Alo. soc.

Adverse Effects and Precautions

As for Senna, p. 1885.3, although aloes has a more drastic and irritant action.

Preparations

Proprietary Preparations (details are given in Volume B)

Pharmacopoeial Preparations

BP 2014: Compound Benzoin Tincture;
Ph. Eur.: Aloes Dry Extract, Standardised;
USP 36: Compound Benzoin Tincture.

Aloglutamol

Trometamol Glucaldrate; Алоглутамол.

2-Amino-2-hydroxymethylpropane-1,3-diol gluconate dihydroxyaluminate.

$C_{10}H_{24}AlNO_{12}$=377.3

CAS — 13755-41-4.

ATC — A02AB06.

ATC Vet — QA02AB06.

Profile

Aloglutamol has been used as an antacid (p. 1803.1).

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Mex.*: Sabro.

Aloin *(BAN)*

Alloin; Aloína; Алоин.

CAS — 5133-19-7; 8015-61-0; 1415-73-2 (barbaloin).

UNII — W41H6S09F4.

Profile

Aloin is a crystalline substance obtained from aloes (see above). It consists of *C*-glycosides such as barbaloin. Aloin is an anthraquinone stimulant laxative. Like aloes it is very irritant and other less toxic laxatives are generally preferred. Aloin is used as a flavouring agent.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *UK*: Calsalettes.

Multi-ingredient Preparations. *Austral.*: Ford Pills†; *Braz.*: Pilulas Ross; *Canad.*: Bicholate†; *Israel*: Laxative Compound; *Ital.*: Boldina He; Cuscutine†; Grani di Vals†; *Mex.*: Redotex NF; Redotex; *S.Afr.*: Brooklax Pills†; Doans Backache Pills†; SB 3 Triple Action Pills†; *Spain*: Laxante Bescansa Aloico†; *UK*: Dual-Lax Extra Strong; Modern Herbals Laxative.

Alosetron Hydrochloride

(BANM, USAN, rINNM)

Alosétron, Chlorhydrate d'; Alosetrón, hidrocloruro de; Alosetroni Hydrochloridum; GR-68755C; Hidrocloruro de alosetrón; Алосетрона Гидрохлорид.

2,3,4,5-Tetrahydro-5-methyl-2-[(5-methyl-imidazol-4-yl)methyl]-1*H*-pyrido[4,3-*b*]indol-1-one hydrochloride.

$C_{17}H_{18}N_4O$,HCl=330.8

CAS — 122852-42-0 (alosetron); 122852-69-1 (alosetron hydrochloride).

ATC — A03AE01.

ATC Vet — QA03AE01.

UNII — 2F5R1A46YW.

Uses and Administration

Alosetron is a 5-HT$_3$ antagonist used in the treatment of severe diarrhoea-predominant irritable bowel syndrome (p. 1810.3) in women who have not responded to conventional therapy; efficacy in men has not been established. It is given orally as the hydrochloride but doses are expressed in terms of the base; alosetron hydrochloride 1.12 mg is equivalent to about 1 mg of alosetron.

The initial dose is the equivalent of alosetron 500 micrograms twice daily. Patients who become constipated on this dose should stop alosetron until the constipation resolves; they may then be restarted on 500 micrograms once daily. If constipation recurs at the lower dose, alosetron treatment should be stopped. Patients who tolerate 500 micrograms once or twice daily may continue this dose for 4 weeks. If symptom control is still inadequate after this time, the dose may then be increased up to 1 mg twice daily. If symptoms are not adequately controlled after 4 weeks of treatment with the higher dose, alosetron should be stopped.

Adverse Effects

Serious gastrointestinal adverse effects have occurred with alosetron, and as a result, it was withdrawn from the market in the USA and subsequently reintroduced with more restricted indications. These adverse effects include severe constipation leading to obstruction, ileus, perforation, impaction, toxic megacolon, and secondary ischaemia, as well as ischaemic colitis. Fatalities have been reported.

Other gastrointestinal effects reported include abdominal distension and pain, nausea, reflux, and haemorrhoids. Adverse effects reported rarely include cardiac arrhythmias, cholecystitis, altered bilirubin levels, tremor, headache, myalgia, malaise, fatigue, and CNS effects such as confusion, anxiety, depression, and sedation. Urticaria, skin reactions, nail disorders, and alopecia can occur. Hyperglycaemia, hypoglycaemia, and disorders of calcium and phosphate metabolism have been reported.

Incidence of adverse effects. The incidence of serious gastrointestinal adverse effects with alosetron has been reviewed.[1,2] Pooled data from clinical studies suggested that the rate of ischaemic colitis in patients taking alosetron was about 0.15%, or 6.4 cases per 1000 patient-years. Results from postmarketing surveillance (before and after its temporary withdrawal from the US market) were estimated to represent a rate of 1 case per 1000 patient-years. Serious complications of constipation are less markedly increased in the population of alosetron users. A meta-analysis of 8 studies[3] reported that the incidence of serious complications of constipation was 0.08% in alosetron users; the incidence of ischaemic colitis was 0.16%. Overall, constipation and abdominal discomfort were the only adverse effects significantly associated with alosetron use, the relative risks being 4.35 and 1.96 respectively.

2. Chang L, *et al.* Ischemic colitis and complications of constipation associated with the use of alosetron under a risk management plan: clinical characteristics, outcomes, and incidences. *Am J Gastroenterol* 2010; 105: 866–75.
3. Rahimi R, *et al.* Efficacy and tolerability of alosetron for the treatment of irritable bowel syndrome in women and men: a meta-analysis of eight randomized, placebo-controlled, 12-week trials. *Clin Ther* 2008; 30: 884–901.

Precautions

Alosetron should be stopped immediately in patients who develop constipation or symptoms of ischaemic colitis such as new or worsening abdominal pain or blood in the stool. Treatment with alosetron should not be resumed in patients who develop ischaemic colitis.

Alosetron should not be used in patients with a history of severe or chronic constipation, intestinal obstruction or stricture, toxic megacolon, or gastrointestinal perforation or adhesions. It is also contra-indicated in patients with a history of ischaemic colitis, impaired intestinal circulation,

thrombophlebitis, or hypercoagulable state, and those with current or previous inflammatory bowel disease or diverticulitis.

Alosetron should not be used in those with severe hepatic impairment or a history thereof; it should be used with caution in patients with mild to moderate hepatic impairment. Elderly patients may be at increased risk of severe complications if constipation develops.

Interactions

Plasma concentrations of alosetron are markedly increased, and its half-life prolonged roughly threefold, when given with fluvoxamine; such a combination should be avoided. Licensed product information recommends that use with other more moderate inhibitors of cytochrome P450 isoenzyme CYP1A2 (such as quinolone antibacterials and cimetidine) should be avoided unless clinically necessary, because of the risk of similar interactions. Ketoconazole also increases plasma alosetron concentrations; care should be taken if alosetron is used with this or other potent inhibitors of the CYP3A4 isoenzyme (including clarithromycin, telithromycin, HIV-protease inhibitors, voriconazole, and itraconazole).

Pharmacokinetics

Alosetron is rapidly absorbed from the gastrointestinal tract; peak plasma concentrations occur about 1 hour after an oral dose. Plasma concentrations are 30 to 50% lower in men than in women given the same oral dose; clearance is lower in women. Bioavailability is about 60%; the extent and rate of absorption are slightly reduced by food. Plasma protein binding is about 82%. Alosetron is extensively metabolised via cytochrome P450 isoenzymes, particularly CYP1A2, although CYP2C9 and CYP3A4 also play a role. Numerous metabolites are excreted in the urine and faeces; only 6% of a dose is recovered unchanged from the urine. The terminal elimination half-life of alosetron is reported to be about 1.5 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *USA*: Lotronex.

Basic Aluminium Carbonate

Aluminium Hydroxycarbonate; Aluminum Carbonate, Basic (USAN); Basic Aluminum Carbonate; Carbonato básico de aluminio; Основный Углекислый Алюминий.

UNII — 1GA689N629.

Profile

Basic aluminium carbonate is a combination of aluminium hydroxide and aluminium carbonate. It is an antacid with general properties similar to those of aluminium hydroxide (below).

Basic aluminium carbonate has also been given orally as a phosphate binder in the treatment of hyperphosphataemia. For a discussion of the choice of phosphate binders, see Renal Osteodystrophy, p. 1170.1.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Fr.*: Lithiagel.

Multi-ingredient Preparations. *Port.*: Gastropensan†.

Aluminium Formate

Aluminium Triformate; Aluminum Formate; Муравьиноки-слый Алюминий; Формиат Алюминия.

$Al(CHO_2)_3.3H_2O$=216.1

CAS — 7360-53-4 (anhydrous aluminium formate).

UNII — 0D34KG724V.

Profile

Aluminium formate has astringent properties and has been used in topical preparations for mouth disorders.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Ger.*: Dynexan Zahnfleischtropfen.

Multi-ingredient Preparations. *Austria*: Cional; Dynexan; *S.Afr.*: Dynexan; *Switz.*: Mucosan†.

Aluminium Glycinate

Alluminio, glicinato de; Aluminum Glycinate; Basic Aluminium Aminoacetate; Dihydroxyaluminum Aminoacetate; Алюминия Гликинат.

(Glycinato-*N,O*)dihydroxyaluminium hydrate.

$C_2H_6AlNO_4(+xH_2O)$=135.1 (anhydrous)

CAS — 13682-92-3 (anhydrous aluminium glycinate); 41354-48-7 (aluminium glycinate hydrate).

ATC — A02AB07.

ATC Vet — QA02AB07.

UNII — DQ250MG0W6 (aluminium glycinate hydrate); 1K713C615K (anhydrous aluminium glycinate).

Pharmacopoeias. In *Br.* and *US.*

BP 2014: (Aluminium Glycinate). A white or almost white, odourless or almost odourless, powder. It contains 34.5 to 38.5% of Al_2O_3 calculated on the dried substance, and not more than 12% loss of weight on drying. Practically insoluble in water and in organic solvents; it dissolves in dilute mineral acids and in aqueous solutions of alkali hydroxides. A 4% suspension in water has a pH of 6.5 to 7.5.

USP 36: (Dihydroxyaluminum Aminoacetate). A white, odourless, powder. It may contain small amounts of aluminium oxide and aminoacetic acid. It loses not more than 14.5% of its weight on drying. Insoluble in water and in organic solvents; soluble in dilute mineral acids and in solutions of fixed alkalis. A 4% suspension in water has a pH of 6.5 to 7.5.

Profile

Aluminium glycinate is an antacid with general properties similar to those of aluminium hydroxide (below). It has been given in oral doses of up to 1.5 g.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Arg.*: Dafne; *Austria*: Acidrine; *Belg.*: Alucid; *Chile*: Sinacid†; *Denm.*: Alminox; *Fr.*: Acidrine; *Gr.*: Novalox; *Indon.*: Acidrine; *Ital.*: Acidrine; *Pol.*: Proacid†; *Spain*: Meteoril; Secrepat; *Thai.*: New Gel; *Turk.*: Acidrine; Alma; *Ukr.*: Secrepat Forte (Секрепат Форте).

Used as an adjunct in: *Austria*: Indobene; *Braz.*: Somalgin; *Chile*: Butartrol; Flexono; *Ital.*: Aspirina 03; *Switz.*: Bonidon†; *USA*: Buffex.

Pharmacopoeial Preparations

USP 36: Dihydroxyaluminum Aminoacetate Magma.

Aluminium Hydroxide

Alluminio hidroksidas; Alumiinihydroksidi; Aluminii Hydroxidum; Aluminii oxidum hydricum; Aluminium Oxidum Hydricum; Aluminium (oxyde d') hydraté; Aluminiumhydroxid; Aluminum Hydroxide; Alūminyum Hidroksit; Glinu wodorotlenek; Hidróxido de aluminio; Hydroxid hlinitý; Wasserhaltiges Aluminiumoxid; Алюминий Гидроксид.

CAS — 21645-51-2 [$Al(OH)_3$].

ATC — A02AB01.

ATC Vet — QA02AB01.

UNII — 5QB0T2IUN0.

NOTE. Algeldrate (*USAN, pINN*) is defined as a hydrated aluminium hydroxide with the general formula of $Al(OH)_3$.xH_2O.

Compounded preparations of aluminium hydroxide may be represented by the following names:

- Co-magaldrox *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of magnesium hydroxide and aluminium hydroxide respectively.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 8: (Aluminium Oxide, Hydrated; Dried Aluminium Hydroxide BP 2014). It contains the equivalent of 47 to 60% Al_2O_3. It is a white or almost white, amorphous powder. Practically insoluble in water; it dissolves in dilute mineral acids and in solutions of alkali hydroxides. Store in airtight containers at a temperature not exceeding 30 degrees.

Ph. Eur. 8: (Aluminium Hydroxide, Hydrated, for Adsorption; Aluminii Hydroxidum Hydricum ad Adsorptionem). A white or almost white, translucent, viscous, colloidal gel. A supernatant may be formed upon standing. A clear or almost clear solution is obtained with alkali hydroxide solutions and with mineral acids. pH 5.5 to 8.5. Store at a temperature not exceeding 30 degrees. Do not allow to freeze.

USP 36: (Aluminum Hydroxide Gel). A suspension of amorphous aluminium hydroxide in which there is a partial substitution of carbonate for hydroxide. It is a white viscous suspension from which small amounts of clear liquid may separate on standing. It has a pH of between 5.5 and 8.0. Store in airtight containers. Avoid freezing.

USP 36: (Dried Aluminum Hydroxide Gel). An amorphous form of aluminium hydroxide in which there is a partial substitution of carbonate for hydroxide. It contains the equivalent of not less than 76.5% of $Al(OH)_3$ and may contain varying quantities of basic aluminium carbonate and bicarbonate. The labelling requirements states that 1 g of dried aluminium hydroxide gel is equivalent to 765 mg of $Al(OH)_3$. It is a white, odourless, tasteless, amorphous powder. Insoluble in water and in alcohol; soluble in dilute mineral acids and in solutions of fixed alkali hydroxides. A 4% aqueous dispersion has a pH of not more than 10.0. Store in airtight containers.

Uses and Administration

Aluminium hydroxide is used as an antacid (p. 1803.1). It is given orally in doses of up to about 1 g, between meals and at bedtime. In order to reduce the constipating effects, aluminium hydroxide is often given with a magnesium-containing antacid, such as magnesium oxide or magnesium hydroxide.

Aluminium hydroxide binds phosphate in the gastrointestinal tract to form insoluble complexes and reduces phosphate absorption. It may thus be used to treat hyperphosphataemia in patients with chronic renal failure (although aluminium accumulation may be a problem—see Renal Osteodystrophy, p. 1170.1) or associated secondary hyperparathyroidism (p. 1170.3). With this use the dose must be adjusted to the individual patient's requirement but up to about 10 g daily may be given orally in divided doses with meals.

Aluminium hydroxide is also used as an adjuvant in adsorbed vaccines.

Polymyositis and dermatomyositis. Corticosteroids form the basis of the management of polymyositis (p. 1611.1) but the calcinosis that may occur in dermatomyositis does not always respond well. Aluminium hydroxide 1.68 to 2.24 g daily produced clinical improvement with complete clearing of most calcified nodules after 1 year in a patient with calcinosis cutis complicating juvenile dermatomyositis.[1] The calcified masses are made up of hydroxyapatite and amorphous calcium phosphate and reduction in phosphate absorption by aluminium hydroxide probably helped to reverse their formation. Subsequent cases[2,3] have also reported benefit from aluminium hydroxide treatment in the management of calcinosis.

2. Nakagawa T, Takaiwa T. Calcinosis cutis in juvenile dermatomyositis responsive to aluminium hydroxide treatment. *J Dermatol* 1993; 20: 558–60.
3. Wananukul S, *et al.* Calcinosis cutis presenting years before other clinical manifestations of juvenile dermatomyositis: report of two cases. *Australas J Dermatol* 1997; 38: 202–5.

Adverse Effects and Precautions

Aluminium hydroxide, like other aluminium compounds, is astringent and may cause constipation; large doses can cause intestinal obstruction.

Excessive doses, or even normal doses in patients with low-phosphate diets, may lead to phosphate depletion accompanied by increased bone resorption and hypercalciuria with the risk of osteomalacia.

Aluminium salts are not, in general, well absorbed from the gastrointestinal tract, and systemic effects are therefore rare in patients with normal renal function. However, care is necessary in patients with chronic renal impairment: osteomalacia or adynamic bone disease, encephalopathy, dementia, and microcytic hypochromic anaemia have been associated with aluminium accumulation in such patients given large doses of aluminium hydroxide as a phosphate-binding agent. Similar adverse effects have also been associated with the aluminium content of dialysis fluids.

Aluminium hydroxide used as an adjuvant in adsorbed vaccines has been associated with the formation of granulomas.

Children. For the suggestion that aluminium-containing antacids should not be used in infants, see Toxicity, below.

Porphyria. UK licensed product information states that aluminium hydroxide may be unsafe in patients with porphyria undergoing haemodialysis. However, the Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, has not classified aluminium hydroxide.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 06/10/11)

Toxicity. References to aluminium toxicity in dialysis patients and the possible association between aluminium

ingestion and Alzheimer's disease are included under Aluminium (see p. 2440.1).

Aluminium accumulation does not generally appear to be significant in patients with normal renal function taking therapeutic doses of aluminium-containing antacids, and there is little evidence that such antacids are a risk factor for Alzheimer's disease.[1] Elevated plasma-aluminium concentrations have been reported in infants with normal renal function given aluminium-containing antacids but there were no obvious signs of toxicity.[2] There have, however, been reports of phosphate depletion and rickets in a few infants caused by the use of antacids containing magnesium and aluminium hydroxides. In these cases the antacid had been started within a few months of birth and continued for up to 8 months. In reports that described a total of 3 infants,[3,4] the authors suggested that the use of soya-based infant feeding formulas, the phytates of which can interfere with mineral absorption, may have exacerbated the phosphate-binding effect of the antacid. In another case[5] a dosing error resulted in the infant receiving an excessive dose of antacid for 6 months. The *BNFC* advises against the use of any aluminium-containing antacid in neonates and infants.

Aluminium accumulation resulting in osteomalacia or encephalopathy with seizures and dementia has been reported in children with renal failure (but not on dialysis) treated with aluminium-containing phosphate binders.[6-10] In an adult male patient with severe chronic renal failure who was not on dialysis, self-medication with antacids for at least 3 years resulted in aluminium toxicity associated with encephalopathy, bone disease, and microcytic anaemia.[11] Aluminium-containing antacids should therefore be used with caution in patients with chronic renal failure, especially children.

Oral citrate salts increase the absorption of aluminium from the gastrointestinal tract[12] and patients with renal failure taking aluminium compounds should avoid citrate-containing preparations, which include many effervescent or dispersible tablets.[13,14] Ascorbic acid has also been reported to enhance aluminium absorption.[15]

Interactions

As outlined on p. 1803.1, aluminium compounds used as antacids interact with many other drugs, both by alterations in gastric pH and emptying, and by direct adsorption and formation of complexes that are not absorbed. Interactions can be minimised by giving the aluminium compound and any other medication 2 to 3 hours apart. The absorption of aluminium from the gastrointestinal tract may be enhanced if aluminium compounds are taken with citrates or ascorbic acid (see Toxicity, p. 1817.3).

Pharmacokinetics

Aluminium hydroxide, given orally, slowly reacts with the hydrochloric acid in the stomach to form soluble aluminium chloride, some of which is absorbed. The presence of food or other factors that decrease gastric emptying prolongs the availability of aluminium hydroxide to react and may increase the amount of aluminium chloride formed. About 100 to 500 micrograms of the cation is reported to be absorbed from standard daily doses of an aluminium-containing antacid, leading to about a doubling of usual aluminium concentrations in the plasma of patients with normal renal function.

Absorbed aluminium is eliminated in the urine, and patients with renal failure are therefore at particular risk of accumulation (especially in bone and the CNS), and aluminium toxicity (see p. 1817.3).

The aluminium compounds remaining in the gastrointestinal tract, which account for most of a dose, form insoluble, poorly absorbed aluminium salts in the intestines including hydroxides, carbonates, phosphates and fatty acid derivatives, which are excreted in the faeces.

Preparations

Proprietary Preparations (details are given in Volume B)

Aluminium Hydroxide-Magnesium Carbonate Co-dried Gel

Aluminum Hydroxide-Magnesium Carbonate Co-dried Gel; F-MA 11; Hidróxido de aluminio y carbonato de magnesio desecado, gel de.

Profile

Aluminium hydroxide-magnesium carbonate co-dried gel is a co-precipitate of aluminium hydroxide and magnesium carbonate dried to contain a proportion of water for antacid activity. It is an antacid with general properties similar to those of aluminium hydroxide (p. 1817.2) and magnesium carbonate (p. 1856.2). It has been given in oral doses of about 450 to 900 mg, usually 3 times daily after meals and before bedtime.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies combinations and complexes of aluminium, calcium, and magnesium compounds for acid related disorders as not porphyrinogenic; they may be used as drugs of first choice and no precautions are needed.[1]

CAS — 7784-30-7 ($AlPO_4$).

ATC — A02AB03.

ATC Vet — QA02AB03.

UNII — F92V3S521O.

Pharmacopoeias. In *Viet.*

Eur. (see p. vii) includes hydrated aluminium phosphate and also a gel. *US* includes as a gel.

Ph. Eur. 8: (Aluminium Phosphate, Hydrated; Aluminii Phosphas Hydricus; Dried Aluminium Phosphate BP 2014). A white or almost white powder. Very slightly soluble in water; practically insoluble in alcohol. It dissolves in dilute solutions of alkali hydroxides and mineral acids. A 4% suspension in water has a pH of 5.5 to 7.2. Store in airtight containers.

Ph. Eur. 8: (Aluminium Phosphate Gel; Aluminii Phosphatis Liquamen). It is aluminium phosphate in gel form containing 19 to 21% of $AlPO_4$. Practically insoluble in water, in alcohol, and in dichloromethane. It dissolves in dilute solutions of mineral acids. pH 6.0 to 8.0. Store in airtight containers.

USP 36: (Aluminum Phosphate Gel). A 4 to 5% suspension of aluminium phosphate ($AlPO_4$) in water and has a pH of 6.0 to 7.2. It is a white viscous suspension from which small amounts of water separate on standing. Store in airtight containers.

Profile

Aluminium phosphate is an antacid with general properties similar to those of aluminium hydroxide (p. 1817.2), but it does not produce phosphate depletion.

Aluminium phosphate is also used as an adjuvant in adsorbed vaccines.

N-Ethyl-3,3'-diphenyldipropylamine citrate.

$C_{20}H_{27}N,C_6H_8O_7$=473.6

CAS — 150-59-4 (alverine); 5560-59-8 (alverine citrate).

ATC — A03AX08.

ATC Vet — QA03AX08.

UNII — 9JFB58YK1E.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Alverine Citrate). A white or almost white crystalline powder. Slightly soluble in water and in dichloromethane; sparingly soluble in alcohol. A 0.5% solution in water has a pH of 3.5 to 4.5. Protect from light.

Uses and Administration

Alverine is an antispasmodic that acts directly on intestinal and uterine smooth muscle. It is used for the relief of smooth muscle spasm in the treatment of gastrointestinal disorders such as irritable bowel syndrome (p. 1810.3). It is also used in the treatment of dysmenorrhoea (p. 8.2).

Alverine citrate is given in oral doses of 60 to 120 mg one to three times daily. Alverine has also been given by suppository as the base.

Administration in children. Alverine citrate may be given to adolescents from the age of 12 years in the same doses as adults, see above.

Irritable bowel syndrome. Alverine citrate is widely used as an antispasmodic in the management of irritable bowel syndrome. However, a 12-week study[1] in 107 patients found that alverine citrate was no better than placebo for the relief of symptoms and improvement in general well-being. A marked placebo effect occurred and symptomatic improvement was reported by at least half the placebo group.

1. Mitchell SA, *et al.* Alverine citrate fails to relieve the symptoms of irritable bowel syndrome: results of a double-blind, randomized, placebo-controlled trial. *Aliment Pharmacol Ther* 2002; 16: 1187–95.

Adverse Effects and Precautions

Nausea, headache, pruritus, rash, and dizziness have been reported. Allergic reactions, including anaphylaxis, have also occurred. Alverine is contra-indicated in patients with intestinal obstruction or paralytic ileus.

Effects on the liver. Acute hepatitis was attributed to alverine citrate in 2 separate cases.[1,2] Evidence of an immune reaction, including antinuclear antibodies, was found in 1 case.[1]

1. Malka D, *et al.* Acute hepatitis caused by alverine associated with anti-lamin A and C autoantibodies. *J Hepatol* 1997; 27: 399–403.
2. Arhan M, *et al.* Alverine citrate induced acute hepatitis. *World J Gastroenterol* 2004; 10: 2303–4.

Pharmacokinetics

Alverine is absorbed from the gastrointestinal tract after oral doses and is rapidly metabolised to an active metabolite, peak plasma concentrations of which occur 1 to 1.5 hours after an oral dose. Further metabolism to inactive metabolites occurs; metabolites are excreted in the urine by active renal secretion.

Alvimopan *(BAN, USAN, rINN)*

ADL-8-2698; Alvimopán; Alvimopanum; LY-246736; Альвимопан.

[((2*S*)-2-[((3*R*,4*R*)-4-(3-Hydroxyphenyl)-3,4-dimethylpiperidin-1-yl]methyl]-3-phenylpropanoyl)amino]acetic acid.

$C_{25}H_{32}N_2O_4$=424.5

CAS — 156053-89-3 (anhydrous alvimopan); 170098-38-1 (alvimopan dihydrate).

ATC — A06AH02.

ATC Vet — QA06AH02.

UNII — 677C126AET (alvimopan); Q153V49P3Z (anhydrous alvimopan).

Uses and Administration

Alvimopan is a peripherally acting selective antagonist of opioid μ-receptors that is used in the treatment of postoperative ileus after partial large or small bowel resection surgery with primary anastomosis. It is given in a 12-mg oral dose between 30 minutes and up to 5 hours before surgery followed by 12 mg twice daily beginning the day after surgery for a maximum of 7 days or until discharge. A maximum of 15 doses of alvimopan should be given.

5. Bream-Rouwenhorst HR, Cantrell MA. Alvimopan for postoperative ileus. *Am J Health-Syst Pharm* 2009; 66: 1267–77.

Adverse Effects and Precautions

Gastrointestinal disorders such as constipation, dyspepsia, and flatulence have been reported after use of alvimopan. Anaemia, back pain, hypokalaemia, and urinary retention have also occurred.

Alvimopan should not be used in patients who have taken therapeutic doses of opioids for more than 7 consecutive days, as they are expected to be more sensitive to its effects. Use in patients with severe hepatic impairment or end-stage renal disease is not recommended due to a lack of data. Alvimopan is also not recommended in patients undergoing surgery for complete bowel obstruction.

Pharmacokinetics

Plasma-alvimopan concentrations peak about 2 hours after an oral dose. High-fat meals decrease the extent and rate of absorption. Alvimopan binds to albumin, with an average plasma protein binding of 80%. Biliary secretion is considered the primary pathway for elimination of alvimopan, but renal excretion also contributes. Unabsorbed alvimopan is metabolised by gut microflora to an amide hydrolysis compound which is also an antagonist of opioid μ-receptors. This metabolite is then excreted in the faeces and urine. The mean terminal half-life of alvimopan after multiple oral doses ranged from 10 to 17 hours.

Single-ingredient Preparations. *USA*: Entereg.

Aprepitant *(USAN, rINN)*

Aprépitant; Aprepitantum; L-754030; MK-0869; MK-869; Апрепитант.

3-[((2*R*,3*S*)-3-(*p*-Fluorophenyl)-2-[[(*αR*)-α-methyl-3,5-bis(trifluoromethyl)benzyl]oxy]morpholino)methyl]-Δ^2-1,2,4-triazolin-5-one.

$C_{23}H_{21}F_7N_4O_3$=534.4

CAS — 170729-80-3.

ATC — A04AD12.

ATC Vet — QA04AD12.

UNII — 1NF15YR6UY.

Uses and Administration

Aprepitant is a neurokinin-1 (NK_1) receptor antagonist used in the management of nausea and vomiting (p. 1811.3). It is given orally in doses up to 125 mg, with a corticosteroid and a 5-HT_3 antagonist, in the prevention of acute and delayed nausea and vomiting associated with highly emetogenic or moderately emetogenic cancer chemotherapy (for details, see Administration, below).

For the prevention of postoperative nausea and vomiting a single oral dose of aprepitant 40 mg may be given within the 3 hours before induction of anaesthesia.

Where the intravenous route is preferred, it may be given as its prodrug, fosaprepitant (for details of regimens, see Uses and Administration, under Fosaprepitant, p. 1843.3).

References.

3. Massaro AM, Lenz KL. Aprepitant: a novel antiemetic for chemotherapy-induced nausea and vomiting. *Ann Pharmacother* 2005; 39: 77–85.
4. Warr D. The neurokinin1 receptor antagonist aprepitant as an antiemetic for moderately emetogenic chemotherapy. *Expert Opin Pharmacother* 2006; 7: 1653–8.
5. Curran MP, Robinson DM. Aprepitant: a review of its use in the prevention of nausea and vomiting. *Drugs* 2009; 69: 1853–78.

Administration. Licensed product information for aprepitant suggests the following 4-day regimen for the prevention of acute and delayed nausea and vomiting associated with highly emetogenic cancer chemotherapy:

- day 1: oral aprepitant 125 mg (given 1 hour before chemotherapy) with oral dexamethasone 12 mg and intravenous ondansetron 32 mg (both 30 minutes before chemotherapy)
- days 2 and 3: oral aprepitant 80 mg with oral dexamethasone 8 mg in the morning
- day 4: oral dexamethasone 8 mg in the morning.

In patients receiving moderately emetogenic chemotherapy, a 3-day regimen has been suggested as follows:

- day 1: oral aprepitant 125 mg (given 1 hour before chemotherapy) with oral dexamethasone 12 mg (30 minutes before chemotherapy); ondansetron is given in 2 oral doses of 8 mg, one taken 30 to 60 minutes before chemotherapy, and one taken 8 hours after the first dose
- days 2 and 3: oral aprepitant 80 mg in the morning.

Administration in renal impairment. A study in 8 patients with severe renal impairment (24-hour creatinine clearance less than 30 mL/minute per 1.73 m^2) and 8 patients with end-stage renal disease requiring haemodialysis found that pharmacokinetic parameters of aprepitant were not sufficiently different from those in 16 matched controls to warrant dosage adjustment in renal impairment.[1] Licensed product information concurs with this.

1. Bergman AJ, *et al.* Effect of impaired renal function and haemodialysis on the pharmacokinetics of aprepitant. *Clin Pharmacokinet* 2005; 44: 637–47.

Pruritus. An improvement in pruritus was reported after oral aprepitant 80 mg daily was started in 3 patients with the Sézary syndrome. Topical corticosteroid treatment had previously been unsuccessful, but improvements were noted within 2 days of starting aprepitant.[1] Beneficial results were also reported[2] in 16 of 20 patients with refractory chronic pruritus of various causes who were given 80 mg daily for 3 to 13 days; 4 patients had complete or nearly complete cessation of itch and 12 had lesser degrees of reduction. Patients with atopic dermatitis or prurigo appeared to respond better than those in whom pruritus was associated with chronic kidney disease. Aprepitant is an antagonist of the neurokinin-1 receptor, a receptor for substance P which is a mediator in the itch sensation.[1,2]

For reference to aprepitant's efficacy in managing erlotinib-induced pruritus, see Effects on the Skin, Hair, and Nails, under Erlotinib, p. 789.2.

1. Duval A, Dubertret L. Aprepitant as an antipruritic agent? *N Engl J Med* 2009; 361: 1415–16.
2. Ständer S, *et al.* Targeting the neurokinin receptor 1 with aprepitant: a novel antipruritic strategy. *PLoS One* 2010; 5: e10968.

Adverse Effects and Precautions

The most common adverse effects associated with aprepitant are headache, constipation, diarrhoea, dyspepsia, anorexia, fatigue, hiccups, eructation, and dizziness. Increases in alanine aminotransferase (ALT) or aspartate aminotransferase (AST) concentrations are common. Other reported effects have included abdominal pain, oedema, tinnitus, neutropenic colitis, chills, gait disturbances, and flushing. Epigastric discomfort, dysgeusia, dry mouth, and stomatitis have also occurred. Thirst, polyuria, dysuria, haematuria, urinary frequency, arthralgia, myalgia, muscular weakness, hyperglycaemia, disorientation, euphoria, anxiety, photosensitivity, and skin disorders such as rash and pruritus have been reported. Anaemia and febrile neutropenia have occurred with aprepitant, as have cardiovascular disorders including hypertension or hypotension, palpitations, and bradycardia. Other adverse effects reported include hyponatraemia, hypokalaemia, insomnia, drowsiness, miosis, reduced visual acuity, weight changes, sensory disturbances, throat irritation, sneezing, abnormal bowel sounds, acid reflux, perforating duodenal ulcer,

dyspnoea, cough, wheezing, and hyperhidrosis. Conjunctivitis, pharyngitis, respiratory-tract infections, urinary-tract infections, candidiasis, and herpes simplex can occur. Hypersensitivity reactions including anaphylaxis, Stevens-Johnson syndrome, and angioedema with urticaria have been reported.

Licensed product information recommends caution in patients with severe hepatic impairment as clinical data are lacking in this patient group.

Interactions

During its use for 3 or 4 days in the prevention of nausea and vomiting associated with cancer chemotherapy, aprepitant produces moderate inhibition of the cytochrome P450 isoenzyme CYP3A4. Exposure to oral CYP3A4 substrates may increase substantially; the effect of aprepitant on intravenous CYP3A4 substrates is expected to be less. However, on cessation of aprepitant a transient mild induction of CYP3A4 may become apparent with a maximum effect reached 3 to 5 days later; this effect is maintained for a few days then slowly declines and is clinically insignificant about 2 weeks after stopping aprepitant. Caution is therefore required when using it with drugs that are primarily metabolised by this isoenzyme. Aprepitant should not be given with astemizole, cisapride, pimozide, terfenadine, or tolvaptan as increased plasma concentrations of these drugs could cause serious life-threatening reactions. As aprepitant is also a substrate for CYP3A4, other drugs that inhibit or induce this isoenzyme may in turn increase or decrease plasma concentrations of aprepitant.

When aprepitant is used to prevent postoperative nausea and vomiting, in a single lower dose than that used with cancer chemotherapy, the effect of aprepitant on CYP3A4 is not expected to be clinically significant.

Aprepitant also causes a delayed induction of CYP2C9 and may lower plasma concentrations of drugs metabolised by this isoenzyme, such as warfarin, phenytoin, or tolbutamide.

Aprepitant may increase systemic exposure to corticosteroids; when given together it is recommended that the usual dose of oral dexamethasone be reduced by 50%, and the dose of methylprednisolone by about 25% when given intravenously, and by 50% when given orally. It should be noted that the dose of dexamethasone in the regimens recommended for nausea and vomiting associated with cancer chemotherapy already accounts for this interaction (see Administration, p. 1819.3).

The efficacy of oral contraceptives might be reduced by aprepitant. Licensed product information suggests that alternative methods of contraception should be used during and for 1 to 2 months after stopping any dose of aprepitant.

Pharmacokinetics

Aprepitant is absorbed from the gastrointestinal tract with peak plasma concentrations occurring after about 4 hours. Bioavailability is about 60% at usual doses. It crosses the blood-brain barrier; plasma protein binding is reported to be more than 95%. Aprepitant undergoes extensive hepatic metabolism, mainly via oxidation by the cytochrome P450 isoenzyme CYP3A4; the isoenzymes CYP1A2 and CYP2C19 mediate minor metabolic pathways. The resultant metabolites have weak activity and are excreted in the urine and in the faeces. Aprepitant is not excreted unchanged in the urine. The terminal half-life is about 9 to 13 hours.

Attapulgite

Atapulgit; Atapulgita; Аттапульгит.

CAS — 1337-76-4; 12174-11-7.

ATC — A07BC04.

ATC Vet — QA07BC04.

UNII — U6V729APAM.

Pharmacopoeias. In *Br.*

Activated attapulgite is included in *Br., It.,* and *US.* Colloidal activated attapulgite is included in *US.*

BP 2014: (Attapulgite). A purified native hydrated aluminium magnesium silicate essentially consisting of the clay mineral palygorskite. A light, cream or buff, very fine powder, free or almost free from gritty particles. A 5% suspension in water has a pH of 7.0 to 9.5.

BP 2014: (Activated Attapulgite). Attapulgite that has been carefully heated to increase its adsorptive capacity.

USP 36: (Activated Attapulgite). Processed native aluminium magnesium silicate which has been carefully heated. It is a cream-coloured, micronised, nonswelling powder, free from gritty particles. Insoluble in water.

USP 36: (Colloidal Activated Attapulgite). A native aluminium magnesium silicate that has been purified. It is a cream-coloured, micronised, nonswelling powder, free from gritty particles. Insoluble in water. A 10% suspension in water has a pH of 7.0 to 9.5.

NOTE. Another native aluminium magnesium silicate is described on p. 2168.2.

Profile

Attapulgite is highly adsorbent and is used in a wide range of products including fertilisers, pesticides, and pharmaceuticals. Activated attapulgite is an adsorbent antidiarrhoeal used as an adjunct in the management of diarrhoea (p. 1805.2) in a daily dose of up to 9 g orally in divided doses.

Azasetron Hydrochloride *(INNM)*

Azasétron, Chlorhydrate d'; Azasetrón, hidrocloruro de; Azasetroni Hydrochloridum; Hidrocloruro de azasetrón; Nazasetron Hydrochloride; Y-25130; Азасетрона Гидрохлорид.

(±)-6-Chloro-3,4-dihydro-4-methyl-3-oxo-*N*-3-quinuclidinyl-2*H*-1,4-benzoxazine-8-carboxamide hydrochloride.

$C_{17}H_{20}ClN_3O_3,HCl$=386.3

CAS — 123040-69-7 (azasetron); 141922-90-9 (azasetron hydrochloride).

UNII — 2BSS7XL60S.

Profile

Azasetron is a 5-HT_3 antagonist with general properties similar to those of ondansetron (p. 1872.1). It is used as an antiemetic in the management of nausea and vomiting induced by cytotoxic therapy. Azasetron hydrochloride is given in a usual dose of 10 mg once daily by mouth or intravenously.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***China***: An Shi Tong (安世通); Ding Yue (丁悦); Gan Su (感苏); Ou Li Kang Ding (欧立康定); Ou Ting (欧亭); Ri An (日安); Rui Di Su (瑞帝苏); Tan Si Ke (坦斯克); Wan Wei (万唯); Yi Qiong (依琼); Yi Su Lin (怡苏林); ***Jpn***: Serotone.

Balsalazide Sodium *(BANM, rINNM)*

Balsalazida sódica; Balsalazide Disodium (USAN); Balsalazide Sodique; Balsalazine Disodium; BX-661A; Natrii Balsalazidum; Натрий Балсалазид.

5-[4-(2-Carboxyethylcarbamoyl)phenylazo]salicylic acid, disodium salt, dihydrate.

$C_{17}H_{13}N_3Na_2O_6,2H_2O$=437.3

CAS — 80573-04-2 (balsalazide); 150399-21-6 (balsalazide disodium dihydrate).

ATC — A07EC04.

ATC Vet — QA07EC04.

UNII — 1XL6BJI034 (balsalazide disodium dihydrate); 15ASW03C9S (anhydrous balsalazide sodium).

Pharmacopoeias. In *US.*

USP 36: (Balsalazide Disodium). An orange to yellow powder. Freely soluble in water and in isotonic saline; sparingly soluble in alcohol and in methyl alcohol; practically insoluble in all other organic solvents. Store in airtight containers at a temperature of 25 degrees, excursions permitted between 15 degrees and 30 degrees.

Uses and Administration

Balsalazide consists of mesalazine linked to 4-aminobenzoylalanine via an azo bond. This bond is broken by colonic bacteria, releasing the active mesalazine (p. 1859.2). Balsalazide sodium is given in the treatment of mild to moderate active ulcerative colitis (p. 1808.3), in an oral dose of 2.25 g three times daily until remission or for up to 12 weeks. For maintenance of remission of ulcerative colitis a dose of 1.5 g twice daily is recommended, adjusted as necessary up to 6 g daily. For doses in children, see below.

Reviews.

1. Muijsers RBR, Goa KL. Balsalazide: a review of its therapeutic use in mild-to-moderate ulcerative colitis. *Drugs* 2002; **62**: 1689–705.
2. Patil SA, Muss AC. Balsalazide disodium for the treatment of ulcerative colitis. *Expert Rev Gastroenterol Hepatol* 2008; **2**: 177–84.
3. Rahimi R, *et al.* Comparison of mesalazine and balsalazide in induction and maintenance of remission in patients with ulcerative colitis: a meta-analysis. *Dig Dis Sci* 2009; **54**: 712–21.

Administration in children. Balsalazide sodium is not licensed in the UK for use in children under 18 years of age. However, the *BNFC* recommends that, in those aged 12 years and over, 2.25 g may be given orally three times daily for an acute attack of mild to moderate ulcerative colitis, until remission occurs, or for up to 12 weeks. For maintenance, 1.5 g twice daily is recommended, adjusted according to response up to a maximum of 6 g daily.

In the USA, licensed doses in children aged 5 to 17 years are 750 mg three times daily by mouth, or 2.25 g three times daily; treatment may be continued for up to 8 weeks.

Adverse Effects and Precautions

As for Mesalazine, p. 1860.1. If a blood dyscrasia is suspected treatment should be stopped immediately and a blood count performed. Patients or their carers should be told how to recognise signs of haematotoxicity and should be advised to seek immediate medical attention if symptoms such as fever, sore throat, mouth ulcers, bruising, or bleeding develop. Balsalazide should not be used in patients with severe hepatic impairment or moderate or severe renal impairment; care is required in those with lesser degrees of hepatic or renal impairment, and in asthma, bleeding disorders, or active peptic ulcer disease.

Reviews.

1. Baker DE. Safety of balsalazide therapy in the treatment of inflammatory bowel disease. *Rev Gastroenterol Disord* 2005; **5**: 135–41.

Effects on the cardiovascular system. Myocarditis similar to that seen with mesalazine (see p. 1860.2) has been described in a patient some days after his treatment was altered from mesalazine to balsalazide; the condition resolved once balsalazide was withdrawn.[1]

See also Hypersensitivity, below.

1. Robertson E, *et al.* Balsalazide-induced myocarditis. *Int J Cardiol* 2008; **130**: e121–e122.

Hypersensitivity. A case of acute pericarditis, cholestasis, and vasculitis resulting from hypersensitivity to balsalazide has been reported.[1] The authors noted similarities to mesalazine-associated pericarditis and lupus-like syndrome (see Effects on the Cardiovascular System, p. 1860.2).

1. Adhiyaman V, *et al.* Hypersensitivity reaction to balsalazide. *BMJ* 2000; **320**: 613.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies balsalazide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Pharmacokinetics

Very little of an oral dose of balsalazide is absorbed via the upper gastrointestinal tract, and almost the entire dose reaches its site of action in the colon intact. It is broken down by the colonic bacterial flora into 5-aminosalicylic acid (mesalazine), which is active, and 4-aminobenzoylalanine, which is considered to be an inert carrier. About 25% of the released mesalazine is absorbed and acetylated, as described under mesalazine (p. 1861.2). A small proportion of 4-aminobenzoylalanine is absorbed and

acetylated by first-pass metabolism through the liver. The acetylated metabolites are excreted in the urine.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Benoquin; *Austral.*: Colazide; *China*: Ao Rui Xin (奥瑞欣); Bei Le Si (贝乐司); Sai Lai De (塞莱得); *Denm.*: Premid; *India*: Balacol; Colorex; Cozabal; Intazide; *Ital.*: Balzide; *Norw.*: Colazid; *UK*: Colazide; *USA*: Colazal.

UNII — 10X0709Y6I.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Bisacodyl). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; soluble in acetone. It dissolves in dilute mineral acids. Protect from light.

USP 36: (Bisacodyl). A white to off-white crystalline powder. Practically insoluble in water; soluble in benzene; soluble 1 in 210 of alcohol, 1 in 2.5 of chloroform, and 1 in 275 of ether; sparingly soluble in methyl alcohol.

Bisacodyl Tannex *(BANM, USAN, rINNM)*

CAS — 1336-29-4.
ATC — A06AB02; A06AG02.
ATC Vet — QA06AB02; QA06AG02.

Uses and Administration

Bisacodyl is a diphenylmethane stimulant laxative (p. 1804.1) used for the treatment of constipation (p. 1804.3) and for bowel evacuation before investigational procedures or surgery. Its action is mainly in the large intestine and it is usually effective within 6 to 12 hours after oral doses, within 15 to 60 minutes after rectal use by suppository, and within 5 to 20 minutes when given as an enema. Bisacodyl tablets should be swallowed whole and should not be taken within 1 hour of milk or antacids.

For constipation, bisacodyl is given in usual doses of 5 to 10 mg daily as enteric-coated tablets given at night; up to 20 mg may be given if necessary. Alternatively a dose of 10 mg as a suppository or enema may be given in the morning. For complete bowel evacuation, an oral dose of 10 to 20 mg may be given the night before the procedure, followed by 10 mg as a suppository the next morning. Alternatively, an oral dose of 10 mg may be given on each of the 2 nights before the procedure. For doses in children, see below.

A complex of bisacodyl with tannic acid (bisacodyl tannex) has been given with a barium sulfate enema before radiographic examination of the colon.

Administration in children. For **constipation**, the following oral doses of bisacodyl are recommended for children, to be taken at night:
- 4 to 10 years: 5 mg
- over 10 years: 5 to 10 mg, increased if necessary to a maximum of 20 mg

Alternatively, the following rectal doses are recommended, to be inserted in the morning:
- up to 10 years: 5 mg
- over 10 years: 10 mg

The *BNFC* gives similar doses, but limits the use of suppositories in children to those aged over 2 years.

For **bowel clearance before surgery or radiological investigation**, the following doses are recommended:
- 4 to 10 years: 5 mg orally the night before, followed by 5 mg as a suppository the next morning
- over 10 years: 10 to 20 mg orally the night before, followed by 10 mg as a suppository the next morning

The *BNFC* gives similar doses but allows for the use of oral doses for 2 nights before the procedure, followed, if necessary, by the rectal dose 1 hour before the procedure.

Adverse Effects

Bisacodyl and other stimulant laxatives may cause abdominal discomfort such as colic or cramps. Prolonged use or overdosage can result in diarrhoea with excessive loss of water and electrolytes, particularly potassium; there is also the possibility of developing an atonic non-functioning colon. Haematochezia (blood in the stool) may be seen but is usually mild and self-limiting; more severe bloody diarrhoea may be associated with colonic mucosal ischaemia. Hypersensitivity reactions, including angioedema and anaphylactoid reactions, have been reported rarely. When given rectally, bisacodyl sometimes causes irritation and may cause proctitis or sloughing of the epithelium. To avoid gastric irritation bisacodyl tablets are enteric-coated.

Precautions

As with other laxatives, prolonged use should be avoided. Bisacodyl should not be given to patients with intestinal obstruction or acute abdominal conditions such as appendicitis; care should also be taken in patients with inflammatory bowel disease. It should not be used in patients with severe dehydration. The suppositories should preferably be avoided in patients with anal fissures, proctitis, or ulcerated haemorrhoids.

Handling. Inhalation of bisacodyl powder and contact with eyes, skin, and mucous membranes should be avoided.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies bisacodyl as probably not porphyrinogenic when given as tablets or suppositories, and not porphyrinogenic as an enema; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 10/11/11)

Pharmacokinetics

On oral or rectal use bisacodyl is converted to the active desacetyl metabolite bis(*p*-hydroxyphenyl)pyridyl-2-methane by intestinal and bacterial enzymes. Absorption from the gastrointestinal tract is minimal with enteric-coated tablets or suppositories; the small amount absorbed is excreted in the urine as the glucuronide. Bisacodyl is mainly excreted in the faeces.

Bismuth Compounds

Bismuto, compuestos de; Висмут Соединения.

Profile

Bismuth compounds have been used for their astringent and antidiarrhoeal properties in a variety of gastrointestinal disorders, and have been applied topically in skin disorders and anorectal disorders such as haemorrhoids. Certain salts are active against *Helicobacter pylori* and are used in the treatment of peptic ulcer disease.

Bismuth Aluminate *(USAN)*

Aluminato de bismuto; Aluminum Bismuth Oxide; Алюминат Висмута.
$Bi_2(Al_2O_4)_3$,10H_2O=952.0
CAS — 12284-76-3 (anhydrous bismuth aluminate).
UNII — JB5Y63JDHJ.

Pharmacopoeias. In *Chin.* and *Fr.*

Bismuth Citrate

Citrato de bismuto; Цитрат Висмута.
$BiC_6H_5O_7$=398.1
CAS — 813-93-4.
UNII — N04867Y76N.

NOTE. Do not confuse with bismuth subcitrate potassium (p. 1822.1) or tripotassium dicitratobismuthate (colloidal bismuth subcitrate, p. 1822.2).

Pharmacopoeias. In *US*.

USP 36: (Bismuth Citrate). A white, amorphous or crystalline powder. Insoluble in water and in alcohol; soluble in dilute ammonia solution and in solutions of alkali citrates. Store in airtight containers. Protect from light. Prevent exposure to temperatures above 40 degrees.

Bismuth Oxide

Bismuth Trioxide; Óxido de bismuto; Оксид Висмута.
Bi_2O_3=466.0
CAS — 1304-76-3.
UNII — A614E79QF1.

Bismuth Salicylate

Basic Bismuth Salicylate; Bázisos bizmut-szalicilát; Bismuth Oxysalicylate; Bismuth, sous-salicylate de; Bismuth Subsalicylate (USAN); Bismuthi subsalicylas; Bismuto subsalicilatas; Bismutsalicylat, Basisches; Salicilato de bismuto; Salicylan bismutitý zásaditý; Vismutsubsalicylat; Vismuttisubsalisylaatti; Салицилат Висмута.
$C_7H_5BiO_4$=362.1
CAS — 14882-18-9.
UNII — 62TEY51RR1.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Bismuth Subsalicylate). A complex of bismuth and salicylic acid. It contains not less than 56% and not

more than 59.4% of Bi, calculated with reference to the dried substance. A white or almost white powder. Practically insoluble in water and in alcohol; dissolves in mineral acids with decomposition. Protect from light.

USP 36: (Bismuth Subsalicylate). A basic salt corresponding to $C_7H_5BiO_4$ and containing not less than 56.0% and not more than 59.4% of Bi and not less than 36.5% and not more than 39.3% of total salicylates. It is a fine, odourless, white to off-white microcrystalline powder. Practically insoluble in water, in alcohol, and in ether. It reacts with alkalis and mineral acids. Store in airtight containers. Protect from light.

Bismuth Subcarbonate *(USAN)*

Basic Bismuth Carbonate; Basisches Wismutkarbonat; Bázisos bizmutkarbonát; Bism. Carb.; Bismutcarbonat, Basisches; Bismuth Carbonate; Bismuth Oxycarbonate; Bismuth, sous-carbonate de; Bismuthi Subcarbonas; Bismuto subkarbonatas; Bismutylum Carbonicum; Carbonato de Bismutila; Subcarbonato de bismuto; Uhličitan bismutitý zásaditý; Vismutsubkarbonat; Vismuttisubkarbonaatti; Основный Углекислый Висмут.

CBi_2O_5=510.0

CAS — 5892-10-4 (anhydrous bismuth subcarbonate); 5798-45-8 (bismuth subcarbonate hemihydrate).

UNII — M41L2IN55T (bismuth subcarbonate); NJT50MK51G (bismuth subcarbonate hemihydrate).

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Ph. Eur. 8: (Bismuth Subcarbonate). A white or almost white powder. Practically insoluble in water and in alcohol. It dissolves in mineral acids with effervescence. Protect from light.

USP 36: (Bismuth Subcarbonate). A white or almost white powder. Practically insoluble in water, in alcohol, and in ether; dissolves in dilute acids with effervescence. Protect from light.

Bismuth Subcitrate Potassium *(USAN)*

1001277; Biskalcitrate potassium; Bismuth Biscalcitrate; Bismuth biskalcitrate; Основный Калиевый Цитрат Висмута. Bismuth pentapotassium dihydroxide bis(2-hydroxypropane-1,2,3-tricarboxylate hydrate).

$C_{12}H_{14}BiK_5O_{17}$=834.7

CAS — 880149-29-1.

UNII — R3O80H60KX.

NOTE. Do not confuse with bismuth citrate (p. 1821.3) or tripotassium dicitratobismuthate (colloidal bismuth subcitrate, below).

Bismuth Subgallate *(USAN)*

Basic Bismuth Gallate; Basisches Wismutgallat; Bázisos bizmut-gallát; Bism. Subgall.; Bismutgallat, Basisches; Bismuth Oxygallate; Bismuth, sous-gallate de; Bismuthi Subgallas; Bismuto subgalatas; Bizmut Subgalat; Bizmutu galusan zasadowy; Gallan bismutitý zásaditý; Subgalato de bismuto; Vismutsubgallat; Vismuttisubgallaatti; Основный Галловокислый Висмут.

$C_7H_5BiO_6$=394.1

CAS — 99-26-3.

UNII — YIW503MI7V.

Pharmacopoeias. In *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Bismuth Subgallate). A complex of bismuth and gallic acid. It contains not less than 48% and not more than 51% of Bi, calculated with reference to the dried substance. A yellow powder. Practically insoluble in water and in alcohol; dissolves in mineral acids with decomposition and in alkali hydroxides, producing a reddish-brown liquid. Protect from light.

USP 36: (Bismuth Subgallate). A basic salt containing 52 to 57% of Bi_2O_3 when dried at 105 degrees for 3 hours. It is an odourless amorphous bright yellow powder. Practically insoluble in water, in alcohol, in chloroform, and in ether; insoluble in very dilute mineral acids; dissolves readily with decomposition in warm, moderately dilute hydrochloric, nitric, or sulfuric acids; readily dissolves in solutions of alkali hydroxides to form a clear yellow liquid which rapidly becomes deep red. Store in airtight containers. Protect from light.

Bismuth Subnitrate

Subazotato de Bismuto; Basic Bismuth Nitrate; Basisches Wismutnitrat; Bázisos bizmut-nitrát; Bism. Subnit.; Bismuth Hydroxide Nitrate Oxide; Bismuth Nitrate, Heavy; Bismuth Oxynitrate; Bismuth (Sous-Nitrate de) Lourd; Bismuth, sous-nitrate de; Bismuthi Subnitras; Bismuthyl Nitrate; Bismuto subnitratas; Bismuto subnitratas sunkusis; Bizmut Subnitrat; Bizmutu azotan zasadowy; Bizmutu(III) azotan zasadowy; Magistery of Bismuth; Nitrato de Bismutilo; Subnitrato de bismuto; Vismutsubnitrat; Vismuttisubnitraatti; White Bismuth; Основный Азотнокислый Висмут.

$Bi_5O(OH)_9(NO_3)_4$=1462.0

CAS — 1304-85-4.

ATC — A02BX12.

ATC Vet — QA02BX12.

UNII — H19J064BA5.

Pharmacopoeias. In *Eur.* (see p. vii), *Jpn*, and *US*.

Fr. also includes Bismuth (Sous-Nitrate de) Léger (Bismuthi Subnitras Levis) which is described as a variable mixture of bismuth hydroxide, carbonate, and subnitrate.

Ph. Eur. 8: (Bismuth Subnitrate, Heavy). It contains not less than 71% and not more than 74% of Bi, calculated with reference to the dried substance. A white or almost white powder. Practically insoluble in water and in alcohol; dissolves in mineral acids with decomposition.

USP 36: (Bismuth Subnitrate). A basic salt containing not less than 79% of Bi_2O_3 calculated on the dried basis. It is a white, slightly hygroscopic powder. Practically insoluble in water and in alcohol; readily dissolves in nitric and hydrochloric acids.

Tripotassium Dicitratobismuthate

Bizmut Subsitrat; Colloidal Bismuth Subcitrate; Dicitratobismutato tripotásico; Tripotasyum Disitratobizmutat; Висмут Трикалия Дицитрат.

CAS — 57644-54-9.

ATC — A02BX05.

ATC Vet — QA02BX05.

NOTE. Do not confuse with bismuth citrate (p. 1821.3) or bismuth subcitrate potassium (above).

Uses and Administration

Some insoluble salts of bismuth are given orally for their supposed antacid action and for their mildly astringent action in various gastrointestinal disorders, including diarrhoea (p. 1805.2) and dyspepsia (p. 1806.3). Such salts include the aluminate, salicylate, subcarbonate, and subnitrate. Bismuth salicylate, which is given as an antidiarrhoeal and weak antacid in doses up to about 4 g daily in divided doses, possesses in addition the properties of the salicylates.

Tripotassium dicitratobismuthate is active against *Helicobacter pylori* and has been used as triple therapy (with metronidazole and either tetracycline or amoxicillin) to eradicate this organism and thereby prevent relapse of duodenal ulcer. It is also used as a mucosal protectant for the treatment of peptic ulcer disease (p. 1813.2). Bismuth subcitrate potassium and bismuth salicylate are also active against *H. pylori* and have been used similarly in eradication regimens.

The usual oral dose of tripotassium dicitratobismuthate in benign gastric and duodenal ulceration is 240 mg twice daily, or 120 mg four times daily before food. Treatment is for a period of 4 weeks, extended to 8 weeks if necessary. Maintenance therapy with tripotassium dicitratobismuthate is not recommended although treatment may be repeated after a drug-free interval of one month. When used as part of triple therapy the usual dose of tripotassium dicitratobismuthate has been 120 mg four times daily for 2 weeks. The usual dose of bismuth salicylate as part of triple therapy is 525 mg four times daily for 2 weeks. Appropriate antisecretory treatment with a histamine H_2-antagonist or a proton pump inhibitor is usually added to these regimens.

A complex of bismuth citrate with ranitidine, ranitidine bismuth citrate (p. 1883.3), has also been used in the treatment of peptic ulcer disease. Colloidal bismuth pectin, a complex salt of bismuth, potassium, and *d*-polygalacturonic acid, has also been used.

Some insoluble salts of bismuth have been used topically in the treatment of skin disorders, wounds, and burns. Some have been used as ingredients of ointments or suppositories (sometimes containing more than one bismuth salt) in the treatment of haemorrhoids and other anorectal disorders (p. 1808.1). Bismuth compounds that have been used topically and/or rectally include the oxide, subgallate, and subnitrate; bismuth resorcinol compounds have also been used. For the use of bismuth subnitrate and iodoform paste as a wound dressing, see Iodoform, p. 1758.2.

Numerous other salts and compounds of bismuth have been promoted for various therapeutic purposes. Glycobiarsol was formerly given orally as an amoebicide.

Homoeopathy

Bismuth has been used in homoeopathic medicines under the following names: Bismuthum; Bismutum metallicum; Bismuthum metallicum; Bismuth met.

Bismuth oxide has been used in homoeopathic medicines under the following names: Bismuthum oxydatum; Bismuth oxyd; Bis. ox.

Bismuth subnitrate has been used in homoeopathic medicines under the following names: Heavy bismuth subnitrate; Bismuthi subnitras ponderosus; Bismuthum subnitricum; Bismuth sub; Bismutum subnitricum; Bism sub.

Adverse Effects, Treatment, and Precautions

The bismuth compounds listed above are insoluble or very poorly soluble, and bismuth toxicity does not appear to be common if they are used for limited periods. However excessive or prolonged dosage may produce symptoms of bismuth poisoning, and for this reason long-term systemic therapy is not recommended. Reversible encephalopathy (see below) was once a problem in some countries, notably France and Australia; bone and joint toxicity had also occurred, sometimes associated with the encephalopathy. This led to restrictions on the use of bismuth salts and a virtual disappearance of these toxic effects.

Nausea and vomiting have been reported. Darkening or blackening of the faeces and tongue may occur due to conversion to bismuth sulfide in the gastrointestinal tract.

The effects of *acute bismuth intoxication* include gastrointestinal disturbances, skin reactions, stomatitis, and discoloration of mucous membranes; a characteristic blue line may appear on the gums. There may be renal failure and liver damage.

Other adverse effects may not be related to the bismuth content. With bismuth subnitrate given orally there is a risk of the nitrate being reduced in the intestines to nitrite and the development of methaemoglobinaemia. Absorption of salicylate occurs from oral bismuth salicylate and therefore the adverse effects, treatment of adverse effects, and precautions of aspirin (p. 24.2) should be considered.

Gastric lavage should be considered in overdosage; oral activated charcoal and the use of a chelating agent such as dimercaprol, succimer, or unithiol have been recommended (see also Overdosage, below). Renal function should be monitored for 10 days after acute overdosage.

Bismuth compounds should not be given to patients with moderate to severe renal impairment.

Encephalopathy. Reviews[1,2] and reports[3-11] of reversible bismuth encephalopathy. Many of the original reports implicated bismuth subgallate or subnitrate, in most but not all cases at high doses or for prolonged periods; toxicity has also occurred with other salts.[6-9] Patients receiving the subcitrate (480 mg daily) or the subnitrate (1.8 g daily) for 8 weeks in the treatment of *Helicobacter pylori* infection, showed no evidence of neurological changes compared with a control group.[12]

TOPICAL APPLICATION. Encephalopathy has been associated with the use of bismuth iodoform paraffin paste (BIPP) for the packing of wound cavities after surgery to the head and neck, although there is some debate as to whether the bismuth or the iodoform component is responsible—see p. 1758.2.

Overdosage. Bismuth salicylate or tripotassium dicitratobismuthate in recommended doses are rarely associated with serious adverse effects but there are reports of renal failure,[1-7] encephalopathy,[8-10] and neurotoxicity[1] in acute[1-6,9] or chronic[8,10] overdose. Bismuth has been detected in the blood, urine, stools, and kidneys of these patients; a blood concentration of 1.6 micrograms/mL was found[2] 4 hours after an oral dose of 9.6 g.

The optimal treatment of bismuth overdosage is unknown. Gastric lavage, purgation, and hydration should be considered, even if the patient presents late, as bismuth may be absorbed from the colon.[1,2] Chelating agents may be effective; unithiol has been reported to increase the renal clearance of bismuth with a reduction in the blood concentration.[8] *Haemodialysis* may be necessary[1-3] but

whether this hastens tissue clearance is uncertain. Haemodialysis plus unithiol treatment has been reported to successfully eliminate bismuth.[6] Peritoneal dialysis has also been effectively used in a paediatric patient.[5]

Prolonged ingestion of bismuth salicylate in excessive doses by an elderly diabetic was associated with hearing disturbances, vertigo, acid–base abnormalities and mild clotting disturbances.[11] The toxicity was thought to be due to the salicylate component.

Toxicity from non-conventional use. The FDA has warned against use of an injectable product called bismacine or chromacine, which contains large amounts of bismuth. There are reports of death or serious adverse effects associated with its use. Although unlicensed for any use, bismacine has apparently been used in alternative medicine to treat Lyme disease.[1]

1. FDA. FDA warns consumers and health care providers not to use bismacine, also known as chromacine (Issued 21st July 2006). Available at: http://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/2006/ucm108696.htm (accessed 15/07/10)

Interactions

Bismuth salts given orally reduce the absorption of tetracyclines, possibly by chelation or by reducing tetracycline solubility as a result of increasing the gastric pH. This interaction can be minimised by separating doses of the two drugs by a couple of hours. The clinical significance of this interaction to the use of bismuth salts for peptic ulcer disease is unclear; tripotassium dicitratobismuthate or bismuth salicylate have been given at the same time as tetracycline as part of triple therapy for the eradication of *Helicobacter pylori*.

Antisecretory drugs. Pretreatment with *omeprazole* resulted in about a threefold increase in absorption of bismuth from tripotassium dicitratobismuthate in 6 healthy subjects.[1] The mean peak plasma concentration of bismuth after a single dose of 240 mg of tripotassium dicitratobismuthate was increased from 36.7 to 86.7 nanograms/mL after omeprazole suggesting an increased risk of toxicity from combined therapy. The mechanism was thought to be the increase in gastric pH produced by the antisecretory drug as similar results had been reported with *ranitidine*.[2] However, the clinical significance of these interactions to the use of antisecretory drugs with bismuth compounds for eradication of *Helicobacter pylori* is unclear; bismuth compounds have been combined with proton pump inhibitors or H_2 antagonists in short-term regimens as part of triple or quadruple therapy.

Pharmacokinetics

Poorly soluble bismuth compounds are largely converted to insoluble bismuth oxide, hydroxide, and oxychloride in the acidic environment of the stomach. Most of the bismuth compounds included in this monograph are thus only slightly absorbed. Increased gastric pH may increase bismuth absorption—see Antisecretory Drugs, above. Unabsorbed bismuth is excreted in the faeces. Absorbed bismuth is distributed throughout body tissues, including bone, and is slowly excreted in the urine and bile. It has a plasma half-life of about 5 days and continues to be excreted for about 12 weeks after stopping therapy.

2,2-Bis(4-hydroxyphenyl)-1,4-benzoxazin-3(2*H*,4*H*)-one diacetate.

$C_{24}H_{19}NO_6$=417.4

CAS — 17692-24-9 (bisoxatin); 14008-48-1 (bisoxatin acetate).

ATC — A06AB09.

ATC Vet — QA06AB09.

UNII — 79WSLFS83K.

Profile

Bisoxatin acetate is a stimulant laxative that has been used in a usual oral dose of 120 mg at night in the treatment of constipation (p. 1804.3).

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Belg.*: Wylaxine; *Venez.*: Regoxal.

Bran

Crusca; Farelo; Kleie; Salvado; Son; Отруби.

UNII — 1L922R9NG2 (bran, fibre); KQX236OK4U (oat bran); R60QEP13IC (rice bran); 6L966A1IMR (wheat bran).

Description. Bran consists of the fibrous outer layers of cereal grains. It contains celluloses, polysaccharides or hemicelluloses, protein, fat, minerals, and moisture and may contain part of the germ or embryo. Bran provides water-insoluble fibre and, depending on the source, may also provide water-soluble fibre (see also Dietary Role, below). It comprises about 12% of the weight of the grain and is a byproduct of flour milling. It is available in various grades.

Pharmacopoeias. *US* includes wheat bran.

USP 36: (Wheat Bran). The outer fraction of the cereal grain (comprising the pericarp, seed coat (testa), nucellar tissue, and aleurone layer) derived from *Triticum aestivum, T. compactum, T. durum*, or other common einkorn and emmer wheat cultivars. It is obtained by milling and processing the whole wheat grain, and is available in a variety of particle sizes depending on the degree of milling. It contains not less than 36% of dietary fibre. It is a light tan powder having a characteristic aroma. Practically insoluble in cold water and in alcohol.

Uses and Administration

The main use of bran is as a bulk laxative and source of dietary fibre in the management of disorders of the gastrointestinal tract such as constipation (p. 1804.3), especially in diverticular disease (p. 1806.2); it is also widely used in irritable bowel syndrome, although its value has been questioned (see p. 1810.3). It should always be taken with plenty of fluid.

Bran is used as the basis for some breakfast cereals.

Dietary role. There is no precise definition for the complex mixture of substances known as dietary fibre. It has been defined as *plant* polysaccharides and lignin resistant to hydrolysis by the digestive enzymes of humans but this covers many substances other than cell-wall and related polysaccharides. Non-starch polysaccharides are the major component of the plant cell wall and are used as an index of dietary fibre. They comprise water-soluble fibres such as pectins, gums, and mucilages and water-insoluble fibres such as cellulose. Wheat, maize, and rice contain mainly insoluble non-starch polysaccharides whereas oats, barley, and rye have a significant proportion of soluble fibres.[1] Because the USA originally included nondigestible *animal* carbohydrates in the definition of fibre, the Food and Nutrition Board in the USA proposed a new definition of fibre, whereby dietary fibre consists of nondigestible carbohydrates and lignin that are intrinsic and intact in plants, and functional fibre consists of isolated, nondigestible plant or animal carbohydrates that have beneficial physiological effects in humans. Total fibre is the sum of dietary and functional fibre.[2]

In the UK, dietary reference values (DRV) have been published for non-starch polysaccharides.[1] It has been proposed[1] that adult diets should contain an average for the population of 18 g daily (individual range 12 to 24 g daily) non-starch polysaccharide from a variety of foods whose constituents contain it as a naturally integrated component. Children should receive proportionately less non-starch polysaccharide according to body size. No evidence exists for benefit of intakes of non-starch polysaccharide in excess of 32 g daily, and therefore there is no advantage in exceeding this amount.

In the USA, a total dietary fibre intake of 14 g of fibre per 1000 calories consumed has been suggested for adults and children aged from 1 year.[3]

Disease prevention. Diseases such as colorectal cancer, ischaemic heart disease, diabetes mellitus, and obesity are common in affluent developed countries but occur rarely

in rural Africa. This difference in disease patterns has been linked to the low fibre intake in developed countries compared with rural Africans. However, there are many other differences in diet and lifestyle, such as a lower intake of fat, protein, and sugar in rural Africans and less exposure to toxins and pollutants, any of which could contribute to the difference. The excessive consumption of energy-rich foods may be more to blame for diseases of affluence than is deficiency of dietary fibre.[1]

Results from large prospective cohort studies have been conflicting as to whether there is any *reduction in risk* of **colorectal cancer** associated with a high intake of dietary fibre, and have mostly failed to show a reduction in the *recurrence rate* of colorectal adenomas (although most adenomas do not develop into cancer, and so the relevance of these results is unclear[2]). A pooled analysis of 13 prospective cohort studies found a significant inverse association between dietary fibre intake and colorectal cancer. However, after adjusting for other risk-factors, this association was attenuated and no longer statistically significant. There was some suggestion that intake of dietary fibre from cereals and from whole-grain foods were both associated with a weak reduction in the risk of rectal cancer.[3] Some have commented[4] that fibre is a broad term encompassing a wide range of organic material, which may have a large number of actions on digestive physiology. Furthermore, there is some concern that the use of fibre supplements is not entirely without harmful effects: it has been pointed out that fermentable fibre substrates can stimulate cell proliferation in the colon.[5] However, the role of cell proliferation as a marker for the development of colonic cancer is questioned by some authors.[6]

A small randomised crossover study[7] in patients with type 2 **diabetes mellitus** suggested that an increased intake of dietary fibre was associated with improved glycaemic control, decreased hyperinsulinaemia, and lower plasma lipid concentrations. In prospective cohort studies, inverse associations were found between whole-grain intake and the risk of type 2 diabetes mellitus;[8-11] in some studies, this inverse association persisted for cereal fibre intake,[9-11] but in one the protective effect of whole grain could not entirely be explained by fibre content.[8]

Fibre may act as an obstacle to energy intake by displacing available calories and nutrients from the diet, by increasing satiety, and by decreasing the absorption efficiency of the small intestine. Epidemiological studies support the hypothesis that a higher dietary fibre intake prevents **obesity**; populations that report higher fibre consumption also demonstrate lower obesity rates.[12] Weight gain was inversely associated with increases in the intake of whole grains but positively associated with increases in the intake of refined grains, emphasising the importance of distinguishing whole-grain from refined-grain products.[13]

A large prospective cohort study in men found an inverse association between whole-grain intake and the incidence of **coronary heart disease**; the finding was even stronger for bran intake. These associations were attenuated, but not eliminated, by adjustment for other risk factors for coronary heart disease.[14] There is some suggestion that diets high in fibre may have a moderate effect on blood pressure reduction.[15]

3. Miller DL, *et al.* Small-bowel obstruction from bran cereal. *JAMA* 1990; **263**: 813–14.

Precautions

Bran is contra-indicated in patients with intestinal obstruction or with undiagnosed abdominal symptoms. There is a particular risk of intestinal or oesophageal obstruction if bulk laxatives are swallowed dry; they should be taken with sufficient fluid and should not be taken immediately before going to bed. Wheat bran should be avoided in gluten enteropathies and coeliac disease.

Interactions

Bran may reduce the absorption of some drugs when given together orally. Interference with iron, zinc, and calcium absorption has been reported; calcium phosphate may be added to bran to neutralise fytic acid, which can contribute to such interference.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Braz.*: Trifibra Mix; *China*: Fiberform (非比获); *Fr.*: Doses-O-Son; Infibran†; *India*: Imbran; *Neth.*: Fiberform; *Port.*: Infibran†; *Swed.*: Fiberform Mix†; Fiberform†.

Multi-ingredient Preparations. *Arg.*: Adelgacin; Gelax; *Chile*: Naticare; *Mex.*: Psilumax†; *Pol.*: Magnezytki†; Otrebuski†.

Bromopride *(rINN)*

Bromoprida; Bromopridum; CM-8252; VAL-13081; Бромоприд.

4-Amino-5-bromo-*N*-(2-diethylaminoethyl)-*o*-anisamide.

$C_{14}H_{22}BrN_3O_2$=344.3

CAS — 4093-35-0.

ATC — A03FA04.

ATC Vet — QA03FA04.

UNII — 75473V2YZK.

Profile

Bromopride is a substituted benzamide similar to metoclopramide (p. 1862.2), used in a variety of gastrointestinal disorders including nausea and vomiting (p. 1811.3) and motility disorders. It is given in a usual oral dose of 20 to 60 mg daily in divided doses, or 10 to 20 mg daily by intramuscular or intravenous injection. The hydrochloride is also used.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Braz.*: Bilenzima†; Bromogex; Bromopan; Digerex†; Digesan; Digesprid; Digestil; Digestina; Pangest; Plamet; Pridecil; *Ital.*: Procirex; Valopride.

Multi-ingredient Preparations. *Braz.*: Digecap-Zimatico; Lansoprid†; Primeral; *Port.*: Modulanzime.

Buckthorn

Bacca Spinae Cervinae; Espino Cerval; Kreuzdorn; Nerprun; Крушина Слабительная; Жостер Слабительный.

UNII — B4R1EZ1R1D (buckthorn extract).

NOTE. Distinguish from Alder Buckthorn Bark (see Frangula Bark, p. 1843.3) and from Sea Buckthorn (p. 2611.3).

Pharmacopoeias. In *Ger.*

Profile

Buckthorn is the dried ripe fruit of *Rhamnus cathartica* (Rhamnaceae); the bark is also occasionally used. Buckthorn is an anthraquinone stimulant laxative.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Austral.*: Colon Care; Detox Pro gram; Neo-Cleanse; *Rus.*: Laxantis Species No 1 (Слабительный Сбор 1); Proctophytol (Проктофитол); Vicalin (Викалин); *UK* Cleansing Herbs; Lion Cleansing Herbs; *USA*: Detox.

Butropium Bromide *(rINN)*

Bromuro de butropio; Butropii Bromidum; Butropio, bromuro de; Butropium, Bromure de; Бутропия Бромид.

(-)-(1*R*,3*r*,5*S*)-8-(4-Butoxybenzyl)-3-[(*S*)-tropoyloxy]tropanium bromide.

$C_{28}H_{38}BrNO_4$=532.5

CAS — 29025-14-7.

UNII — R3K4503MV7.

Pharmacopoeias. In *Jpn.*

Profile

Butropium bromide is a quaternary ammonium antimuscarinic with peripheral effects similar to those of atropine (p. 1312.1). It has been used in the symptomatic treatment of visceral spasms in an oral dose of 30 mg daily in 3 divided doses.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Indon.*: Coliopan†; *Jpn*: Coliopan; *Malaysia*: Coliopan.

Calcium Carbonate

Calcii carbonas; Calcii Carbonas Praecipitatus (precipitated calcium carbonate); Calcium, carbonate de; Calciumcarbonat; Carbonato de calcio; Creta Preparada; E170; Kalcio karbonatas; Kalciumkarbonat; Kalcium-karbonát; Kalsiumkarbonaatti; Kalsiyum Karbonat; Precipitated Calcium Carbonate; Precipitated Chalk; Uhličitan vápenatý; Wapnia węglan; Wapnia węglan strącony (precipitated calcium carbonate); Кальция Карбонат.

$CaCO_3$=100.1

CAS — 471-34-1.

ATC — A02AC01; A12AA04.

ATC Vet — QA02AC01; QA12AA04.

UNII — H0G9379FGK.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.*

US includes Ground Limestone.

Ph. Eur. 5: (Calcium Carbonate). A white or almost white powder. Practically insoluble in water.

USP 36: (Calcium Carbonate). A fine, white, odourless microcrystalline powder. Practically insoluble in water; its solubility in water is increased by the presence of carbon dioxide or ammonium salts although the presence of any alkali hydroxide reduces its solubility; insoluble in alcohol; dissolves with effervescence in acetic acid, in hydrochloric acid, and in nitric acid.

USP 36: (Ground Limestone). A white to off-white, fine microcrystalline powder mostly consisting of calcium carbonate.

Uses and Administration

Calcium carbonate is used as an antacid (p. 1803.1), usually in oral doses of up to about 1.5 g. It is often given with other antacids, especially magnesium-containing antacids.

Calcium carbonate is also used as a calcium supplement in deficiency states and as an adjunct in the management of osteoporosis, as described under Calcium, p. 1784.3.

Calcium carbonate binds phosphate in the gastrointestinal tract to form insoluble complexes and reduces phosphate absorption. It is used to treat hyperphosphataemia in patients with chronic renal failure (see Renal Osteodystrophy, p. 1170.1) or associated secondary hyperparathyroidism (p. 1170.3). Doses are adjusted according to serum phosphate concentrations. Typical oral doses of calcium carbonate range from about 3 to 7 g (1.2 to 2.8 g calcium) daily in divided doses, although the US National Kidney Foundation suggests that the total dose of elemental calcium provided by the calcium-based phosphate binder should not exceed 1.5 g daily in those with kidney failure. For doses in children, see p. 1825.1.

Calcium carbonate is also used as a food additive.

Homoeopathy

Native forms of calcium carbonate have been used in homoeopathic medicines under the following names: Calcarea Carbonica; Calc. Carb.; Calcium carbonicum

Hahnemanni; Conchae; Calcium Carbonate of Hahnemann; Cal. carb.

Administration in children. Calcium carbonate can be used as a phosphate binder in children with renal failure and hyperphosphataemia. The *BNFC* suggests the following oral doses of calcium carbonate, given 3 or 4 times daily with or before meals, and adjusted as necessary:

- 1 month to 1 year of age: 120 mg
- 1 to 6 years: 300 mg
- 6 to 12 years: 600 mg
- 12 to 18 years: 1.25 g

Adverse Effects, Treatment, and Precautions

Calcium carbonate may occasionally cause constipation. Flatulence from released carbon dioxide may occur in some patients. High doses or prolonged use may lead to gastric hypersecretion and acid rebound. Like other calcium salts (see p. 1786.1), calcium carbonate can cause hypercalcaemia, particularly in patients with renal impairment or after high doses. Alkalosis (p. 1775.3) may also occur as a result of the carbonate anion. There have been rare reports of the milk-alkali syndrome, see below, and tissue calcification. The possibility of an increased risk of myocardial infarction associated with the use of calcium supplements has been raised (see Effects on the Cardiovascular System, p. 1786.1).

For precautions to be observed with the use of calcium carbonate, see Calcium, p. 1786.1.

Milk-alkali syndrome. The milk-alkali syndrome of hypercalcaemia, alkalosis and renal impairment was first identified in the 1920s and may still occur in patients who take large amounts of calcium and absorbable alkali.[1-3] With chronic ingestion, abnormal calcification can develop.[3]

Calcium carbonate is a common source of calcium and alkali, and milk-alkali syndrome can be seen in patients being treated for osteoporosis and after high intake of antacids.[3] Although an elemental calcium intake of up to 2 g daily is considered safe, milk-alkali syndrome has been reported with even lower daily doses.[1,3] Some patients may be more susceptible; predisposing factors include the chronic vomiting associated with bulimia or hyperemesis of pregnancy,[3] pre-existing renal failure, and concomitant use of other medicines which alter calcium homoeostasis.[1,3]

For reference to thiazide diuretics increasing the risk of the milk-alkali syndrome in patients taking moderately large doses of calcium carbonate, see p. 1406.2.

3. Medarov BI. Milk-alkali syndrome. *Mayo Clin Proc* 2009; 84: 261–7.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies calcium carbonate as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 06/10/11)

Interactions

As for other calcium salts, p. 1786.1.

As outlined on p. 1803.1, antacids, including calcium salts, interact with many other drugs both by alterations in gastric pH and emptying, and by formation of complexes that are not absorbed. Interactions can be minimised by giving calcium carbonate and any other medication 2 to 3 hours apart.

Omeprazole. In a study[1] of 18 women over the age of 65, the use of omeprazole for a week significantly reduced the absorption of calcium from a calcium carbonate supplement given on an empty stomach. Fractional calcium absorption was reduced from 9.1% with placebo to 3.5% with omeprazole.

1. O'Connell MB, *et al.* Effects of proton pump inhibitors on calcium carbonate absorption in women: a randomized crossover trial. *Am J Med* 2005; 118: 778–81.

Pharmacokinetics

Calcium carbonate is converted to calcium chloride by gastric acid. Some of the calcium is absorbed from the intestines and the unabsorbed portion is excreted in the faeces, as described for other calcium salts, p. 1786.2.

Preparations

Proprietary Preparations (details are given in Volume B)

Carbenoxolone Sodium *(BANM, USAN, rINNM)*

Carbenoxolona sódica; Carbénoxolone Sodique; Disodium Enoxolone Succinate; Karbenoksolon Sodyum; Natrii Carbenoxolonum; Натрий Карбеноксолон.

3β-(3-Carboxypropionyloxy)-11-oxo-olean-12-en-30-oic acid, Disodium Salt.

$C_{34}H_{48}Na_2O_7$=614.7

CAS — 5697-56-3 (carbenoxolone); 7421-40-1 (carbenoxolone disodium).

ATC — A02BX01.

ATC Vet — QA02BX01.

UNII — F1MP7242Z5.

Pharmacopoeias. In *Br.*

BP 2014: (Carbenoxolone Sodium). A white or pale cream-coloured, hygroscopic powder. Freely soluble in water; sparingly soluble in alcohol; practically insoluble in chloroform and in ether. A 10% solution in water has a pH of 8.0 to 9.2.

Profile

Carbenoxolone sodium is a synthetic derivative of glycyrrhizic acid (p. 2520.2) that is one of many topical treatments for the symptomatic management of mouth ulceration (p. 1811.2). It is usually used as a 2% gel; a 1% mouthwash has been used. It was formerly also used as a mucosal protectant in peptic ulcer disease and has been given with antacids and alginic acid in gastro-oesophageal reflux disease.

Adverse effects. Carbenoxolone has mineralocorticoid-like effects and ingestion has been associated with sodium and water retention and hypokalaemia. Muscle weakness,[1-5] muscle necrosis,[4] myopathy,[1] hypertension,[2] headache,[2] cardiac failure,[2] mental confusion,[4] areflexia,[3] renal tubular dysfunction,[5] and acute tubular necrosis[4] have all been associated with carbenoxolone-induced hypokalaemia. Carbenoxolone-induced hypertension may have precipitated the onset of fatal polyarteritis in a patient predisposed to this condition.[6]

2. Davies GJ, *et al.* Complications of carbenoxolone therapy. *BMJ* 1974; 3: 400–2.
3. Royston A, Prout BJ. Carbenoxolone-induced hypokalaemia simulating Guillain-Barré syndrome. *BMJ* 1976; 2: 150–1.
4. Descamps C, *et al.* Rhabdomyolysis and acute tubular necrosis associated with carbenoxolone and diuretic treatment. *BMJ* 1977; 1: 272.
5. Dickinson RJ, Swaminathan R. Total body potassium depletion and renal tubular dysfunction following carbenoxolone therapy. *Postgrad Med J* 1978; 54: 836–7.
6. Sloan J, Weaver JA. A case of polyarteritis developing after carbenoxolone therapy. *Ir Med J* 1968; 1: 505–7.

Handling. Carbenoxolone sodium powder is irritant to nasal membranes.

Mental function. High cortisol concentrations have been associated with poorer memory and neuronal loss in some patients. Carbenoxolone inhibits 11-β-hydroxysteroid dehydrogenase type 1, and thus may selectively lower intracellular cortisol. In a small crossover study[1] in 10 healthy elderly men, oral carbenoxolone 100 mg three times daily for 4 weeks significantly improved verbal fluency compared with placebo, but did not influence visual or verbal memory, nonverbal reasoning, or processing speed. Twelve patients with stable type 2 diabetes were given carbenoxolone at the same dose for 6 weeks. Verbal memory was significantly improved compared with placebo, but verbal fluency and other scores were unaltered. All subjects were given amiloride 10 mg daily to prevent mineralocorticoid adverse effects[1] (although this has been reported to reduce the efficacy of carbenoxolone).

Casanthranol *(USAN)*

Casantranol; Казантранол.
CAS — 8024-48-4.
UNII — 3SJ3U7J6V2.

Pharmacopoeias. In *US*.

USP 36: (Casanthranol). It is obtained from cascara. It contains not less than 20% of total hydroxyanthracene derivatives calculated on the dried basis, of which not less than 80% consists of cascarosides, both calculated as cascaroside A ($C_{27}H_{32}O_{14}$=580.5).

It is a light tan to brown, amorphous, hygroscopic powder. Freely soluble in water with some residue; partially soluble in methyl alcohol and in hot isopropyl alcohol; practically insoluble in acetone. Store in airtight containers at a temperature not exceeding 30 degrees. Protect from light.

Profile

Casanthranol is an anthraquinone stimulant laxative with general properties similar to those of senna (p. 1885.1). It is given in usual oral doses of 30 to 60 mg daily with a faecal softener. In severe cases a dose of 90 mg daily, or 60 mg twice daily, may be given.

Preparations

Proprietary Preparations (details are given in Volume B)

CAS — 8047-27-6; 8015-89-2 (cascara sagrada extract).
ATC — A06AB07.
ATC Vet — QA06AB07.
ATC Herb — HA06AB5014 (Rhamnus purshiana: bark).
UNII — 4VBP01X99F.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Cascara). The dried, whole or fragmented bark of *Rhamnus purshianus* (=*Frangula purshiana*). It contains not less than 8.0% of hydroxyanthracene glycosides of which not less than 60% consists of cascarosides, both expressed as cascaroside A ($C_{27}H_{32}O_{14}$=580.5). and calculated with reference to the dried drug. Protect from light.

USP 36: (Cascara Sagrada). The dried bark of *Rhamnus purshianus* (Rhamnaceae). It contains not less than 7% of total hydroxyanthracene derivatives calculated on the dried basis, of which not less than 60% consists of cascarosides, both calculated as cascaroside A. It has a distinct odour.

Profile

Cascara is an anthraquinone stimulant laxative with general properties similar to those of senna (p. 1885.1). It has been used in the treatment of constipation in oral doses equivalent to about 20 to 30 mg of total hydroxyanthracene derivatives daily.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving cascara, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

Single-ingredient Preparations. *Arg.*: Natulax†; *Belg.*: Laxafytol; *Braz.*: Laxsotrin†; Verilax; *Fr.*: Peristaltine†; *Ger.*: Legapas.

Multi-ingredient Preparations. *Arg.*: Bilidren; Cascara Sagrada Bouzen; Cascara Sagrada Oligoplex; Cascara Sagrada Puler; Natulax Plus; Veracolate†; *Austral.*: Colax†; Colax; Peritone; *Austria*: Silberne†; *Belg.*: Vethoine; *Braz.*: Chofraninа†; Eparema; Solvobil; *Canad.*: Bicholate†; Bilonat; Cas-Mag; Control†; Depuratif des Trappistes; Doulax; Eliminex; Formula B-1†; Formula T5 Tea†; Hepaticol; Herba Tone†; Herbal Laxative plus Yogurt†; Herbal Laxative†; Herbal Tabs†; Herbanat†; Herbolax†; Laxanat; Melange de Plantes Formula LI Laxatif†; Metab Herbs No 1†; Stomach Ease; Traditional Herbal Laxative†; Traditional Laxative; Ultra-Lax†; *Chile*: Bulgarolax†; *Fr.*: Dragees Fuca; Dragees Vegetales Rex; Imegul†; Mucinum a l'Extrait de Cascara; Spevin†; *Hong Kong*: Mucinum†; *India*: Hepachol; Livotone; *Ital.*: Alosen†; Amaro Medicinale; Combilax; Confetti Lassativi CM; Dis-Cinil Complex; Draverex; Eparema-Levul; Eparema; Estilax; Eupatol; Fave di Fuca; Grani di Vals†; Hepatos B12; Hepatos; Solvobil†; *Neth.*: Temoe Lawak; *Norw.*: Cosylan; *Port.*: Doce Alivio; Mucinum; *S.Afr.*: Moultons Herbal Extract†; *Spain*: Crislaxo; Fave de Fuca; Favilax; Fucapan; Laxodiex; Lipograsil†; Nico Hepatocyn; Pildoras Zeninas; *Switz.*: Padma-Lax; Padmed Laxan; *Thai.*: Corisul; Flataco; Flatulence†; Hemolax†; Patarcolate; Patarsul; Veracolate†; *UK*: Cassilax; Dual-Lax Extra Strong; Dual-Lax Normal Strength; Jacksons Herbal Laxative; Laxative Tablets; Modern Herbals Laxative; Modern Herbals Pile; Napiers Oral Skin Soother Herbal Relief; Natural Herb Tablets; Out-of-Sorts; Pileabs; Piletabs; Rhuaka; Senokot Dual Relief; Skin Eruptions Mixture; *USA*: Concentrated Milk of Magnesia-Cascara†; Detox; *Venez.*: Gameral.

Homoeopathic Preparations. *Canad.*: Cynara Complex†.

Pharmacopoeial Preparations
BP 2014: Cascara Tablets;
USP 36: Aromatic Cascara Fluidextract; Cascara Sagrada Extract; Cascara Sagrada Fluidextract; Cascara Tablets.

Casopitant *(rINN)*

Capsipitant; Casopitantum; GW-679769; Казопитант.
(2*R*,4*S*)-4-(4-Acetylpiperazin-1-yl)-*N*-[(1*R*)-1-[3,5-bis(trifluoromethyl)phenyl]ethyl]-2-(4-fluoro-2-methylphenyl)-*N*-methylpiperidine-1-carboxamide.
$C_{30}H_{35}F_7N_4O_2$=616.6
CAS — 414910-27-3.
ATC — A04AD13.
ATC Vet — QA04AD13.
UNII — 3B03KPM27L.

Casopitant Mesilate *(rINNM)*

Casopitant, Mésilate de; Casopitant Mesylate (USAN); Casopitanti Mesilas; GW-679769B; Mesilato de casopitant; Казопитанта Мезилат.
(2*R*,4*S*)-4-(4-Acetylpiperazin-1-yl)-*N*-[(1*R*)-1-[3,5-bis(trifluoromethyl)phenyl]ethyl]-2-(4-fluoro-2-methylphenyl)-*N*-methylpiperidine-1-carboxamide methanesulfonate.
$C_{30}H_{35}F_7N_4O_2CH_3SO_3H$=712.7
CAS — 414910-30-8.
ATC — A04AD13.
ATC Vet — QA04AD13.
UNII — 7VSV9BL497.

Profile

Casopitant is a neurokinin-1 receptor antagonist like aprepitant (p. 1819.2) that has been investigated for the prevention of chemotherapy-induced nausea and vomiting.

Cassia Pulp

Fístula, pulpa de caña; Мякоть Амалтас.
ATC Herb — HA06AX5001 (Cassia fistula: fruit).

Profile

Cassia pulp is the evaporated aqueous extract of crushed ripe cassia fruits (cassia pods), *Cassia fistula* (Leguminosae). It is a mild anthraquinone stimulant laxative with general properties similar to those of senna (p. 1885.1).

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Braz.*: Fitolax†; Florlax; Fontolax; Laxtam; Naturetti; Tamaril; Tamarine; Tamarine; *Fr.*: Benetransit†; *Gr.*: Tamarine; *Ital.*: Tamarine; *Mex.*: MD Lax; Naturetti; *Rus.*: Pilex (Пайлекс); *Spain*: Pruina; *Ukr.*: Softovak (Софтовак).

Cerium Oxalate

Cerii Oxalas; Cerio, oxalato de; Ceriumoksalaatti; Ceriumoxalat; Церия Оксалат.
CAS — 139-42-4 (anhydrous cerous oxalate); 15053-73-3 (cerous oxalate decahydrate).
ATC — A04AD02.
ATC Vet — QA04AD02.
UNII — 96P72VE680 (cerium oxalate); 0UV74P3R0J (cerium oxalate nonahydrate).

NOTE. Cerium oxalate has been defined as consisting of abou 50% of cerous oxalate ($(C_2O_4)_3Ce_2.10H_2O$) with th oxalates of numerous other rare earths, especiall lanthanum, praseodymium, and neodymium. Oxalates o the form $(C_2O_4)_3Ce_2.xH_2O$ are also referred to as cerium o cerous oxalate.

Profile

Cerium oxalate has been used as an antiemetic.

Preparations

Proprietary Preparations (details are given in Volume B)

Homoeopathic Preparations. *Canad.*: Ubicoenzyme; *Fr.*: Aurun Complexe No 38†; Badiaga Complexe No 47.

Cetraxate Hydrochloride *(JAN, rINNM)*

Cétraxate, Chlorhydrate de; Cetraxati Hydrochloridum, Cetraxato, hidrocloruro de; DV-1006; Hidrocloruro de cetraxato; Цетраксата Гидрохлорид.
4-(2-Carboxyethyl)phenyl tranexamate hydrochloride; 4-(2-Carboxyethyl)phenyl *trans*-4-aminomethylcyclohexanecarboxylate hydrochloride.
$C_{17}H_{23}NO_4.HCl$=341.8
CAS — 34675-84-8 (cetraxate); 27724-96-5 (cetraxate hydrochloride).
UNII — 08IT6P8VHY.

NOTE. The names Eluglilu, Lacmarze, LK, and Reslart hav been used as trade marks for cetraxate hydrochloride.

Pharmacopoeias. In *Jpn*.

Profile

Cetraxate hydrochloride is stated to be a mucosal protectan with actions on gastric microcirculation as well a prostaglandin synthesis and kallikrein. It is used in th treatment of gastritis and peptic ulcer disease (p. 1813.2) i oral doses of 600 to 800 mg daily in divided doses.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Neuer.

Chalk

Creta; Prepared Chalk; Men.
$CaCO_3$=100.1
CAS — 13397-25-6.

Pharmacopoeias. In *Br*.

BP 2014: (Chalk). A native form of calcium carbonate free from most of its impurities by elutriation and dried. I consists of the calcareous shells and detritus of variou foraminifera and contains not less than 97.0% and not mor than 100.5% of $CaCO_3$, calculated with reference to th dried substance.

White or greyish-white, odourless or almost odourless amorphous, earthy, small friable masses, usually conical i form, or in powder. Practically insoluble in water; slightl soluble in water containing carbon dioxide; it absorbs wate readily.

Profile

Chalk has been used as an adsorbent antidiarrhoeal Calcium carbonate (precipitated chalk) is used as an antacid calcium supplement, and phosphate binder, see p. 1824.3.

Calabash chalk, also known as Calabar stone, la craie o argile, nzu, mabele, ebumba, or ulo, is ingested by some pregnant women to alleviate morning sickness. It i traditionally used by Nigerian or West African women in th form of blocks, pellets, or powders. Calabash chalk eithe occurs naturally or is produced from clay and mud that may be mixed with other ingredients including sand, wood ash and sometimes, salt. However, it contains high levels o lead, as well as arsenic (see Contamination, below).

Contamination. Concern with regard to the safety of calabash chalk has arisen, particularly with regard to its lead and arsenic content.[1-4] Analysis of calabash chalk samples available in the UK found that the major component of calabash chalk was an aluminium silicate hydroxide from the kaolin clay group. Lead concentrations in the samples were found to be about 40 mg/kg, almost 40 times the EU recommended guidelines. Potentially toxic chromium con centrations (dependent on the oxidation state) were also found. Arsenic, cadmium, and mercury were not detect

able in any of the analysed samples. Persistent organic pollutants were also identified in one sample.[1] Calabash chalk is traditionally used by pregnant women, often those from Nigerian and West African communities, as a remedy for morning sickness. Health authorities in various countries have issued warnings, and advised people, especially pregnant and breast-feeding women, not to consume calabash chalk.[2-4]

3. Food Standards Agency. Lead contamination of calabash chalk (issued 15th October 2002). Available at: http://www.food.gov.uk/enforcement/alerts/2002/oct/94151 (accessed 03/10/07)
4. FDA. Nzu, traditional remedy for morning sickness (issued 31st December 2009). Available at: http://www.fda.gov/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/ucm196045.htm (accessed 01/03/10)

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *S.Afr.*: Behoedmiddel vir Kinders; *Thal.*: Antidiarrhoeals for children.

Pharmacopoeial Preparations
BP 2014: Compound Magnesium Trisilicate Oral Powder.

Ciclonium Bromide *(rINN)*

Asta-3746; Bromuro de ciclonio; Ciclonii Bromidum; Cidonio, bromuro de; Ciclonium, Bromure de; Циклония бромид.
Diethylmethyl[2-[(α-methyl-α-5-norborneni-2-ylbenzyl)oxy]ethyl]ammonium bromide.
$C_{22}H_{34}BrNO$=408.4
CAS — 29546-59-6.
UNII — 72R7F44611.

NOTE. The name Cyclonium or Ciclonium Iodide has been used to describe an unrelated antispasmodic, Oxapium Iodide (p. 1874.3).

Profile

Ciclonium bromide is an antimuscarinic that has been used in the treatment of gastrointestinal and urinary-tract disorders associated with smooth muscle spasm.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Turk.*: Doladamon.

Cimetidine *(BAN, USAN, rINN)*

Cimetidin; Cimetidina; Cimetidinas; Cimétidine; Cimetidinum; Cymetydyna; Simetidiini; Simetidin; SKF-92334; Циметидин.
2-Cyano-1-methyl-3-[2-(5-methylimidazol-4-ylmethylthio)ethyl]guanidine.
$C_{10}H_{16}N_6S$=252.3
CAS — 51481-61-9.
ATC — A02BA01.
ATC Vet — QA02BA01.
UNII — 80061L1WGD.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 8: (Cimetidine). A white or almost white, polymorphic powder. Slightly soluble in water; soluble in alcohol; practically insoluble in dichloromethane. It dissolves in dilute mineral acids. Protect from light.

USP 36: (Cimetidine). A white to off-white crystalline powder, odourless or with a slight mercaptan odour. Slightly soluble in water and in chloroform; soluble in alcohol and in macrogol 400; practically insoluble in ether; sparingly soluble in isopropyl alcohol; freely soluble in methyl alcohol. Store in airtight containers. Protect from light.

Cimetidine Hydrochloride *(BANM, USAN, rINNM)*

Cimetidina, hidrocloruro de; Cimétidine, chlorhydrate de; Cimetidin-hidroklorid; Cimetidinhydroklorid; Cimetidin-hydrochlorid; Cimetidinhydroklorid; Cimetidini Hydrochloridum; Cimetidino hidrochloridas; Hidrocloruro de cimetidina; Simetidiinihydrokloridi; Циметидина Гидрохлорид.
$C_{10}H_{16}N_6S.HCl$=288.8
CAS — 70059-30-2.
ATC — A02BA01.
ATC Vet — QA02BA01.
UNII — WE10491673.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Cimetidine Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water; sparingly soluble in dehydrated alcohol. A 1% solution in water has a pH of 4.0 to 5.0. Protect from light.

USP 36: (Cimetidine Hydrochloride). Store in airtight containers. Protect from light.

Uses and Administration

Cimetidine is a histamine H_2-antagonist and inhibits actions of histamine mediated by H_2-receptors such as gastric acid secretion and pepsin output. It is used where inhibition of gastric acid secretion may be beneficial, as in peptic ulcer disease, including stress ulceration (p. 1813.2), gastro-oesophageal reflux disease (p. 1807.2), selected cases of persistent dyspepsia (p. 1806.3), scleroderma of the oesophagus, pathological hypersecretory states such as the Zollinger-Ellison syndrome (p. 1814.3), and in patients at risk of acid aspiration (p. 1804.2) during general anaesthesia or child birth. Cimetidine may also be used to reduce malabsorption and fluid loss in patients with the short bowel syndrome and to reduce the degradation of enzyme supplements given to patients with pancreatic insufficiency.

Cimetidine may be given orally or parenterally by the intravenous or intramuscular routes; the total daily dose by any route should not normally exceed 2.4 g. Although some formulations are prepared as the hydrochloride, strengths and doses are expressed in terms of the base. Cimetidine 100 mg is equivalent to about 114.5 mg of cimetidine hydrochloride. Doses should be reduced in renal impairment and may also need to be reduced in hepatic impairment (see below).

For doses in children, see Administration in Children, below.

In the management of benign **gastric** and **duodenal ulceration** a single daily oral dose of 800 mg at bedtime or 400 mg twice daily is recommended, which should be given for at least 4 weeks for duodenal ulcers (6 weeks for gastric ulcers, 8 weeks for NSAID-associated ulcers); when necessary the dose may be increased to 400 mg four times daily. Where appropriate a maintenance dose of 400 mg may then be given once daily at bedtime, or twice daily in the morning and at bedtime. Other regimens have also been used for treatment and maintenance.

In **gastro-oesophageal reflux disease** the recommended oral dose is 400 mg four times daily (with meals and at bedtime), or 800 mg twice daily, for 4 to 12 weeks. In pathological hypersecretory conditions, such as the **Zollinger-Ellison syndrome**, an oral dose of 300 or 400 mg four times daily is normally used, although sometimes higher doses may be necessary.

Doses of 200 to 400 mg orally every 4 to 6 hours are recommended for prophylaxis of haemorrhage from **stress ulceration**. In patients at risk of developing the **acid aspiration syndrome**, an oral dose of 400 mg may be given 90 to 120 minutes before the induction of anaesthesia, or at the start of labour (in obstetric practice), and doses of up to 400 mg may be repeated at intervals of 4 hours if required.

Doses of up to 800 mg daily in divided doses have been taken for non-ulcer **dyspepsia**; 100 mg at night has been used in the prophylaxis of nocturnal heartburn.

For **scleroderma of the oesophagus**, the usual dose is 1.2 g orally in divided doses.

For **short bowel syndrome**, an initial oral dose of cimetidine 400 mg twice daily is adjusted according to response.

To reduce the degradation of pancreatic enzyme supplements, patients with **pancreatic insufficiency**, as in cystic fibrosis (p. 177.2), may be given oral cimetidine 800 mg to 1.6 g daily in 4 divided doses, 60 to 90 minutes before meals.

PARENTERAL ADMINISTRATION.

Cimetidine may be diluted before intravenous use; commonly used intravenous solutions such as sodium chloride 0.9%, glucose 5 or 10%, and lactated Ringer's solution are compatible. Parenteral dosage recommendations are 300 mg every 6 to 8 hours by intramuscular injection or by slow intravenous injection, diluted to 20 mL, over at least 5 minutes; the same dosage may be given by intermittent intravenous infusion, diluted to at least 50 mL, over 15 to 20 minutes. If higher doses are required, intravenous injections or infusions may be given more frequently up to the maximum total daily dose of 2.4 g. For continuous intravenous infusion (diluted in up to 1 litre) the recommended rate is 37.5 mg/hour, which may be preceded by 150 mg as an intravenous loading dose. Higher rates may be required in some patients; a rate of 50 mg/hour is recommended for prevention of stress ulceration.

Administration in children. Cimetidine is used in children in the management of conditions where gastric acid reduction is beneficial including benign duodenal and gastric ulceration, reflux oesophagitis, and Zollinger-Ellison syndrome. Experience in children is more limited than that in adults and regulatory authorities in some countries do not recommend its use unless the benefits of cimetidine outweigh its potential risks; an oral or intravenous dose of 20 to 40 mg/kg daily in divided doses has been suggested for children under 16 years of age. Licensed oral doses for children over 1 year of age range from 20 to 30 mg/kg daily in divided doses. An oral dose of 20 mg/kg daily in divided doses has been suggested for infants under 1 year. A lower dose of 10 to 15 mg/kg daily in 4 to 6 divided doses is recommended for neonates.

For differences in pharmacokinetics in children which may affect dosing, see p. 1831.2.

Administration in hepatic impairment. The bioavailability of cimetidine may be increased in patients with cirrhosis[1,2] and a dosage reduction of up to 40% has been suggested in patients with portal systemic encephalopathy.[3] However, UK and US licensed product information does not include recommendations for dosage adjustment in hepatic impairment.

1. Gugler R, *et al.* Altered disposition and availability of cimetidine in liver cirrhotic patients. *Br J Clin Pharmacol* 1982; 14: 421–30.
2. Cello JP, Øie S. Cimetidine disposition in patients with Laennec's cirrhosis during multiple dosing therapy. *Eur J Clin Pharmacol* 1983; 25: 223–9.
3. Ziemniak JA, *et al.* Hepatic encephalopathy and altered cimetidine kinetics. *Clin Pharmacol Ther* 1983; 34: 375–82.

Administration in renal impairment. The dosage of cimetidine should be reduced in patients with renal impairment. UK licensed product information suggests the following oral doses according to creatinine clearance (CC):

- CC over 50 mL/minute: normal dosage
- CC 30 to 50 mL/minute: 200 mg four times daily
- CC 15 to 30 mL/minute: 200 mg three times daily
- CC 0 to 15 mL/minute: 200 mg twice daily

US licensed product information suggests a dose of 300 mg every 12 hours orally or by intravenous injection in those with severe impairment, increasing the frequency with caution if required. Patients with a creatinine clearance of < 30 mL/minute who are being treated for prevention of stress ulceration should be given half the usual intravenous dose, see Uses and Administration, above.

Cimetidine is removed by haemodialysis, but not significantly removed by peritoneal dialysis.

Bladder disorders. Cimetidine effectively relieved symptoms in patients with painful bladder disease (encompassing conditions including cystitis, painful bladder syndrome, and urethral syndrome), especially suprapubic pain and nocturia, despite no apparent histological change in the bladder mucosa after treatment.[1]

1. Thilagarajah R, *et al.* Oral cimetidine gives effective symptom relief in painful bladder disease: a prospective, randomized, double-blind placebo-controlled trial. *BJU Int* 2001; 87: 207–12.

Dapsone toxicity. Cimetidine might reduce methaemoglobinaemia associated with dapsone. For references supporting this suggestion, see Effects on the Blood, under Dapsone, p. 282.2.

Diagnostic use. Cimetidine blocks renal tubular secretion of creatinine and has been used experimentally to improve the accuracy of estimations of glomerular filtration rate from creatinine clearance.[1] Although the optimal dose has not been established, in renal transplant recipients an oral dose of 1 g given in 4 divided doses seemed to provide a useful measure of glomerular filtration rate when the plasma creatinine concentration was below 2.5 mg/litre. At higher creatinine concentrations, a higher dose was required to block tubular excretion effectively.

1. Kabat-Koperska J, *et al.* Creatinine clearance after cimetidine administration— is it useful in the monitoring of the function of transplanted kidney? *Ren Fail* 2007; 29: 667–72.

Echinococcosis. Cimetidine has been given with albendazole to increase its effect (by inhibiting its metabolism) in the treatment of echinococcosis (p. 145.2).

Immunomodulation. Studies in *mice* and humans have shown that H_2-antagonists have an immunoregulatory effect.[1] T-lymphocyte suppressor cells have histamine H_2 receptors and cimetidine has been reported to reduce activity of these cells, thus enhancing immune response.[1,2] There is also some evidence that it enhances cellular immunity, notably natural killer cell activity.[3] This discovery has led to the investigation of cimetidine in disorders associated with alteration of the immune response including eosinophilic fasciitis, herpesvirus infections, mucocuta-

neous candidiasis,[4] hypogammaglobulinaemia,[5] and various malignancies.[1]

5. White WB, Ballow M. Modulation of suppressor-cell activity by cimetidine in patients with common variable hypogammaglobulinemia. *N Engl J Med* 1985; 312: 198–202.

EOSINOPHILIC FASCIITIS. Eosinophilic fasciitis is a scleroderma-like syndrome of inflammation of the muscle fascia and associated eosinophilia and hypergammaglobulinaemia. Although it responds well to corticosteroid therapy in most cases, cimetidine has also been tried. The effect of cimetidine on eosinophilic fasciitis is unpredictable with both remission[1-4] and lack of response[5,6] having been reported in a few patients. In one case series of 17 patients, 9 remitted with initial cimetidine treatment, while 5 showed a partial response.[7]

HERPESVIRUS AND PAPILLOMAVIRUS INFECTIONS. Although there have been numerous isolated and anecdotal reports of a beneficial response to cimetidine in patients with infections due to various *herpesviruses* (p. 954.1), including genital herpes simplex,[1] infectious mononucleosis,[2,3] and herpes zoster[4-7] some of these reports have been criticised[8,9] mainly on the grounds that the majority of cases of herpes zoster will resolve within 2 to 3 weeks whether any treatment is given or not. Also, a double-blind placebo-controlled study involving 63 patients with herpes zoster[10] found no evidence that cimetidine relieved the pain or accelerated the rate of healing of lesions.

There are reports[11] of benefit from the use of cimetidine in patients with *viral warts* (p. 1689.3) and an 8-year retrospective analysis of 216 patients with plantar warts reported a success rate of about 80%, although warts recurred in 12 patients.[12] However, controlled studies have failed to show significant benefit,[13,14] and a review concluded that use of H_2-antagonists for warts could not be recommended based on the available evidence.[15]

MALIGNANT NEOPLASMS. Because of its immunomodulatory effects cimetidine has been tried as an adjuvant in the management of a variety of malignant neoplasms such as those of the gastrointestinal tract (see p. 705.2). Cimetidine may also have inhibitory effects on tumour growth and inhibit cancer cell migration and adhesion to epithelial cells.[1] Positive effects on survival have been reported in some studies in gastrointestinal cancer,[2-4] although a large, randomised, placebo-controlled study with cimetidine,[5] and a similar study with ranitidine,[6] failed to show any benefit. A study in colorectal cancer found improved survival and a reduced frequency of metastasis with cimetidine in patients whose tumour cells expressed high levels of the sialyl Lewis-X and sialyl Lewis-A antigens. The presence of these antigens mediates the adhesion of cancer cells to endothelium and is considered to lead to metastasis.[7]

Famotidine has also been investigated as an adjunct in patients with malignant neoplasms, usually given with interleukin-2; some success has been reported in small numbers of patients.[8,9]

Mastocytosis. Cimetidine, alone or with an antihistamine (histamine H_1-antagonist), has been reported to relieve gastrointestinal symptoms,[1,2] pruritus, and urticaria[3,4] in patients with mastocytosis (p. 1226.3).

Paracetamol toxicity. It has been suggested that cimetidine might be of use in the treatment of paracetamol poisoning (see p. 116.2) because of its inhibition of the cytochrome P450 system. However, there appears to be no strong evidence to support its use.[1,2]

Skin disorders. Cimetidine has been used alone[1-6] or with an antihistamine (H_1-antagonist)[5,8,9] in various skin disorders. H_2-antagonists such as cimetidine and ranitidine have produced improvement in certain types of *urticaria* (p. 1689.2), especially those associated with cold or angioedema. Although they may act by antagonism of H_2-receptors on cutaneous blood vessels, other mechanisms of action may be involved.[6] A pharmacokinetic interaction between cimetidine and hydroxyzine resulting in increased serum concentrations of hydroxyzine has been reported when such a combination was given, see p. 631.2. Routine use of H_2-antagonists in urticaria is controversial, but in practice they may be added to conventional treatment in resistant cases.[10-12] Little additional benefit has been found with combination therapy in dermographic urticaria.[13]

Patients with *pruritus* (p. 1687.3) of various causes may also respond to H_2-antagonists,[1,2,6,7,9] but studies in larger groups of patients have found no benefit.[3-5,14]

Adverse Effects

Adverse reactions to cimetidine and other histamine H_2-antagonists are generally infrequent. The commonest adverse effects reported have been diarrhoea and other gastrointestinal disturbances, dizziness, tiredness, headache, and rashes. Myalgia and arthralgia can occur.

Altered liver function tests have occurred and there have been rare reports of hepatotoxicity. Reversible confusional states, especially in the elderly or in seriously ill patients such as those with renal failure, have occasionally occurred. Other adverse effects that have been reported rarely are hypersensitivity reactions and fever, reversible alopecia, blood disorders including agranulocytosis, leucopenia, and thrombocytopenia, acute pancreatitis, interstitial nephritis, hallucinations and depression, and cardiovascular disorders including bradycardia, tachycardia, and heart block. Rapid intravenous injection should be avoided as there have been rare associations with cardiac arrest and arrhythmias; transient hypotension has also been seen.

In patients such as the elderly, those with chronic lung disease, diabetes mellitus, or the immunocompromised, treatment with H_2-antagonists may be associated with an increased risk of developing community-acquired pneumonia.

Cimetidine has a weak anti-androgenic effect and gynaecomastia and impotence have also occasionally occurred in men; these are usually reversible.

Incidence of adverse effects. In a meta-analysis of 24 double-blind placebo-controlled studies,[1] the incidence of adverse effects with cimetidine was not significantly different from placebo. The most common adverse effects reported by patients taking cimetidine who were followed up for at least one year[2,3] were diarrhoea, headache, fatigue, skin rash or pruritus, and gynaecomastia. The incidence of adverse effects was dose-related and decreased with length of treatment.[3] No fatal adverse effect of cimetidine could be found in a mortality survey involving 9928 patients taking cimetidine and 9351 controls;[4] although the mortality rate was higher in the cimetidine patients, this was explained by the presence of underlying disease (known or unknown) before starting cimetidine treatment and the use of cimetidine to counter adverse gastric effects of other drugs. Follow-up of 9377 of these cimetidine-treated patients for a further 3 years[5] still revealed no fatal disorder attributable to cimetidine treatment and a steady fall in the excess death rate in cimetidine users was seen with increasing length of follow-up; by the fourth year there was little difference between the observed and expected death rate. Cimetidine still appeared to be safe after 10 years of follow-up.[6]

Carcinogenicity. An association between H_2-antagonists and gastric cancer was proposed after individual case reports, the finding of tumours in long-term high-dose *animal* studies, and the possibility that nitrites and nitroso compounds may be produced, but seemed of little clinical relevance.[1,2] Although a small increase in the risk of gastric cancer has been reported with the use of H_2-antagonists,[3] the excess risk in patients taking cimetidine[4-7] or ranitidine[7] decreases with time and there is no evidence for any long-term persistence of the effect.[7] The increased risk may be explained by misdiagnosis and inappropriate cimetidine treatment of existing malignancy,[4-6] or by confounding by indication,[3] since the excessive gastric-acid production for which the drugs are given may itself be associated with an increased risk of gastric cancer. An apparently protective effect has been seen for H_2-antagonist use starting 10 or more years before diagnosis of gastric cancer.[7]

The observed excess risk for cancers of the respiratory system is probably related to smoking, since this is causally related to both peptic ulcer and lung cancer and the excess risk does not decline with time.[4-6]

The hormonal effects of cimetidine have also led to study into its association with cancers of the breast or prostate. In general, use of cimetidine or other H_2-antagonists has no

affected the risk of breast cancer,[8-10] although current use of ranitidine was associated with an increased risk for hormone receptor-positive ductal carcinoma in one study.[9] In prostate cancer, a large cohort study found an increased risk only in men who took cimetidine daily over 10 years compared with men who did not use H_2-antagonists.[11] Prostate cancer risk was not affected by less frequent cimetidine use or by any use of other H_2-antagonists. Another study[10] found a modest increase in the risk of prostate cancer only in men who had received more than 20 prescriptions for cimetidine, compared with patients who had taken other H_2-antagonists.

Effects on the blood. A review[1] in 1988 noted that leucopenia, thrombocytopenia, and pancytopenia have all been reported with cimetidine and ranitidine, with neutropenia and agranulocytosis occurring most often. There were also isolated reports of haemolytic anaemia and leucocytosis associated with cimetidine therapy. The overall incidence of cimetidine-associated blood cytopenia was estimated as 2.3 per 100 000 treated patients; the incidence for ranitidine was less and although there were reports with famotidine the incidence had not been determined. A subsequent case-control study,[2] concluded that the risk of hospitalisation due to neutropenia in patients receiving a 6-week course of cimetidine was no more than 1 in 116 000, while agranulocytosis did not occur in more than 1 in 573 000 patients.

A review[3] of the safety profile of famotidine noted that as of May 1992 there had been 60 reports of serious blood dyscrasias in patients receiving famotidine, of which 22 were considered possibly related to drug therapy (6 cases of pancytopenia or bone marrow depression, 5 of thrombocytopenia, 4 of leucopenia, 3 of combined leucopenia and thrombocytopenia, and 3 of agranulocytosis).

Effects on bone. An observational study[1] of the role of histamine in bone turnover, found that bone mineral density (BMD) at the femoral neck was reduced in patients taking H_2-antagonists, especially when calcium or vitamin D intake was reduced. The authors concluded that although the risk estimates of the BMD changes did not seem to be large, the clinical sequelae were uncertain.

Effects on the cardiovascular system. Reports of cardiovascular effects associated with H_2-antagonists have mostly involved dysrhythmias;[1] bradycardia, AV block, sinus or cardiac arrest, atrial fibrillation, ventricular extrasystoles, tachycardia, and ventricular fibrillation have all been reported with cimetidine, the oldest H_2-antagonist. Similar adverse effects have been reported with ranitidine; with famotidine, QT prolongation has also been described.[2,3] Although cardiovascular adverse effects are considered infrequent, they have occurred after intravenous and oral dosage, as well as after single-dose or long-term treatment.[1]

Studies into the haemodynamic effects of H_2-antagonists have reported disparate results. Apparent differences in effect have been seen for different H_2-antagonists at equipotent doses.[1] Some studies in healthy subjects,[4-6] and critically ill[7,8] and other[9] patients being treated with H_2-antagonists found no adverse haemodynamic effects with cimetidine, famotidine, or ranitidine. However, other studies in healthy subjects have noted negative inotropic effects with both famotidine and nizatidine. Falls in heart rate and cardiac output with nizatidine were not reproduced after pre-treatment with ranitidine[10] or pirenzepine,[11] and falls in cardiac output and stroke volume with famotidine[12] were delayed by pre-treatment with ranitidine.[10] It has been suggested that there is a small proportion of patients more susceptible to the cardiovascular effects of H_2-antagonists.[5] Caution is recommended if H_2-antagonists are given intravenously to patients with cardiovascular disease (see Precautions, p. 1830.2).

Effects on the endocrine system. Cimetidine has dose-related mild anti-androgenic properties and reduced sperm counts and raised serum-prolactin concentrations have been reported in men during cimetidine treatment[1] as have gynaecomastia, breast tenderness, and impotence.[2] Those symptoms resolved after withdrawal of cimetidine,[1,2] reduction of the dose,[2] or transfer to ranitidine.[2]

A study by the Boston Collaborative Drug Surveillance Program, using data from 81 535 men in the UK, found that cimetidine was associated with an incidence of 3.29 cases of gynaecomastia per 1000 person years, representing a relative risk 7.2 times greater than that of non-users.[3] The period at highest risk seemed to be between the seventh and twelfth month after starting treatment, and the occurrence was related to dose, with most of the risk associated with doses over 1 g daily. This large study found no significant risk of gynaecomastia with ranitidine or omeprazole.

Unlike cimetidine, famotidine, nizatidine, and ranitidine are considered to have little, if any, anti-androgenic effect. Studies in men taking ranitidine for the management of duodenal ulcer[4,5] reported no significant changes in the plasma concentrations of testosterone, luteinising hormone, follicle-stimulating hormone, or prolactin after up to 2 years of treatment; no significant changes in sperm concentration, motility, or morphology were noted.[4] However, there have been isolated reports of galactorrhoea with famotidine,[6] gynaecomastia with ranitidine,[7,8] hyperprolactinaemia with famotidine[6,9] and ranitidine,[8] and impotence with famotidine,[10] nizatidine,[10] and ranitidine.[8,10]

Effects on the eyes. Ocular pain, blurred vision, and a rise in intra-ocular pressure occurred in a patient with chronic glaucoma during treatment with cimetidine; ocular symptoms associated with raised intra-ocular pressure subsequently developed during ranitidine treatment.[1] However, a study suggested that cimetidine had no effect on intra-ocular pressure.[2] A cohort study involving 140 128 patients receiving anti-ulcer therapy, 68 504 of whom received cimetidine, found no evidence that any of the drugs were associated with a major increased risk of vascular or inflammatory disorders of the eye.[3]

Effects on the kidneys. A review[1] of the nephrotoxicity and hepatotoxicity of H_2-antagonists noted that mild elevation of serum-creatinine was relatively common after use of cimetidine but appeared to have no clinical significance. However, the authors found 25 published reports of acute interstitial nephritis associated with this class of drug (20 with cimetidine, 4 with ranitidine, and 1 with famotidine) and 16 cases reported to the Australian Drug Reaction Advisory Committee (ADRAC) between 1972 and 1999 (11 with cimetidine, 4 with ranitidine, and 1 with famotidine). Symptoms were mostly non-specific, and did not seem to be associated with the rash, arthralgia, and flank pain that may be seen in nephritis induced by other drugs. Nephritis was rare (an earlier analysis estimated an incidence of around 1 in 100 000 treated patients[2]) and invariably resolved when the drug was withdrawn. In 6 cases, rechallenge resulted in prompt return of clinical features, although there was some evidence that patients who developed nephrotoxicity with one H_2-antagonist might be able to tolerate substitution with another.

Effects on the liver. Hepatotoxicity has been reported with cimetidine,[1,2] ranitidine,[3-5] and famotidine.[1,6] A cohort study[7] involving 108 891 patients given cimetidine, ranitidine, famotidine, or omeprazole between 1990 and 1993, found 33 cases meeting the authors' definition of clinically serious liver injury (cholestatic in 8 cases, hepatocellular in 15 and mixed in 10), most of whom presented with jaundice. Of these cases of liver injury, 12 were among current users of cimetidine, compared with 5 among users of ranitidine and 1 omeprazole user. It was estimated that the incidence of hepatotoxicity among patients using cimetidine was 2.3 cases per 10 000 users, and the adjusted relative risk was 5.5 times that of non-users. The relative risk for use of ranitidine or omeprazole was calculated at 1.7 and 2.1 respectively. The risk with cimetidine was greatest at high doses (800 mg daily or above) and at the beginning of therapy. A review concluded that although hepatotoxicity is very rare, it can occur with all H_2-antagonists and can include both hepatocellular and cholestatic features.[8]

Effects on the nervous system. CNS reactions have been reported with all H_2-antagonists.[1] These reactions occurred within 2 weeks of starting therapy in most cases, and resolved within 3 to 7 days of stopping treatment. After a reaction, it has been reported that most patients tolerate a different H_2-antagonist, but some will react to more than one. Confusion, disorientation, agitation, hostility, delirium, and hallucinations were most commonly described; obtundation, drowsiness, psychosis, and paranoia have also been reported. Proposed risk factors for CNS reactions associated with H_2-antagonist use include increasing age, critical illness, concomitant use of psychotropic medicines, pre-existing psychiatric disease, and liver or kidney disease. However, the evidence is sparse and the risk factors and the relative incidence of reactions with different H_2-antagonists remain to be established.

The effect of H_2-antagonists on cognitive function has also been studied. Despite early data suggesting their use was associated with a reduced risk of Alzheimer's disease, further analysis did not confirm the link.[2] Furthermore, a 5-year prospective study[3] suggested that continuous use of H_2-antagonists was associated with an increased risk of cognitive impairment in elderly African Americans.

Effects on the skin. Widespread erythrosis-like lesions in a 36-year-old man were probably induced by cimetidine.[1]

There has been a report[2] of a skin eruption clinically consistent with erythema annulare centrifugum developing in a patient after 6 months of treatment with cimetidine; the eruption resolved after withdrawal of cimetidine and reappeared on rechallenge. The condition had not recurred during therapy with ranitidine. A mainly symmetrical, intertriginous pattern of erythema has also been reported with cimetidine use.[3] Erythema multiforme eruptions occurred after both cimetidine and famotidine in one patient.[4] There have been reports of the Stevens-Johnson syndrome during cimetidine treatment in patients with a history of hypersensitivity to penicillin[5] or sulfonamides,[6] and toxic epidermal necrolysis has been reported with cimetidine[7] and famotidine.[8] Vasculitic rashes have been reported with cimetidine,[9] nizatidine,[10] and ranitidine.[11] Alopecia[12] has been associated with cimetidine treatment.

Hypersensitivity. Facial oedema,[1] laryngospasm,[1] pruritus,[2,3] rash,[2,3] angioedema[3] and anaphylaxis[4] have been reported in patients receiving cimetidine orally or intravenously. Respiratory stridor and a diffuse urticarial rash occurred in a patient shortly after taking the first oral dose of ranitidine;[5] the symptoms responded to subcutaneous adrenaline. Anaphylaxis has also been reported after famotidine.[6] See also Effects on the Skin, p. 1829.3.

It has also been suggested that cimetidine might potentiate hypersensitivity reactions to other antigens through its actions on histamine and H_2-receptors.[7]

Infection. For discussion of the possible increased risk of infections with acid suppressing drugs, see Omeprazole, p. 1870.1.

Malabsorption. A case-control study[1] in elderly patients found that chronic use (12 months or more) of acid-suppressive therapy, including H_2-antagonists, increased the risk of vitamin B_{12} deficiency. It has been suggested that deficiency might result from impaired release of vitamin B_{12} from food protein, which requires gastric acid and pepsin.[2]

2. Ruscin JM, *et al.* Vitamin B_{12} deficiency associated with histamine$_2$-receptor antagonists and a proton-pump inhibitor. *Ann Pharmacother* 2002; 36: 812–16.

Overdosage. No serious toxic effects were noted in reports[1-3] of overdosage in patients who took cimetidine 5.2 to 20 g (including one patient who took about 12 g daily for 5 days[1]). Resultant plasma concentrations had been up to 57 micrograms/mL compared with a usual peak plasma concentration of 1 microgram/mL after a 200-mg dose. However, an overdose of about 12 g produced high pulse rate, dilated pupils, speech disturbances, agitation and disorientation in one patient[4] and respiratory depression in another patient who had chronic schizophrenia and was also taking trifluoperazine and hydroxyzine.[5] Also, fatal bradycardia has been reported after overdosage with an unknown amount of cimetidine and diazepam.[6] In a review of 881 cases of cimetidine overdose, excluding cases where several drugs were taken, it was concluded that the toxicity of cimetidine after acute overdose was very low.[7] No symptoms were seen in 79% of cases, which included ingestions of up to 15 g of cimetidine, and only 3 patients had moderate clinical manifestations (dizziness and bradycardia; CNS depression; vomiting). No patients had major medical outcomes and there were no fatalities. Gastric emptying was performed in 34% of cases but supportive measures and symptomatic treatment alone may be adequate. Forced diuresis does not appear to enhance the excretion of cimetidine from the body, and is not recommended.[3]

Precautions

Before giving cimetidine or other histamine H_2-antagonists to patients with gastric ulcers the possibility of malignancy should be considered since these drugs may mask symptoms and delay diagnosis. They should be given in reduced dosage to patients with renal impairment.

Intravenous injections of cimetidine should be given slowly and intravenous infusion is preferred, particularly for high doses and in patients with cardiovascular impairment.

Allergy testing. A small study in 21 patients found that ranitidine suppressed the cutaneous response to allergens in skin-prick tests.[1] The authors highlighted the importance of considering the possible influence of H_2-antagonists on allergy diagnosis and treatment.

1. Kupczyk M, *et al.* Ranitidine (150 mg daily) inhibits wheal, flare, and itching reactions in skin-prick tests. *Allergy Asthma Proc* 2007; 28: 711–15.

Breast feeding. In the UK, licensed product information advises that mothers receiving cimetidine avoid breast feeding. Cimetidine is reported to be actively transported into breast milk, resulting in a milk:serum ratio 5.5 times higher than that expected with passive diffusion.[1] In one case, where cimetidine was detected in the milk of a nursing mother in concentrations higher than in her plasma, it was calculated[2] that the maximum amount of cimetidine that an infant could ingest assuming an intake of about 1 litre of milk daily and fed at the time of peak concentrations would be about 6 mg. However, the Committee on Drugs of the American Academy of Pediatrics has pointed out that there was no evidence of signs or symptoms attributable to the drug in the infant in this case,[3] despite 6 months of breast feeding, and cimetidine has been classified by that body as usually compatible with breast feeding.[4]

Burns. The clearance of cimetidine has been reported to be increased in burn patients, with the increase correlating to the size of the burn.[1] Despite another study that reported a decreased renal clearance (but an increased non-renal clearance) early in the evolution of burn injury,[2] it has been recommended that the dosage of cimetidine be increased in patients with burns, depending on the extent of injury. A requirement for increased dosage has also been noted in paediatric burns patients.[3]

3. Martyn JAJ, *et al.* Alteration by burn injury of the pharmacokinetics and pharmacodynamics of cimetidine in children. *Eur J Clin Pharmacol* 1989; 36: 361–7.

Helicobacter pylori testing. A study in 118 patients with *Helicobacter pylori* infection showed that 14 days of treatment with ranitidine could produce false negative results with urea breath testing, regardless of the dose used.[1] All breath tests became positive within 14 days of stopping treatment. The manufacturers of the breath test recommend it should not be performed for at least 2 weeks after stopping antisecretory drug therapy.

1. Savarino V, *et al.* Negative effect of ranitidine on the results of urea breath test for the diagnosis of Helicobacter pylori. *Am J Gastroenterol* 2001; 96: 348–52.

Hepatic impairment. An increased resistance to H_2-receptor antagonists has been reported in patients with cirrhosis.[1] Plasma concentrations were higher in responders than nonresponders; however, the authors considered concentrations in both groups to be sufficient for an effect and could not account for the results.

For a suggestion that dosage reduction of cimetidine may be required in patients with portal systemic encephalopathy, see Administration in Hepatic Impairment, p. 1827.3

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies cimetidine as not porphyrinogenic: it may be used as a drug of first choice and no precautions are needed.[1]

For reference to clinical and biochemical improvement in porphyric patients receiving cimetidine, see p. 1828.2.

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pregnancy. Data from prospective[1,2] and retrospective[3] cohort studies in pregnant women who had taken H_2-antagonists mainly during the first trimester, have not indicated an increased risk of major malformations. H_2-antagonists were also not associated with perinatal mortality, low birth-weight, or low Apgar scores;[1-3] although one study noted a higher rate of preterm births in the group exposed to H_2-antagonists,[2] this was not supported by other studies.[1,3] Additionally, UK licensed product information states that ranitidine has been given to women in labour or undergoing caesarean section without any adverse effects on labour, delivery, or the child. However, product information for cimetidine and ranitidine advises they should be avoided during pregnancy unless essential, as both cross the placenta.

Interactions

Cimetidine and other H_2-antagonists can reduce the absorption of drugs such as dasatinib, ketoconazole, itraconazole, and possibly posaconazole, whose absorption is dependent on an acid gastric pH. For the effect of itraconazole on cimetidine see Antifungals, p. 1831.1.

Cimetidine may inhibit the hepatic metabolism of many drugs by binding to cytochrome P450 isoenzymes, including CYP1A2, CYP2C9, CYP2D6, CYP3A3, CYP3A4, and CYP2C18. Although many such interactions may occur, only a few are considered clinically significant, notably those with phenytoin, theophylline, lidocaine, and oral anticoagulants. Avoidance of the combination, or a reduction in the dosage of these drugs may be required.

Cimetidine can affect many drugs[1-4] but these interactions are of clinical significance for only a few, particularly those that have a narrow therapeutic index where the risk of toxicity may necessitate adjustment of dosage. The majority of interactions are due to binding of cimetidine to cytochrome P450 isoenzymes in the liver with subsequent inhibition of microsomal oxidative metabolism and increased bioavailability or plasma concentrations of drugs metabolised by these enzymes. A few interactions are due to competition for renal tubular secretion. Other mechanisms of interaction such as changes in hepatic blood flow play only a minor role.

Significant interactions have occurred with:

- antiarrhythmics such as dofetilide (p. 1367.2), lidocaine (p. 1991.2), and procainamide (p. 1477.2)
- antiepileptics such as phenytoin (p. 544.3) and carbamazepine (p. 517.3)
- biguanide antidiabetics (p. 469.1)
- moclobemide (p. 438.1)
- nifedipine (p. 1454.1)
- opioid analgesics (p. 111.3)
- nitrosoureas such as carmustine (p. 762.1)
- sildenafil (p. 2366.3)
- theophylline (p. 1236.1)
- tricyclic antidepressants such as amitriptyline (p. 407.1)
- warfarin and other oral anticoagulants (p. 1534.1)
- zalcitabine (p. 1023.3)
- zolmitriptan (p. 682.3)

Combinations of these drugs and cimetidine should be avoided or used with caution, with monitoring of effects or

plasma-drug concentrations and reductions in dosage as appropriate.

Famotidine, nizatidine, and ranitidine do not inhibit cytochrome P450, and the potential for drug interactions is therefore reduced.

4. Shinn AP. Clinical relevance of cimetidine drug interactions. *Drug Safety* 1992; **7**: 245–67.

Alcohol. Any interaction between H_2-antagonists and alcohol is generally thought unlikely to be clinically significant (see p. 1735.2).

Antacids. Single-dose studies of the interaction between cimetidine famotidine, or ranitidine and antacids[1] have generally shown a reduced bioavailability of H_2-antagonist. The neutralising capacity of the antacid appears to be a factor in determining whether an interaction occurs and a dose with less than 50 mmol neutralising capacity will have little, if any, effect on H_2-antagonist absorption. Smaller doses of antacid taken separately from the H_2-antagonist should reduce the impact of this interaction, and there are some data to suggest that absorption is not as greatly affected with concomitant longer-term use.

1. Gugler R, Allgayer H. Effects of antacids on the clinical pharmacokinetics of drugs: an update. *Clin Pharmacokinet* 1990; **18**: 210–19.

Antifungals. *Itraconazole* increased the area under the concentration-time curve of cimetidine, and reduced the total plasma clearance and renal tubular secretory clearance of cimetidine in a pharmacokinetic study in 8 healthy subjects.[1] The authors proposed that this was due to inhibition of P-glycoprotein-mediated renal tubular secretion.

1. Karyekar CS, *et al.* Renal interaction between itraconazole and cimetidine. *J Clin Pharmacol* 2004; **44**: 919–27.

Antihistamines. Cimetidine may increase the serum concentration of hydroxyzine, see p. 631.2.

Antimuscarinics. The antimuscarinic *propantheline* delays gastric emptying and reduces intestinal motility and has been reported to reduce the bioavailability of cimetidine.[1]

1. Kanto J, *et al.* The effect of metoclopramide and propantheline on the gastrointestinal absorption of cimetidine. *Br J Clin Pharmacol* 1981; **11**: 629–31.

Histamine. For the effect of cimetidine on histamine given exogenously, see p. 2525.3.

Melatonin. For the effect of cimetidine on melatonin, see p. 2552.2.

Probenecid. Probenecid reduced the clearance of both cimetidine[1] and famotidine[2] in small studies in healthy subjects. It was suggested that probenecid inhibited renal tubular secretion, although it was felt that the interaction was unlikely to be clinically significant.[1]

1. Giscion LG, *et al.* The effect of probenecid on the renal elimination of cimetidine. *Clin Pharmacol Ther* 1989; **45**: 444–52.
2. Inotsume N, *et al.* The inhibitory effect of probenecid on renal excretion of famotidine in young, healthy volunteers. *J Clin Pharmacol* 1990; **30**: 50–6.

Prokinetic drugs. *Metoclopramide* may reduce the bioavailability of cimetidine possibly due to reduction of gastrointestinal transit time.[1-3] A similar interaction has been reported between the prokinetic drug *cisapride* and both cimetidine[4] and ranitidine.[5] The clinical significance of this interaction is questionable since such combinations may be clinically effective, although the use of cisapride is now restricted in many countries. For the effect of cimetidine on cisapride, see p. 1833.1.

5. Rowbotham DJ, *et al.* Effect of single doses of cisapride and ranitidine administered simultaneously on plasma concentrations of cisapride and ranitidine. *Br J Anaesth* 1991; **67**: 302–5.

Sucralfate. Licensed product information for the mucosal protectant sucralfate states that it has been shown to reduce the bioavailability of cimetidine and other H_2-antagonists, presumably due to binding in the gastrointestinal tract. The effect can be avoided by separating doses of the two drugs by 2 hours, but it is not clear whether the interaction has a clinical significance.

Pharmacokinetics

Cimetidine is readily absorbed from the gastrointestinal tract and peak plasma concentrations occur after about an hour when given on an empty stomach; a second peak may be seen after about 3 hours. Food delays the rate and may slightly decrease the extent of absorption, with the peak plasma concentration occurring after about 2 hours.

The bioavailability of cimetidine after oral doses is about 60 to 70%, due to hepatic first-pass metabolism. Cimetidine is widely distributed and has a volume of distribution of about 1 litre/kg and is weakly bound, about 20%, to plasma proteins. The elimination half-life from plasma is about 2 hours and is increased in renal and hepatic impairment. Cimetidine is partially metabolised in the liver to the sulfoxide and to hydroxymethylcimetidine. About 50% of an oral dose, and 75% of an intravenous dose, is excreted unchanged in the urine in 24 hours. After an oral or parenteral dose of 300 mg, blood concentrations remain above that required to provide 80% inhibition of basal gastric acid secretion for 4 to 5 hours. Cimetidine crosses the placental barrier and is distributed into breast milk.

Children. Renal function is limited in the first few months of life and half-lives of 1.1 to 3.7 hours have been reported for cimetidine in neonates;[1-3] less frequent dosing may therefore be required for preterm neonates and those with renal impairment.[1]

In older infants and children maturation of renal function is complete and the clearance of cimetidine is increased compared with that in adults; younger children show higher clearance values than older children.[4]

Pharmacopoeial Preparations

BP 2014: Cimetidine Injection; Cimetidine Oral Solution; Cimetidine Oral Suspension; Cimetidine Tablets;

USP 36: Cimetidine in Sodium Chloride Injection; Cimetidine Injection; Cimetidine Tablets.

Cimetropium Bromide *(rINN)*

Bromuro de cimetropio; Cimetropii Bromidum; Cimetropio, Bromuro de; Cimetropium, Bromure de; DA-3177; Hyoscine-*N*-(cyclopropylmethyl) Bromide; Циметропия бромид.

8-(Cyclopropylmethyl)-6β,7β-epoxy-3α-hydroxy-1αH,5αH-tropanium bromide, (-)-(*S*)-tropate.

$C_{21}H_{28}BrNO_4$=438.4

CAS — 51598-60-8.

ATC — A03BB05.

ATC Vet — QA03BB05.

UNII — 0C7M5WE60Q.

Profile

Cimetropium bromide is a quaternary ammonium antimuscarinic with peripheral effects similar to those of atropine (p. 1312.1). It has been used as an antispasmodic in the treatment of gastrointestinal disorders, in usual doses of 50 mg two or three times daily orally or by rectal suppository. It has also been given intramuscularly or intravenously in usual doses of 5 mg.

Cinitapride *(rINN)*

Cinitaprida; Cinitapridum; Цинитаприд.

4-Amino-*N*-[1-(3-cyclohexen-1'-ylmethyl)-4-piperidyl]-2-ethoxy-5-nitrobenzamide.

$C_{21}H_{30}N_4O_4$=402.5

CAS — 66564-14-5.

UNII — R8I9712L24.

Profile

Cinitapride is a substituted benzamide used for its prokinetic properties. It is given as the acid tartrate in oral doses of 1 mg three times daily before meals in the management of gastroparesis and gastro-oesophageal reflux disease (p. 1807.2).

Preparations

Cisapride *(BAN, USAN, rINN)*

Cisaprid; Cisaprida; Cisapridas; Cisapride monohydraté; Cisapridum; Cisapridum monohydricum; Ciszapryd; Cyzapryd jednowodny; R-51619; Sisapridi; Цизаприд.

cis-4-Amino-5-chloro-*N*-[1-[3-(4-fluorophenoxy)propyl]-3-methoxy-4-piperidyl]-2-methoxybenzamide monohydrate.

$C_{23}H_{29}ClFN_3O_4.H_2O$=484.0

CAS — 81098-60-4 (anhydrous cisapride).

ATC — A03FA02.

ATC Vet — QA03FA02.

UNII — UVL329170W (cisapride); VZV0A4I38W (cisapride monohydrate).

Pharmacopoeias. *US.*

USP 36: (Cisapride). A white or almost white powder. Practically insoluble in water; sparingly soluble in methyl alcohol; soluble in dichloromethane; freely soluble in dimethylformamide. Protect from light.

Cisapride Tartrate *(BANM, rINNM)*

Cisaprida, tartrato de; Cisapride, Tartrate de; Cisapridi Tartras; Cisaprido tartratas; Cisaprid-tartarát; Cisapridtartrat; Cisza-

prid-tartarát; Sisapriditartraatti; Tartrato de cisaprida; Цизаприда Тартрат.

$C_{27}H_{35}ClFN_3O_{10}$=616.0

Uses and Administration

Cisapride is a substituted benzamide used for its prokinetic properties. It stimulates gastrointestinal motility, probably by increasing the release of acetylcholine in the gut wall at the level of the myenteric plexus, increases the resting tone of the lower oesophageal sphincter, and increases the amplitude of lower oesophageal contractions. Gastric emptying is accelerated and the mouth-to-caecum transit time is reduced. Colonic peristalsis is also increased which decreases colonic transit time. Cisapride apparently lacks antidopaminergic effects (unlike metoclopramide, p. 1862.2, to which it is chemically related) or direct parasympathomimetic activity and it does not affect prolactin release or gastric secretion. It is reported to be an agonist at serotonin-4 (5-HT_4) receptors.

Cisapride has been used mainly in the treatment of gastro-oesophageal reflux disease (p. 1807.2), in disorders associated with decreased gastric motility (p. 1805.2), and in non-ulcer dyspepsia. However, as mentioned under Effects on the Heart, below, its use is severely restricted by its propensity to cause cardiac arrhythmias, and it has been withdrawn completely in many countries, including the UK.

Cisapride is given as the monohydrate, but doses are calculated in terms of the anhydrous substance. Cisapride monohydrate 10.39 mg is equivalent to about 10 mg of anhydrous cisapride. It is taken orally 15 to 30 minutes before a meal and at bedtime, if necessary. Where still licensed, a usual oral dose is 5 to 10 mg three to four times daily up to a maximum daily dose of 40 mg. For discussion of dosage and use in children, see below.

Doses of cisapride should be reduced in patients with hepatic or renal impairment (see below).

Administration in children. Where still licensed, neonates, infants, and children have been given cisapride 200 micrograms/kg orally three or four times daily up to a maximum daily dose of 800 micrograms/kg. However, there are particular safety concerns over the use of cisapride in children because of the risk of cardiac arrhythmias (see Effects on the Heart, below). Special care is needed in neonates and cisapride is contra-indicated in premature neonates for 3 months after birth due to the increased risk of QT interval prolongation in this patient group.

Its efficacy has also been questioned and a systematic review[1] of the use of cisapride in children found no clear evidence that cisapride had a statistically significant effect in reducing symptoms of gastro-oesophageal reflux disease compared with placebo.

1. MacLennan S, *et al.* Cisapride treatment for gastro-oesophageal reflux in children. Available in The Cochrane Database of Systematic Reviews: Issue 4. Chichester: John Wiley; 2010 (accessed 15/07/10).

Administration in hepatic or renal impairment. In patients with hepatic impairment the dose of cisapride should be half the usual dose, followed by adjustment depending on clinical response. In cases where renal impairment is not considered to contra-indicate the use of cisapride, a similar reduction in dose has been recommended.

Adverse Effects

The most commonly reported adverse effects with cisapride are gastrointestinal disturbances including abdominal cramps, borborygmi, and diarrhoea. Headache and lightheadedness may also occur. Hypersensitivity (including rash, pruritus, and bronchospasm), convulsions, extrapyramidal effects, and increased urinary frequency, have occasionally been reported. Cases of arrhythmia, including ventricular tachycardia, ventricular fibrillation, torsade de pointes, and QT interval prolongation have occurred rarely; fatalities have resulted, and have led to severe restrictions on its use (see Effects on the Heart, below). There have been a few cases of disturbances in liver function among patients receiving cisapride.

Incidence of adverse effects. A comparison of data from prescription-event monitoring in over 13 000 recipients of cisapride and from a further 9726 recipients involved in a controlled study showed that diarrhoea, in about 2 to 4% of patients, was the commonest adverse effect reported.[1] Other relatively common adverse effects were headache, abdominal pain, nausea and vomiting, and constipation, all in around 1 to 1.5% of patients. There were 46 reports in the prescription-event monitoring data of increased urinary frequency (plus a further 20 among the controlled study patients), and 5 reports of arrhythmias.

1. Wager E, *et al.* A comparison of two cohort studies evaluating the safety of cisapride: prescription-event monitoring and a large phase IV study. *Eur J Clin Pharmacol* 1997; 52: 87–94.

Effects on the heart. Seven reports[1] of cardiac effects associated with cisapride were submitted to the WHO Programme for International Drug Monitoring between 1989 and 1991. They included palpitations in 4, tachycardia and hypertension in 1, and extrasystole in 2. Subsequent reports implicated cisapride in the development of prolonged QT interval and torsade de pointes or ventricular fibrillation or both.[2,3] By December 1999 the FDA had received 341 reports of heart rhythm abnormalities associated with cisapride use, including 80 reports of deaths. Most patients were either receiving other drugs known to impair cisapride metabolism (see Interactions, below) or had other factors predisposing to arrhythmias. In the light of earlier reports of cardiac effects and of evidence for a direct effect of cisapride on the heart at therapeutic concentrations, in 1998 the UK CSM **contra-indicated**[2] the use of cisapride in patients receiving drugs that could inhibit cisapride metabolism or that prolong the QT interval, as well as in patients with a history of QT interval prolongation, ventricular arrhythmia, or torsade de pointes, or other risk factors for arrhythmia (see Precautions, below). Neonates[4] (especially of low gestational age[5]) are vulnerable to cisapride-induced QT interval prolongation, and the CSM also specifically contra-indicated use in premature neonates[2] and noted that there were insufficient data to support use in children up to the age of 12. Other studies have also noted a prolongation of QT interval in children.[6,7] However, some commentators have questioned the general contra-indication in prematurity,[8] and one retrospective analysis estimated the rate of serious adverse events such as arrhythmia in premature newborns to be less than 1 in 11 000, excluding those cases related to concurrent treatment with a contra-indicated drug or to overdose.[9] Conversely, others emphasise the lack of objective evidence of benefit for cisapride in most paediatric indications.[10] The European Society of Paediatric Gastroenterology, Hepatology and Nutrition has published recommendations on the use of cisapride in paediatric gastro-oesophageal reflux disease,[11] including that the total daily dose of cisapride should rarely exceed 800 micrograms/kg, and that ECG monitoring should be performed before and after 3 days of treatment in certain groups such as premature infants.

The use of cisapride has also been the subject of warnings and restrictions in other countries. In the USA, prescribing information was amended in January 2000 to recommend that all patients should receive an ECG before beginning cisapride therapy and extending the contra-indications to use; the drug was subsequently **withdrawn** from general supply, remaining available only in severely restricted cases. In July 2000 cisapride was also withdrawn completely from the UK market.[12] In Europe, the European Commission decided that cisapride-containing products could be maintained with restricted indications; all patients given cisapride should be enrolled in either a study or registry of clinical safety, or a study of clinical efficacy.[13] Despite a withdrawal of cisapride from general supply, a retrospective cohort study in South Korea found that it was still in use there up to 2 years later; in many instances cisapride had been given with contra-indicated drugs, which was associated with an increase in the risk of all-cause mortality.[14]

Effects on the respiratory system. Chest tightness, wheezing, and a fall in peak flow rate occurred in a patient with severe brittle asthma after taking cisapride 10 mg.[1] Four other cases of bronchospasm associated with cisapride were discussed in a subsequent report;[2] in 2 of these cases symptoms resolved on withdrawal and recurred on rechallenge.

2. Pillans P. Bronchospasm associated with cisapride. *BMJ* 1995; 311: 14.

Effects on the urinary tract. There had been 12 cases of urinary disturbances associated with use of cisapride[1] reported to the Australian Adverse Drug Reactions Advisory Committee between March 1991 and July 1993. Five reports were of urinary incontinence, 8 involved frequency, and individual reports involved cystitis, hesitancy, and urinary retention. The majority of the cases involved women, and most patients were elderly.

1. Boyd IW, Rohan AP. Urinary disorders associated with cisapride. *Med J Aust* 1994; 160: 579–80.

Precautions

Cisapride should not be used when stimulation of muscular contractions might adversely affect gastrointestinal conditions as in gastrointestinal haemorrhage, obstruction, perforation, or immediately after surgery.

Cisapride is **contra-indicated** in the following patients:

- those receiving potent inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as macrolide antibacterials, azole antifungals, HIV-protease inhibitors, or nefazodone (see also Interactions, below)
- those taking other drugs that predispose to electrolyte disturbances or that prolong the QT interval
- those with a personal or family history of QT interval prolongation
- those with a history of ventricular arrhythmia or torsade de pointes

Furthermore, it should not be given to those with other risk factors for arrhythmia including:

- clinically significant heart disease
- uncorrected electrolyte disturbances (particularly hypokalaemia and hypomagnesaemia)
- renal failure
- respiratory failure

Use is also contra-indicated in premature infants for up to 3 months after birth.

Cisapride should be used with caution and in reduced doses in patients with hepatic or renal impairment. All patients should have their ECG, serum electrolytes, and renal function monitored before and during treatment.

Care should be taken not to exceed the recommended dose.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving cisapride, and the American Academy of Pediatrics considered[1] that it was therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*: 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 07/05/04)

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies cisapride as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 06/10/11)

Interactions

Cisapride is metabolised by the cytochrome P450 isoenzyme CYP3A4. Use with drugs that significantly inhibit this enzyme is contra-indicated as it may result in increased plasma concentrations of cisapride and hence a greater risk of QT interval prolongation and ventricular arrhythmias. Examples of such drugs include the azole antifungals ketoconazole, fluconazole, itraconazole, and miconazole; the macrolide antibacterials troleandomycin, azithromycin, erythromycin, and clarithromycin; the NNRTIs delavirdine and efavirenz; and the HIV-protease inhibitors. Nefazodone may interact similarly.

Cisapride should not be used in patients receiving other medication known to prolong the QT interval, including quinine or halofantrine, terfenadine, astemizole, certain antiarrhythmics such as amiodarone or quinidine, some antidepressants such as amitriptyline, phenothiazine antipsychotics, and sertindole. Cimetidine may enhance cisapride bioavailability. Grapefruit juice also increases the bioavailability of cisapride and they should not be taken together. In addition, drugs such as potassium-sparing diuretics, or insulin in acute settings, can result in altered electrolyte balance, and use with cisapride may also increase the risk of arrhythmias.

Antimuscarinics and possibly opioid analgesics may antagonise the gastrointestinal effects of cisapride. Because

cisapride increases intestinal motility it may affect the absorption of other drugs, either diminishing absorption from the stomach or enhancing absorption from the small intestine. Prothrombin times may be increased in some patients receiving oral anticoagulants, and the effects of alcohol and some other CNS depressants may be enhanced.

Cardiovascular drugs. Near syncope and a prolonged QT interval occurred in a patient taking cisapride and *diltiazem*.[1] Diltiazem may have inhibited the metabolism of cisapride. For mention of cisapride possibly reducing the absorption of *digoxin*, see p. 1357.3.

1. Thomas AR, *et al.* Prolongation of the QT interval related to cisapride-diltiazem interaction. *Pharmacotherapy* 1998; 18: 381–5.

H_2-antagonists. *Cimetidine*[1] but not *ranitidine*[2] has been reported to enhance the bioavailability of oral cisapride, possibly by inhibition of cisapride metabolism (cimetidine is an inhibitor of the cytochrome P450 isoenzyme CYP3A4). Cisapride conversely increases the rate of absorption and decreases the oral bioavailability of both cimetidine[1] and ranitidine (see Prokinetic Drugs, p. 1831.1).

Pharmacokinetics

Cisapride is readily absorbed from the gastrointestinal tract and peak plasma concentrations occur 1 to 2 hours after an oral dose. It undergoes extensive first-pass metabolism in the liver and gut wall, resulting in an absolute bioavailability of 35 to 40%. The main metabolic pathways are oxidative *N*-dealkylation by the cytochrome P450 isoenzyme CYP3A4, producing the major metabolite norcisapride, and aromatic hydroxylation. More than 90% of a dose is excreted as metabolites in the urine and faeces in about equal amounts. A small amount is distributed into breast milk. The elimination half-life is about 10 hours. Cisapride is about 98% bound to plasma proteins.

UNII — H9490V5216.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Clebopride Malate). A white or almost white, crystalline powder. Sparingly soluble in water and in methyl alcohol; slightly soluble in dehydrated alcohol; practically insoluble in dichloromethane. The pH of a 1% solution in water is 3.8 to 4.2. Protect from light.

Profile

Clebopride is a substituted benzamide similar to metoclopramide (p. 1862.2), that is used for its antiemetic and prokinetic actions in nausea and vomiting (p. 1811.3) and various other gastrointestinal disorders. It is given as the malate but doses are expressed in terms of the base. Clebopride malate 679 micrograms is equivalent to about 500 micrograms of clebopride.

Clebopride malate is given in a usual oral dose equivalent to clebopride 500 micrograms three times daily before meals or 0.5 to 1 mg by intramuscular or intravenous injection for acute symptoms. For dosage in children see below.

Administration in children. Adolescents aged 12 to 20 years may be given clebopride malate orally in a dose equivalent to clebopride 250 micrograms three times daily. An oral dose of 15 to 20 micrograms/kg daily in 3 divided doses may be used for children under 12; the following doses have been recommended:

- 1 to 4 years: 50 micrograms 3 times daily
- 4 to 8 years: 100 micrograms 3 times daily
- 8 to 10 years: 150 micrograms 3 times daily
- 10 to 12 years: 200 micrograms 3 times daily

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Gastridin; *China*: Si Wei Si (思清斯); Wei Heng (维恒); *Indon.*: Clast; *Ital.*: Cleboril; Motilex; *Mex.*: Eborix; *Port.*: Clebofex; Clebutec; *Spain*: Cleboril.

Multi-ingredient Preparations. *Arg.*: Eudon; Gastridin-E; Somasedan; *Spain*: Clanzoflat†; Flatoril.

Clidinium Bromide *(BAN, USAN, rINN)*

Bromuro de clidinio; Clidinii Bromidum; Clidinio, bromuro de; Clidinium, Bromure de; Klidiniumbromid; Klidiniumbromidi; Klidinyum Bromür; Ro-2-3773; Клидиния бромид.

3-Benziloyloxy-1-methylquinuclidinium bromide.

$C_{22}H_{26}BrNO_3$=432.4

CAS — 7020-55-5 (clidinium); 3485-62-9 (clidinium bromide).

UNII — 91ZQW5JF1Z.

Pharmacopoeias. In *US*.

USP 36: (Clidinium Bromide). A white or nearly white, practically odourless, crystalline powder. Soluble in water and in alcohol; slightly soluble in ether and in benzene. Store in airtight containers. Protect from light.

Profile

Clidinium bromide is a quaternary ammonium antimuscarinic with peripheral effects similar to those of atropine (p. 1312.1). It has been used alone or more often with chlordiazepoxide in the symptomatic treatment of peptic ulcer disease and other gastrointestinal disorders.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Thai.*: Chlordibrax.

Multi-ingredient Preparations. *Arg.*: Libraxin; *Canad.*: Apo-Chlorax; Librax; Pro Chlorax†; *Chile*: Gastrolen; Lerogin; Libraxin; Tensoliv; *Fin.*: Librax; *Fr.*: Librax; *Gr.*: Distedon; Librax; *Hong Kong*: Librax; *India*: Acirex; Alspas Forte; Cebrex Forte; Cebrex; Cibis; Clidox; Colinorm; Cypa; Dorpep; Equirex; IBS; Librax; Librospas; Neurospas-CD; Normaxin-RT; Normaxin; Orlidox-D; Orlidox; Spasrax; *Indon.*: Braxidin; Cliad; Klidibrax; Librax; Melidox; Renagas; *Israel*: Nirvaxal†; *Ital.*: Librax; *Malaysia*: Liblan; *Port.*: Librax; *S.Afr.*: Librax†; *Singapore*: Apo-Chlorax; Chlobax; Librax†; Medocalum†; Syntabrax; *Switz.*: Librax; Librocol; *Thai.*: Cebarax†; Dirax; Kenspa; Librax; Licon; Modurax; Pobrax; Radibrax; Tumax; Utorax; *Turk.*: Klipaks; Librax; *USA*: Clindex; Librax; *Venez.*: Librax.

Pharmacopoeial Preparations

USP 36: Chlordiazepoxide Hydrochloride and Clidinium Bromide Capsules.

Colocynth

Bitter Apple; Bitter Cucumber; Colocinto; Colocynth Pulp; Colocynthis; Coloquinte; Coloquintidas; Koloquinthen; Колоцинт.

UNII — Z70W98921V (Citrullus colocynthis); 0E49E3V9U6 (Citrullus colocynthis fruit); 23H32AOH17 (Citrullus colocynthis fruit pulp).

NOTE. The synonym Bitter Apple has also been applied to the fruits of *Solanum incanum*.

Pharmacopoeias. *Br.* includes Citrullus Colocynthis Fruit for Homoeopathic Preparations.

BP 2014: (Citrullus Colocynthis Fruit for Homoeopathic Preparations). The dried, peeled fruits of *Citrullus colocynthis* with the seeds removed.

Profile

Colocynth is the dried pulp of the fruit of *Citrullus colocynthis* (Cucurbitaceae). It has a drastic purgative and irritant action and has been superseded by less toxic laxatives.

Homoeopathy

Colocynth has been used in homoeopathic medicines under the following names: Colocynthis; Coloc.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Neth.*: Diarrheel S.

Homoeopathic Preparations. *Austral.*: Colic Relief; IBS Eze; Teething Relief; *Austria*: Diluplex; *Canad.*: Berberis-Homaccord†; Carduus Plex†; Cocyntal; Col 138†; Colic Comp-Drops 8 Uri-Tract†; Diarrhea; Formula ES 211; Formula FV 213; Hylands Formula MC; Hylands Kinder-CL†; Hylands Menstrual Cramps†; Kid's Colic Spascupreel; *Chile*: Lumboplex; *Cz.*: Hepeel; *Fr.*: Aloe Compose; Berberis Complexe No 83; Formica Rufa Compose; Gelsemium Complexe No 70; L 107; Ranunculus Complexe No 79; *Ger.*: Araniforce arthro; Carminativum Hevert; Chole-cyl L Ho-Len-Complex; Colintest-Gastreu; Cranio-cyl Ho-Len-Complex; Diluplex; Dolo-Injektopas; Entero-Gastreu S R4; gastri-loges N; Gastriselect N; Gelsemium Comp; Gelsemium Comp; HanoHepan; Intercostal-Gastreu; Lithias-cyl L Ho-Len-Complex; Lowe-Komplex Nr 6; Magen-Darm-Entoxin N; Neuralgie-Gastreu R70; Neuri-cyl N Ho-Len-Complex; Nuxal H; Pancreas-Gastreu N; Pascofemin spasmo; Pascosabal; Spascupreel; Spasmo-Bomaleb†; Spasmoject F; *Hung.*: Hepeel; Spascupreel; *Neth.*: Apo-STOM; Colocynthis-Homaccord; Entero-Gastreu R4; Gastrifleur; Homeocare Digesto; Kind 0-3 Cinababy; Nux Vomica-Homaccord; Spascupreel H; Spiroflor; *Rus.*: Menalgin (Менальгин); *Switz.*: Diarrheel S; Gastronol; Hepeel; *Ukr.*: Enterocind (Энтероцинд).

Crofelemer *(USAN)*

SP-303.

CAS — 148465-45-6.

Profile

Crofelemer is a proanthocyanidin from the bark latex of the tree *Croton lechleri* that acts locally on the intestinal lumen to normalise flow of chloride ions and water into the gastrointestinal tract. It is used in the management of non-infectious diarrhoea in patients with HIV and AIDS on antiretroviral therapy (see HIV-associated Wasting, p. 959.1). A dose of 125 mg is given orally twice daily.

Crofelemer is also under investigation in the treatment of other forms of secretory diarrhoea and diarrhoea-predominant irritable bowel syndrome.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *USA*: Fulyzaq.

Dantron *(BAN, rINN)*

Antrapurol; Chrysazin; Danthron; Dantrón; Dantrone; Dantroni; Dantronum; Dianthon; Dioxyanthrachinonum; Дантрон.

1,8-Dihydroxyanthraquinone.

$C_{14}H_8O_4$=240.2

CAS — 117-10-2.

ATC — A06AB03.

ATC Vet — QA06AB03.
UNII — Z4XE6I8F3V.

NOTE. Compounded preparations of dantron may be represented by the following names:
- Co-danthramer *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of dantron and poloxamer respectively
- Co-danthrusate (*BAN*)—dantron 5 parts and docusate sodium 6 parts (w/w).

Pharmacopoeias. In *Br.*

BP 2014: (Dantron). An orange, odourless or almost odourless, crystalline powder. Practically insoluble in water; very slightly soluble in alcohol; soluble in chloroform; slightly soluble in ether; dissolves in solutions of alkali hydroxides.

Uses and Administration

Dantron is an anthraquinone stimulant laxative but, unlike senna (p. 1885.1), it is not a glycoside. It is given orally to treat constipation (p. 1804.3) and is effective within 6 to 12 hours. However, because of concern over *rodent* carcinogenicity it has been withdrawn in some countries, and its use restricted in others. In the UK, it may be used only in terminally ill patients.

Dantron is given in doses of 25 to 75 mg when given with poloxamer 188 (p. 2202.1) as co-danthramer, and in doses of 50 to 150 mg when given with docusate sodium (p. 1836.2) as co-danthrusate. Doses are usually given at bedtime. For doses in children, see below.

Administration in children. In the UK, the use of dantron is restricted to the treatment of constipation in terminally ill patients; children under 12 years have been given dantron 12.5 to 25 mg orally as co-danthramer or 50 mg as co-danthrusate. Doses are usually given at bedtime. Children aged 12 years and over may be treated with the adult dose (see Uses and Administration, above).

The *BNFC* recommends similar doses to these, but restricts the use of co-danthramer to children aged 2 years and over, and the use of co-danthrusate to those aged 6 years and over.

Dantron should not be used in infants wearing nappies (diapers) as it may cause discoloration and superficial sloughing of the skin.

Adverse Effects and Precautions

As for Senna, p. 1885.3. Dantron may colour the urine pink or red. Discoloration and superficial sloughing of perianal skin can occur after prolonged contact, therefore dantron should not be used in infants wearing nappies (diapers) and should be used with caution in incontinent patients. The mucosa of the large intestine may be discoloured with prolonged use or high dosage.

In *rodents*, dantron has been associated with the development of intestinal and liver tumours. Consequently, its use has been restricted, see Uses and Administration, above.

References to adverse effects occurring with dantron-containing laxatives include individual cases of leucopenia with liver damage,[1] greyish-blue skin discoloration,[2] and orange vaginal discharge.[3] There has also been a report of intestinal sarcoma in an 18-year-old girl with a history of prolonged use of a dantron-containing laxative.[4] In May 2000 the UK CSM restricted the use of dantron to terminally ill patients on the grounds that pre-clinical evidence had increased and dantron was now established as a potential human carcinogen.[5]

5. CSM/MCA. Dantron restricted to constipation in the terminally ill. *Current Problems* 2000; 26: 4. Also available at: http://www.mhra.gov.uk/home/idcpig?idcService=GET_FILE&dDocName=CON0074626&RevisionSelectionMethod=LatestReleased (accessed 08/11/06)

Breast feeding. The American Academy of Pediatrics[1] state that, although usually compatible with breast feeding, use of dantron by breast-feeding mothers has been reported to cause increased bowel activity in the infant.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*: 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 08/11/06)

Pharmacokinetics

Dantron is metabolised by bacteria in the colon. Dantron or its metabolites are absorbed from the gastrointestinal tract, as indicated by discoloration of urine in some patients. Dantron or its metabolites are excreted in the faeces and the urine, and also in other secretions including breast milk.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Chile:* Modane; *Irl.:* Ailax†; Codalax; Cotron; *Mex.:* Modaton; *NZ:* Pinorax; *UK:* Capsuvac; Codalax; Danlax; Normax.

Pharmacopoeial Preparations
BP 2014: Co-danthrusate Capsules.

Dexlansoprazole *(USAN, rINN)*

Dexlansoprazol; Dexlansoprazolum; *R*-lansoprazole; T-168390; TAK-390; Декспансопразол.
(+)-2-{(*R*)-[[3-Methyl-4-(2,2,2-trifluoroethoxy)pyridin-2-yl]methyl]sulfinyl}-1*H*-benzamidazole.
$C_{16}H_{14}F_3N_3O_2S$=369.4
CAS — 138530-94-6.
UNII — UYE4T5I70X (dexlansoprazole); HS2S9VK3NH (dexlansoprazole sesquihydrate).

Uses and Administration

Dexlansoprazole, the *R*-isomer of the proton pump inhibitor lansoprazole (p. 1851.3), is given for the management of severe or symptomatic gastro-oesophageal reflux disease.

An oral dose of dexlansoprazole 60 mg is given once daily for up to 8 weeks to heal erosive oesophagitis. Once erosions have healed, 30 mg once daily is given for maintenance. For symptomatic non-erosive gastro-oesophageal reflux disease, 30 mg is given once daily for 4 weeks.

For doses in hepatic impairment, see below.

3. Anonymous. Dexlansoprazole (Kapidex) for GERD and erosive esophagitis. *Med Lett Drugs Ther* 2009; 51: 21–2.
4. Abel C, *et al.* Dexlansoprazole in the treatment of esophagitis and gastroesophageal reflux disease. *Ann Pharmacother* 2010; 44: 871–7.
5. Croxtall JD, Scott LJ. Dexlansoprazole modified release: in erosive oesophagitis and non-erosive reflux disease. *Drugs* 2010; 70: 1593–1601.

Administration. Dexlansoprazole is given orally as capsules containing enteric-coated granules, which should be swallowed whole. Alternatively, capsules can be opened and the granules sprinkled on apple sauce before swallowing without chewing.

Administration in hepatic impairment. No dosage adjustment of dexlansoprazole is considered necessary for patients with mild hepatic impairment (Child-Pugh class A). For patients with moderate hepatic impairment (Child-Pugh class B), a daily oral dose of 30 mg should not be exceeded. There are limited data on the use of dexlansoprazole in patients with severe hepatic impairment (Child-Pugh class C).

Adverse Effects and Precautions

As for Omeprazole, p. 1868.1.

Interactions

As for Omeprazole, p. 1870.3.

Pharmacokinetics

After an oral dose of a delayed-release formulation of dexlansoprazole, peak plasma concentrations occur 1 to 2 hours after dosing, followed by a second peak within 4 to 5 hours. Plasma protein binding varies from about 96 to 99%. Dexlansoprazole is extensively metabolised in the liver to inactive metabolites. Oxidative metabolites are formed by cytochrome P450 isoenzymes CYP2C19 and CYP3A4. Dexlansoprazole has a half-life of about 1 to 2 hours. Metabolites are excreted in the urine and faeces.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Canad.:* Dexilant; *Jpn:* Kapidex†; *USA:* Dexilant.

Dicycloverine Hydrochloride

(BANM, rINNM)

Cloridrato de Dicicloverina; Diciclovérine, hidrocloruro de; Dicikloverin-hidroklorid; Dicikloverino hidrochloridas; Dicyclomine Hydrochloride; Dicyclovérine; Chlorhydrate de Dicycloverinhydrochlorid; Dicycloverini Hydrochloridum; Dicykloverin-hydrochlorid; Dicykloverinhydroklorid; Disyklo-verïinihydrokloridi; Hidrocloruro de diciclóverina; Дицикловерина Гидрохлорид.
2-Diethylaminoethyl bicyclohexyl-1-carboxylate hydrochloride.
$C_{19}H_{35}NO_2$,HCl=346.0
CAS — 77-19-0 (dicycloverine); 67-92-5 (dicycloverine hydrochloride).
ATC — A03AA07.
ATC Vet — QA03AA07.
UNII — CQ903KQA31.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Dicycloverine Hydrochloride). A white or almost white, crystalline powder. It shows polymorphism. Soluble in water; freely soluble in alcohol and in dichloromethane. A 1% solution in water has a pH of 5.0 to 5.5.

USP 36: (Dicyclomine Hydrochloride). A fine white practically odourless, crystalline powder. Soluble 1 in 13 of water, 1 in 5 of alcohol, 1 in 2 of chloroform and of glacial acetic acid, and 1 in 770 of ether. pH of a 1% solution in water is between 5.0 and 5.5.

Uses and Administration

Dicycloverine hydrochloride is a tertiary amine antimuscarinic with effects similar to but weaker than those of atropine (p. 1312.1); it also has a direct antispasmodic action.

Dicycloverine is used in gastrointestinal spasm particularly that associated with irritable bowel syndrome. An oral dose of 10 to 20 mg of dicycloverine hydrochloride is given 3 times daily; in the USA, up to 40 mg four times daily may be given where adverse effects permit.

Dicycloverine hydrochloride may be given intramuscularly in doses of 10 to 20 mg 4 times daily to patients in whom oral therapy is temporarily impractical, but should not be used for longer than 1 to 2 days.

For doses in children, see below.

Administration in children. Dicycloverine hydrochloride is used in children for symptomatic relief of gastrointestinal smooth muscle spasm. The following oral doses are given according to age:
- 6 months to 2 years: 5 to 10 mg three or four times daily, 15 minutes before meals; maximum daily dose of 40 mg
- 2 to 12 years: 10 mg three times daily
- over 12 years: adult doses may be given, see above

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p. 1312.1 and p. 1312.2. Dicycloverine hydrochloride should not be given to infants younger than 6 months of age.

Dicycloverine has been reported to suppress lactation. Inadvertent intravenous administration has resulted in thrombosis, thrombophlebitis, and injection site reactions including pain, oedema, skin colour changes, and reflex sympathetic dystrophy syndrome.

Dicycloverine should be used with caution in patients with hepatic or renal impairment; licensed product information states that there is a lack of data in such patients.

Apnoea. Reports[1-3] of severe apnoea in infants aged 5 to 10 weeks associated with the use of dicycloverine.

1. Williams J, Watkin-Jones R. Dicyclomine: worrying symptoms associated with its use in some small babies. *BMJ* 1984; 288: 901.
2. Edwards PDL. Dicyclomine in babies. *BMJ* 1984; 288: 1230.
3. Spoudeas H, Shribman S. Dicyclomine in babies. *BMJ* 1984; 288: 1230.

Pregnancy. For a review of the risks to the fetus of antiemetic therapy during pregnancy, with particular reference to *Debendox* (*Bendectin*: dicycloverine with doxylamine and pyridoxine), see under Antihistamines on p. 614.2.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

Pharmacokinetics

Dicycloverine is rapidly absorbed after oral dosing with peak plasma concentrations occurring within 1 to 1.5 hours. The bioavailability after intramuscular injection is greater than that after oral dosing. Dicycloverine is excreted mainly in the urine (nearly 80% of a dose), with a small amount in the faeces (about 8%). The mean elimination half-life for the first 9 hours after a single dose is about 1.8 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.:* Babypasmil; *Braz.:* Bentyl; *Canad.:* Bentylol; Formulex; Lomine†; Protylol; *Hong Kong:* Cyclomine†; Dicymine; Uni-Cycolact†; *India:* Centwin; Coligon;

Pharmacopoeial Preparations
BP 2014: Dicycloverine Oral Solution; Dicycloverine Tablets;
USP 36: Dicyclomine Hydrochloride Capsules; Dicyclomine Hydrochloride Injection; Dicyclomine Hydrochloride Syrup; Dicyclomine Hydrochloride Tablets.

Difemerine Hydrochloride *(rINNM)*

Difemerina, hidrocloruro de; Difémérine, Chlorhydrate de; Difemerini Hydrochloridum; Hidrocloruro de difemerina; UP-57; Дифемерина Гидрохлорид.
2-Dimethylamino-1,1-dimethylethyl benzilate hydrochloride.
$C_{20}H_{25}NO_3$,HCl=363.9
CAS — 80387-96-8 (difemerine); 70280-88-5 (difemerine hydrochloride).
ATC — A03AA09.
ATC Vet — QA03AA09.
UNII — 00JM91Q28F.

Profile

Difemerine hydrochloride is an antimuscarinic with effects similar to those of atropine (p. 1312.1) and was used in the symptomatic treatment of visceral spasms.

Difenidol Hydrochloride *(BANM, rINNM)*

Difénidol, Chlorhydrate de; Difenidol, hidrocloruro de; Difenidoli Hydrochloridum; Diphenidol Hydrochloride (USAN); Hidrocloruro de difenidol; SKF-478 (difenidol); SKF-478-A; SKF-478-J (difenidol embonate); Дифенидола Гидрохлорид.
1,1-Diphenyl-4-piperidinobutan-1-ol hydrochloride.
$C_{21}H_{27}NO$,HCl=345.9
CAS — 972-02-1 (difenidol); 3254-89-5 (difenidol hydrochloride); 26363-46-2 (difenidol embonate).
UNII — DG35SXWQ4T.

Pharmacopoeias. In *Chin.* and *Jpn.*

Profile

Difenidol hydrochloride is an antiemetic that probably acts through the chemoreceptor trigger zone. It is claimed to control vertigo by means of a specific effect on the vestibular apparatus. Difenidol also has a weak peripheral antimuscarinic action.

It has been used in the treatment of some forms of nausea and vomiting (p. 1811.3) such as those associated with surgery, radiotherapy, and cancer chemotherapy. It has also been used for the symptomatic treatment of vertigo (p. 612.3), nausea and vomiting due to Ménière's disease (p. 611.2), and other labyrinthine disturbances.

It has been given in oral doses equivalent to 25 to 50 mg of difenidol every 4 hours as required. Difenidol hydrochloride has also been given parenterally.

Preparations

Proprietary Preparations *(details are given in Volume B)*

Single-ingredient Preparations. *Chile*: Vontrol; *Jpn*: Cephadol; *Malaysia*: Cephadol†; *Mex.*: Biomitin; Diphafen; Docita; Hemetiken; Lansenol; Nautrol; Normavom; Serratol; Sons; Vontrol; Voxamine; *Philipp.*: Cephadol†; *Singapore*: Cephadol; *Thai.*: Cephadol†.

UNII — VQZ63K01IW.

Profile

Difenoxin is the principal active metabolite of diphenoxylate (below) and has similar actions and uses. It is given orally as the hydrochloride, but doses are in terms of the base; difenoxin hydrochloride 1.1 mg is equivalent to about 1 mg of difenoxin.

In the treatment of diarrhoea (p. 1805.2), the usual dose in adults is the equivalent of difenoxin 2 mg initially, followed by 1 mg after each loose stool or every 3 to 4 hours as required, up to a maximum of 8 mg daily.

Preparations of difenoxin usually contain subclinical amounts of atropine sulfate in an attempt to discourage abuse.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *USA*: Motofen.

Dihexyverine Hydrochloride *(USAN, rINNM)*

Dihexiverina, hidrocloruro de; Dihexiverine Hydrochloride; Dihexyvérine, Chlorhydrate de; Dihexyverini Hydrochloridum; Hidrocloruro de dihexiverina; JL-1078; Дигексиверина Гидрохлорид.
2-Piperidinoethyl bicyclohexyl-1-carboxylate hydrochloride.
$C_{20}H_{35}NO_2$,HCl=358.0
CAS — 561-77-3 (dihexyverine); 5588-25-0 (dihexyverine hydrochloride).
ATC — A03AA08.
ATC Vet — QA03AA08.
UNII — 336704VYVB.

Profile

Dihexyverine hydrochloride is an antimuscarinic with effects similar to those of atropine (p. 1312.1). It has been given in the symptomatic treatment of gastrointestinal spasm.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Fr.*: Spasmodex.

Dihydroxyaluminum Sodium Carbonate

Aluminium Sodium Carbonate Hydroxide; Carbonato sódico de dihidroxialuminio; Dihidroksialüminyum Sodyum Karbonat; Dihydroksialuminiumnatriumkarbonaatti; Dihydroxialuminiinatrii Carbonas; Dihydroxialuminiumnatriumkarbonat; Dihydroxyaluminium Sodium Carbonate; Дигидрооксиалюминия Натрия Карбонат.
Sodium (carbonato)dihydroxyaluminate(1-).
CH_2AlNaO_5=144.0
CAS — 41342-54-5 (carbaldrate); 12011-77-7 (dihydroxyaluminium sodium carbonate); 16482-55-6 (dihydroxyaluminium sodium carbonate).
ATC — A02AB04.
ATC Vet — QA02AB04.
UNII — 84H8Z9550J.

NOTE. The name Carbaldrate (*rINN*) has been applied to (CH_2AlNaO_5,nH_2O), a form of sodium (carbonato)dihydroxyaluminate(1-) hydrate.

Pharmacopoeias. In *US.*

USP 36: (Dihydroxyaluminum Sodium Carbonate). A fine white odourless powder. It loses not more than 14.5% of its weight on drying. Practically insoluble in water and in organic solvents; soluble in dilute mineral acids with the evolution of carbon dioxide. A 4% suspension in water has a pH of 9.9 to 10.2. Store in airtight containers.

Profile

Dihydroxyaluminum sodium carbonate is an antacid with general properties similar to aluminium hydroxide (p. 1817.2) that is given in oral doses of about 300 to 600 mg.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Austria*: Antacidum†; *Denm.*: Noacid; *Ger.*: Kompensan; *Pol.*: Alugastrin; Gastrinal†; *Port.*: Kompensan; *Switz.*: Kompensan†; *Turk.*: Dank; Kompensan; Seskasid.

USP 36: Dihydroxyaluminum Sodium Carbonate Tablets.

Diisopromine Hydrochloride *(rINNM)*

Diisopromina, hidrocloruro de; Diisopromine, Chlorhydrate de; Diisopromine Hydrochloride; Diisopromini Hydrochloridum; Hidrocloruro de diisopromina; Диизопромина Гидрохлорид.
NN-Di-isopropyl-3,3-diphenylpropylamine hydrochloride.
$C_{21}H_{29}N$,HCl=331.9
CAS — 5966-41-6 (diisopromine); 24358-65-4 (diisopromine hydrochloride).
ATC — A03AX02.
ATC Vet — QA03AX02.
UNII — 9E8EN393AL.

Profile

Diisopromine hydrochloride is an antispasmodic used with sorbitol in various gastrointestinal disorders.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *S.Afr.*: Agofell†.

Diphenoxylate Hydrochloride

(BANM, rINNM)

Difenoksilaattihydrokloridi; Difenoksilat Hidroklorür; Difenoksilato hidroclorídas; Difenoxilát-hidroklorid; Difenoxilathydroklorid; Difenoxilato, hidrocloruro de; Difenoxylát-hydrochlorid; Diphénoxylate, Chlorhydrate de; Diphenoxylathydrochlorid; Diphenoxylati Hydrochloridum; Hidrocloruro de difenoxilato; R-1132; Дифеноксилата Гидрохлорид.
Ethyl 1-(3-cyano-3,3-diphenylpropyl)-4-phenylpiperidine-4-carboxylate hydrochloride.
$C_{30}H_{32}N_2O_2$,HCl=489.1
CAS — 915-30-0 (diphenoxylate); 3810-80-8 (diphenoxylate hydrochloride).
ATC — A07DA01.
ATC Vet — QA07DA01.
UNII — W24OD7YW48.

NOTE. Compounded preparations of diphenoxylate hydrochloride may be represented by the following names:
- Co-phenotrope (*BAN*)—diphenoxylate hydrochloride 100 parts and atropine sulfate 1 part (w/w).

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, and *US.*

Ph. Eur. 8: (Diphenoxylate Hydrochloride). A white or almost white, crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol; freely soluble in dichloromethane. Protect from light.

USP 36: (Diphenoxylate Hydrochloride). A white odourless crystalline powder. Slightly soluble in water and in isopropyl alcohol; sparingly soluble in alcohol and in acetone; freely soluble in chloroform; practically insoluble in ether and in petroleum spirit; soluble in methyl alcohol. A saturated solution in water has a pH of about 3.3.

Uses and Administration

Diphenoxylate hydrochloride is a synthetic derivative of pethidine (p. 121.3) with little or no analgesic activity; it reduces intestinal motility and is used in the symptomatic treatment of acute and chronic diarrhoea (p. 1805.2). It may also be used to reduce the frequency and fluidity of the stools in patients with colostomies or ileostomies.

Preparations of diphenoxylate usually contain subclinical amounts of atropine sulfate in an attempt to discourage abuse; UK preparations are all in the form of co-phenotrope (see NOTE, p. 1835.3).

In **acute diarrhoea** the usual initial dose is 10 mg orally, followed by 5 mg every six hours, later reduced as the diarrhoea is controlled. For doses in children, see below.

Similar initial doses are used for **chronic diarrhoea**, and subsequently reduced as necessary. If clinical improvement is not seen after 10 days of treatment with the maximum daily dose of 20 mg (in adults) further use is unlikely to result in any benefit.

Administration in children. Diphenoxylate hydrochloride can be used in children as an adjunct in the symptomatic treatment of acute diarrhoea, and to reduce the frequency and fluidity of the stools in patients with colostomies or ileostomies. In the UK, it is licensed for children from 4 years of age; recommended oral doses of diphenoxylate hydrochloride (given as co-phenotrope) are:

- 4 to 9 years: 2.5 mg three times daily
- 9 to 12 years: 2.5 mg four times daily
- 12 to 16 years: 5 mg three times daily

While emphasising that antimotility drugs are not recommended for acute diarrhoea in children under 12 years of age, the *BNFC* allows for a dose of 1.25 mg three times daily for children aged 2 to 4 years.

In the USA, diphenoxylate is licensed for children from the age of 2 years and an initial dose of 300 to 400 micrograms/kg (up to an effective maximum of 10 mg) daily in 4 divided doses is suggested for children aged 2 to 12 years.

For the view that antidiarrhoeal drugs should not be used at all in children with acute diarrhoea, see p. 1805.2.

Diarrhoea. Co-phenotrope (see NOTE, p. 1835.3) may be considered as an alternative to loperamide in the management of faecal incontinence in adults, see Diarrhoea, under Loperamide, p. 1854.3.

Substance dependence. Diphenoxylate may be useful[1] in the symptomatic management of diarrhoea associated with opioid withdrawal syndromes (p. 109.2).

1. DOH. *Drug misuse and dependence: guidelines on clinical management.* London: HMSO, 1999. Also available at: http://www.dh.gov.uk/assetRoot/04/07/81/98/04078198.pdf (accessed 18/01/06)

Dependence and Withdrawal

Preparations of diphenoxylate usually contain subclinical amounts of atropine sulfate in an attempt to discourage abuse. Short-term use of diphenoxylate with atropine in the recommended dosage carries a negligible risk of dependence, although prolonged use or use of high doses may produce dependence of the opioid type (see p. 109.1).

Adverse Effects and Treatment

Diphenoxylate is related to the opioid analgesics and its adverse effects and their treatment are similar (p. 110.1), particularly in overdosage. Reported adverse effects include: gastrointestinal effects such as anorexia, nausea and vomiting, abdominal distension or discomfort, paralytic ileus, toxic megacolon, and pancreatitis; nervous system effects such as headache, drowsiness, dizziness, restlessness, euphoria, depression, numbness of the extremities; and hypersensitivity reactions including angioedema, urticaria, pruritus, and swelling of the gums. Signs of overdosage may be delayed and patients should be observed for at least 48 hours. Young children are particularly susceptible to the effects of overdosage.

The presence of subclinical doses of atropine sulfate in preparations containing diphenoxylate may give rise to the adverse effects of atropine in susceptible individuals or in overdosage—see Atropine Sulfate, p. 1312.1.

Precautions

Diphenoxylate hydrochloride should be avoided in patients with jaundice, intestinal obstruction, antibiotic-associated colitis, or diarrhoea associated with enterotoxin-producing bacteria, and should be used with caution in patients with hepatic impairment. It should also be used with caution in young children, in whom response is more variable, and is not generally recommended for use in infants. Patients with inflammatory bowel disease receiving diphenoxylate should be carefully observed for signs of toxic megacolon and diphenoxylate stopped promptly should abdominal distension occur.

Interactions

Because of the structural relationship of diphenoxylate to pethidine (p. 121.3) there is a theoretical risk of hypertensive crisis if diphenoxylate is used with MAOIs. Diphenoxylate may potentiate the effects of other CNS depressants such as alcohol, barbiturates, and some anxiolytics.

Pharmacokinetics

Diphenoxylate hydrochloride is well absorbed from the gastrointestinal tract. It is rapidly and extensively metabolised in the liver, mainly to diphenoxylic acid (difenoxin, p. 1835.2), which has antidiarrhoeal activity; other metabolites include hydroxydiphenoxylic acid. It is excreted mainly as metabolites and their conjugates in the faeces; lesser amounts are excreted in urine. It may be distributed into breast milk.

Pharmacopoeias. In *US*.

USP 36: (Docusate Potassium). A white amorphous solid with a characteristic odour suggestive of octil alcohol. Sparingly soluble in water; soluble in alcohol and in glycerol; very soluble in petroleum spirit.

Docusate Sodium *(BAN, USAN, rINN)*

Dioctyl Sodium Sulfosuccinate; Dioctyl Sodium Sulphosuccinate; Docusat-Natrium; Docusate Sodique; Docusato de sodio; Docusato sódico; Docusatum Natricum; Dokusaattinatrium; Dokusát sodná sůl; Dokusatnatrium; Dokuzát-nátrium; Dokuzato natrio druska; DSS; Natrii docusas; Sodium Dioctyl Sulphosuccinate; Sodu dokuzynian; Докузат Натрий.

Sodium 1,4-bis(2-ethylhexyl) sulphosuccinate.

$C_{20}H_{37}NaO_7S$=444.6

CAS — 577-11-7.

ATC — A06AA02.

ATC Vet — QA06AA02.

UNII — F05Q2T2JA0.

NOTE. Compounded preparations of docusate sodium may be represented by the following names:

- Co-danthrusate (*BAN*)—docusate sodium 6 parts and dantron 5 parts.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Docusate Sodium). White or almost white, hygroscopic, waxy masses or flakes. Sparingly soluble in water; freely soluble in alcohol and in dichloromethane. Store in airtight containers.

USP 36: (Docusate Sodium). A white wax-like plastic solid with a characteristic odour suggestive of octil alcohol. Slowly soluble 1 in 70 of water; freely soluble in alcohol and in glycerol; very soluble in petroleum spirit.

Uses and Administration

Docusates are given as the calcium or sodium salt and are used as laxatives in the management of constipation (p. 1804.3) or to reduce straining in patients with haemorrhoids (p. 1808.1) or anal fissure. They are also used as adjuncts for bowel evacuation before abdominal radiological procedures. Docusate potassium has also been used.

Docusates are anionic surfactants which have been considered to act primarily by increasing the penetration of fluid into the faeces, but may also have other effects on intestinal fluid secretion, and probably act both as stimulants and as faecal softening agents.

The usual daily oral dose of docusate calcium is 240 mg. Docusate sodium is given in usual oral doses of 50 to 300 mg daily in divided doses, although doses of up to 500 mg daily may be used. (For doses in children, see below.) The effect is usually seen within 12 to 72 hours. When used as an adjunct to abdominal radiological procedures, an oral dose of 400 mg is given with the barium meal. It is also given rectally as an enema in doses of 120 mg; the effect is usually seen in 5 to 20 minutes. Docusate sodium is also used with anthraquinone stimulant laxatives such as casanthranol (p. 1826.1), dantron (p. 1833.3), and senna (p. 1885.1).

Docusate sodium is used for softening wax in the ear as ear drops containing 0.5 or 5%.

Docusate sodium and other docusate salts are widely used as anionic surfactants in pharmaceutical formulations.

Administration in children. Oral docusate sodium is licensed in the UK for the treatment of **chronic constipation** in children aged 6 months and over. More specific dose details are also provided in the *BNFC* as follows:

- 6 months to 2 years: 12.5 mg three times daily
- 2 to 12 years: 12.5 to 25 mg three times daily

Children aged 12 years and over may be given the adult doses for constipation, either orally or rectally (see Uses and Administration, above). Adult formulations are not licensed for use in children under 12 years.

In the USA, children aged 2 to 12 years may be given docusate sodium in doses of 50 to 150 mg daily, either as a single daily dose or in divided doses. Docusate *calcium* is generally only used in the USA for children aged 12 years and over.

Docusate sodium is also used as an **adjunct in abdominal radiological procedures.** UK licensed product information suggests that children may be given an oral dose of 75 mg (30 mL of docusate sodium paediatric solution 12.5 mg per 5 mL) with the barium meal. The *BNFC* recommends that those aged 12 years and over are given the usual adult dose (see above).

Ear wax removal. Cerumen or ear wax is a normal secretion of the ceruminous glands present in the lining of the external auditory canal. Excessive accumulation or impaction of ear wax may decrease hearing acuity, and may also produce dizziness, vertigo, reflex coughing, tinnitus, and otalgia.

Syringing of the external auditory canal with warm water may be used to remove wax from the ear. However, complications include pain, perforation of the ear drum, deafness, dizziness, vertigo, tinnitus, and infection.[1-6] Contra-indications to ear syringing include past perforation, ear infection, previous ear surgery; syringing may be difficult in children.[1,6]

A ceruminolytic agent may be given as ear drops to soften, loosen, or dissolve cerumen instead. They may also be used immediately before syringing, or for several days beforehand.[1-3,5,6] Traditionally, fixed oils such as arachis oil, olive oil, or almond oil have been used.[1] Some still advocate the use of olive oil to reduce the recurrence of impacted cerumen,[3] while others consider it to be ineffective.[5] Other ceruminolytics that have been reported as effective include docusates,[4,7,8] peroxides such as hydrogen peroxide or urea hydrogen peroxide,[4,9] and trolamine polypeptide oleate-condensate,[4,8] although some studies have found these to be

no more effective in removing wax than a saline control.[10,11] Other agents that have been used include acetic acid,[4] choline salicylate,[12] methyltrypsin solution,[5] and an oily solution of paradichlorobenzene and chlorobutanol.[4,12] Glycerol and sodium bicarbonate solution have also been used. However, a comparative study *in vitro* of the efficacy of various wax dispersing agents found the most effective to be water, which had originally been included as a control,[13] and a systematic review[14] concluded that saline or water ear drops seemed to be as good as proprietary agents for the removal of ear wax, although there was a lack of good quality studies on which to base recommendations.

Ear candling is a traditional folk remedy that has been used to remove cerumen, but studies indicate it is ineffective, and may deposit wax in the ear canal or cause burn injuries.[3,4]

13. Andaz C, Whittet HB. An in vitro study to determine efficacy of different wax-dispersing agents. *ORL J Otorhinolaryngol Relat Spec* 1993; 55: 97–9.
14. Burton MJ, Doree CJ. Ear drops for the removal of ear wax. Available in The Cochrane Database of Systematic Reviews: Issue 1. Chichester: John Wiley; 2009 (accessed 06/07/09).

Adverse Effects and Precautions

Adverse effects occur rarely with docusates; diarrhoea, nausea, abdominal cramps, and skin rash have been reported. Anorectal pain or bleeding have occasionally occurred after rectal doses.

Like all laxatives, docusates should not be used when intestinal obstruction or undiagnosed abdominal symptoms are present; prolonged use should be avoided. Docusate sodium should not be given rectally to patients with haemorrhoids or anal fissures.

Docusate sodium should not be used to soften ear wax when the ear is inflamed or the ear drum perforated.

Hypersensitivity. Docusate salts are widely used as anionic surfactants in pharmaceutical formulations. Allergic contact dermatitis has been reported from one such preparation; patch testing confirmed the reaction to docusate sodium.[1]

1. Lee A-Y, Lee K-H. Allergic contact dermatitis from dioctyl sodium sulfosuccinate in a topical corticosteroid. *Contact Dermatitis* 1998; 38: 355–6.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies docusate sodium as not porphyrinogenic when used as an enema; it may be used as a drug of first choice and no precautions are needed.[1] NAPOS has not classified other formulations.

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pregnancy. Hypomagnesaemia in a neonate, manifested by jitteriness, was considered to be secondary to maternal hypomagnesaemia caused by maternal use of docusate sodium during pregnancy.[1]

1. Schindler AM. Isolated neonatal hypomagnesaemia associated with maternal overuse of stool softener. *Lancet* 1984; ii: 822.

Interactions

Docusates may enhance the gastrointestinal uptake of other drugs, such as liquid paraffin (and the two should not be given together). Dosage of anthraquinone laxatives may need to be reduced if used with docusates. It has also been suggested that giving docusates with aspirin increases the incidence of adverse effects on the gastrointestinal mucosa.

Pharmacokinetics

Docusate salts are absorbed from the gastrointestinal tract and excreted in bile. Docusate sodium is also distributed into breast milk.

Pharmacopoeias. In *US.*

USP 36: (Dolasetron Mesylate). A white to off-white powder. Freely soluble in water and in propylene glycol; slightly soluble in alcohol and in sodium chloride 0.9%. Protect from light.

Stability. A study[1] of the stability of two extemporaneous oral suspensions of dolasetron mesilate 10 mg/mL prepared from commercially available tablets found them to be stable for at least 90 days when stored at 3 to 5 degrees and at 23 to 25 degrees.

Uses and Administration

Dolasetron is a 5-HT_3 antagonist with antiemetic actions similar to those of ondansetron (see p. 1872.2). It is used as the mesilate in the prevention of nausea and vomiting (p. 1811.3) associated with chemotherapy, and in the prevention and treatment of postoperative nausea and vomiting, although licensed indications and doses may vary from country to country. Dolasetron mesilate can be given orally or intravenously, either by bolus injection at a rate of up to 100 mg over 30 seconds or diluted to 50 mL with a suitable infusion solution such as sodium chloride 0.9% or glucose 5% and infused over up to 15 minutes.

For *prevention* of acute **nausea and vomiting** associated with **chemotherapy** dolasetron mesilate may be given orally in a dose of 100 mg or 200 mg within 1 hour before treatment. Alternatively, it may be given in an intravenous dose of 1.8 mg/kg, or 100 mg, about 30 minutes before chemotherapy. To protect against delayed emesis after the end of a chemotherapy cycle, some countries allow for further oral doses of 200 mg once daily. Dolasetron may be given for 4 to 7 consecutive days per chemotherapy cycle.

For the *prevention* of **postoperative** nausea and vomiting dolasetron mesilate may be given orally in a dose of 50 mg at the induction of anaesthesia, or 100 mg within 2 hours before surgery. Alternatively, a single intravenous dose of 12.5 mg may be given about 15 minutes before the end of anaesthesia, or at the end of anaesthesia. The same intravenous dose may be given for the *treatment* of postoperative nausea and vomiting.

For doses in children, see below.

Reviews.

2. Anonymous. Dolasetron for prevention of nausea and vomiting due to cancer chemotherapy. *Med Lett Drug Ther* 1998; 40: 53–4.

Administration in children. The use of dolasetron mesilate in children is licensed in some countries, including the USA. However, others have not licensed such use and in Australia and Canada it is contra-indicated in children and adolescents under 18 years of age because they may be at increased risk of acute changes in the QT interval, and there have been reports of cardiac conduction disorders, cardiac arrest, and myocardial infarction in children treated with dolasetron.

In the USA, children from 2 years of age may be given dolasetron mesilate 1.8 mg/kg orally (within 1 hour before chemotherapy) up to a maximum dose of 100 mg, to prevent acute *chemotherapy-induced* nausea and vomiting. For prevention of *postoperative* nausea and vomiting, an oral dose of 1.2 mg/kg, up to a maximum of 100 mg, may be given within 2 hours before surgery; or an intravenous dose of 350 micrograms/kg, up to a maximum of 12.5 mg, may be given 15 minutes before the end of anaesthesia. The same intravenous dose may be given to treat established postoperative nausea and vomiting.

Pruritus. Dolasetron and other 5-HT_3 antagonists have been investigated for the management of pruritus (see under Ondansetron, p. 1873.1).

Adverse Effects and Precautions

As for Ondansetron, p. 1873.2. Diarrhoea, anorexia, and abdominal pain may also occur.

Various ECG changes have been noted with dolasetron. Dolasetron should be used with caution in patients who have, or may develop, prolongation of the QT interval or other alterations in cardiac conduction intervals, and in those with electrolyte imbalances. In some countries use is considered contra-indicated in children because they are thought to be at increased risk (see Administration in Children, above).

Other adverse effects include dyspepsia, flatulence, taste disturbances, fever, chills or shivering, sleep disorders, fatigue, and drowsiness. There have been rare reports of intestinal obstruction, pancreatitis, jaundice, seizures, bronchospasm, cardiac arrhythmias, and oedema. Local reactions may occur on intravenous use. No dosage reduction is considered necessary in renal or hepatic impairment, despite possible reductions in clearance.

Effects on the cardiovascular system. For a discussion of the effects of 5-HT_3 antagonists on the cardiovascular system, see under Ondansetron, p. 1873.3.

Phlebitis. Venous irritation has been reported after intravenous use of dolasetron; diluting subsequent doses with sodium chloride 0.9% and infusing it more slowly markedly reduced the frequency of phlebitis.[1]

1. Oshiro MM. Dolasetron-associated venous irritation. *Am J Health-Syst Pharm* 2000; 57: 1533–4.

Interactions

Plasma concentrations of hydrodolasetron, the active metabolite of dolasetron, are increased by cimetidine and atenolol and decreased by rifampicin. Dolasetron should be used with caution in patients taking drugs that prolong the QT interval, including those likely to cause electrolyte disturbances (see also p. 1874.2).

Pharmacokinetics

Dolasetron given orally or intravenously is rapidly converted to the active metabolite hydrodolasetron by carbonyl reductase, a ubiquitous enzyme. Peak plasma concentrations of hydrodolasetron occur 1 hour after oral, and 0.6 hours after intravenous, doses of dolasetron. The apparent oral bioavailability of dolasetron determined as hydrodolasetron is about 75%. It has a mean elimination half-life of about 7 to 8 hours.

Hydrodolasetron is partially metabolised by the cytochrome P450 isoenzymes CYP2D6 and CYP3A and about 50 to 60% is eliminated unchanged in the urine. Two thirds of a dose of dolasetron is recovered in the urine and one third in the faeces.

Clearance of hydrodolasetron is increased in children, but is not altered in the elderly. Clearance is reduced in severe hepatic impairment (Child-Pugh category B or C) and in severe renal impairment (creatinine clearance less than 10 mL/min) after oral use. After intravenous use, clearance is reduced in severe renal impairment but apparently unchanged in severe hepatic impairment.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Domperidone Maleate). A white or almost white powder; it exhibits polymorphism. Very slightly soluble in water and in alcohol; sparingly soluble in dimethylformamide; slightly soluble in methyl alcohol. Protect from light.

Uses and Administration

Domperidone is a dopamine antagonist with actions and uses similar to those of metoclopramide (p. 1862.2). It is used as an antiemetic for the short-term treatment of nausea and vomiting of various aetiologies (p. 1811.3). It is not considered suitable for chronic nausea and vomiting, nor for the routine prophylaxis of postoperative vomiting. Domperidone is also used for its prokinetic actions in dyspepsia (p. 1806.3) and has been tried in diabetic gastroparesis (see Diabetic Neuropathy, p. 465.2). It has been given with paracetamol in the symptomatic treatment of migraine (p. 670.3).

Domperidone is used as the maleate in tablet preparations and as the base in suppositories and the oral suspension; doses are expressed in terms of the base. Domperidone maleate 12.73 mg is equivalent to about 10 mg of domperidone. Domperidone has been given parenterally, but this route has been associated with severe adverse effects (see below).

For the treatment of **nausea and vomiting** and for the symptomatic management of non-ulcer **dyspepsia**, domperidone may be given in oral doses of 10 to 20 mg three or four times daily up to a maximum daily dose of 80 mg or it may be given rectally in a dose of 60 mg twice daily. The initial course of treatment is up to 4 weeks. For doses in children see below.

The hydrochloride salt and domperidone betadex (domperidone betacyclodextrin) have also been used.

Administration in children. Domperidone is used in children as an antiemetic for nausea and vomiting and as a motility stimulant for gastrointestinal stasis. For nausea and vomiting, UK licensed product information states that children may be given domperidone in oral doses equivalent to 250 to 500 micrograms/kg three or four times daily; a total daily dose of 2.4 mg/kg or 80 mg, whichever is less, should not be exceeded. Alternatively, children weighing more than 15 kg may be given a rectal dose of 30 mg twice daily. Children over 12 years and weighing 35 kg or more may be given adult doses either orally or rectally, see above.

Although unlicensed for gastrointestinal stasis in the UK, the *BNFC* suggests oral doses given before food, according to age:

- neonates: 100 to 300 micrograms/kg four to six times daily
- 1 month to 12 years: 200 to 400 micrograms/kg (to a maximum of 20 mg) three or four times daily
- 12 years and over: doses similar to those used in adults for nausea and vomiting may be given

Similar doses may be used in infants and young children with gastro-oesophageal reflux disease, but see below.

Gastro-oesophageal reflux disease. A systematic review of the use of domperidone in infants and young children with gastro-oesophageal reflux (GORD; p. 1807.2), which identified 4 randomised controlled studies of such use, considered that there was very little evidence of its efficacy in reducing symptoms.[1] Some suggest that it has been overused because of the lack of a suitable alternative after withdrawal of cisapride in many countries.[2] The *BNFC* reinforces the idea that evidence for the long-term efficacy of motility stimulants (including domperidone) in the management of GORD is unconvincing. If domperidone is to be used, the *BNFC* suggests doses similar to those used for gastrointestinal stasis in children, see above.

2. Vandenplas Y, *et al.* The diagnosis and management of gastro-oesophageal reflux in infants. *Early Hum Dev* 2005; 81: 1011–24.

Parkinsonism. Domperidone is used to control gastrointestinal effects of dopaminergic drugs given in the management of parkinsonism (p. 889.1). It may be of use in those patients who have peripheral effects with levodopa despite the use of peripheral dopa-decarboxylase inhibitors and for patients using dopamine agonists such as bromocriptine or apomorphine since peripheral dopa-decarboxylase inhibitors are ineffective for preventing the peripheral effects of these drugs. Although domperidone does not readily cross the blood-brain barrier there have been isolated reports of extrapyramidal effects associated with its use (see p. 1839.1). Consequently there has been concern over its potential to produce central effects and some consider that domperidone should only be used in patients with parkinsonism when safer antiemetic measures have failed.[1,2] However, this view has been contested both by the manufacturers and other authors.[3,4] In a subsequent review of the use of domperidone in Parkinson's disease it was considered[5] that domperidone might produce central blockade of the therapeutic effects of levodopa if given at a high oral dosage such as 120 mg daily for prolonged periods but also noted that such high doses were rarely required to control levodopa-induced vomiting.

Domperidone was found to significantly improve anorexia, nausea, vomiting, abdominal bloating, and regurgitation in patients taking levodopa.[6] Dysphagia and constipation were unaffected; these are thought to be more likely a reflection of the disease process. Doses ranged from 50 to 120 mg daily, with most patients responding to 80 mg daily. No central effects were noted.

Adverse Effects

Dry mouth occurs commonly with domperidone; other adverse effects occur more rarely. Plasma-prolactin concentrations may increase with use of domperidone, which may lead to galactorrhoea, gynaecomastia, or amenorrhoea. Breast pain and tenderness may also occur. Domperidone does not readily cross the blood-brain barrier and the incidence of central effects such as extrapyramidal reactions or drowsiness may be lower than with metoclopramide (p. 1863.2); however, there have been reports of dystonic reactions and convulsions.

Domperidone has been associated with QT prolongation, serious ventricular arrhythmias, and sudden cardiac death. Fatalities have restricted intravenous use.

Hypersensitivity reactions include anaphylaxis and angioedema. Skin reactions such as rash, pruritus, and urticaria have occurred. Diarrhoea and transient intestinal cramps can also occur. There have been reports of anxiety or nervousness, agitation, loss of libido, asthenia, and headache. Urinary retention, abnormal liver function tests, and oculogyric crisis have also been reported.

Effects on the cardiovascular system. Between 1985 and 2006 Health Canada received 9 reports of heart rate and rhythm disorders suspected of being associated with domperidone use.[1] An increased QT interval was described in 2 cases, torsade de pointes in 4 cases, and the remaining 3 cases described arrhythmia, atrial fibrillation, ventricular tachycardia, bradycardia, and palpitation. Causality was hard to establish as most cases were complex, with multiple medicines prescribed. Prolongation of the QT interval has been reported in an infant given *oral* domperidone, with normalisation after the drug was stopped.[2] A prolonged QT interval was also reported in a small study in neonates given oral domperidone for gastro-oesophageal reflux disease; no cardiac arrhythmias developed.[3] A serum potassium concentration at the upper limit of normal or a gestational age of 32 weeks or more were risk factors for QT prolongation.

Sudden death has occurred in cancer patients given domperidone *intravenously* in high doses.[4-6] Four cancer patients had cardiac arrest after high intravenous doses[7] and 2 of 4 similar patients had ventricular arrhythmias.[8] After such reports the injection has been withdrawn from general use in many countries, including the UK.

A case-control study to investigate the association between the use of domperidone and the occurrence of serious ventricular arrhythmias found that current use of domperidone in high doses (defined as more than 30 mg daily; route not specified) was associated with a substantially increased risk of sudden cardiac death; non-fatal ventricular arrhythmias could not be assessed due to the lack of confirmed cases.[9]

Precautions

Domperidone is not recommended for chronic use or for the routine prophylaxis of postoperative nausea and vomiting. Domperidone should be used with great caution if given intravenously, because of the risk of arrhythmias, especially in patients predisposed to cardiac arrhythmias or hypokalaemia.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were given domperidone, and the last available guidance from the American Academy of Pediatrics considered[1] domperidone to be usually compatible with breast feeding. However, the FDA in the USA has issued a warning against the use of domperidone to increase milk production because of the possibility of serious adverse effects.[2] Others have commented that these warnings were based on data from patients with malignant disease receiving high doses of intravenous domperidone, and that if the mother were taking smaller oral doses, the total amount of drug ingested by an infant would be extremely small. They recommend that low-dose domperidone should still be considered for lactating women with decreased milk supply who are unresponsive to non-pharmacological measures to enhance lactation. However, patients should be warned of the risk of arrhythmias at high doses, and women with known cardiac disease should not take domperidone.[3]

In a small controlled study to determine the effect of domperidone on the nutrient composition of breast milk, breast milk volume was increased with domperidone use, nutrient composition was not substantially altered, and no significant adverse effects were seen in mothers or infants.[4]

Interactions

As with other dopamine antagonists (see Metoclopramide, p. 1864.3), there is a theoretical potential that domperidone may antagonise the hypoprolactinaemic effect of drugs such as bromocriptine. In addition, the prokinetic effects of domperidone may alter the absorption of some drugs. Opioid analgesics and antimuscarinics may antagonise the prokinetic effects of domperidone.

Domperidone is metabolised via the cytochrome P450 isoenzyme CYP3A4; use with ketoconazole has been reported to produce a threefold increase in plasma concentrations of domperidone, and an associated slight prolongation in QT interval. Similar increases in domperidone concentrations might theoretically be seen with other potent inhibitors of CYP3A4 such as erythromycin or ritonavir, and such combinations may be best avoided.

Pharmacokinetics

Although absorption is rapid, the systemic bioavailability of domperidone is only about 15% in fasting subjects given an oral dose; this is increased when domperidone is given after food. The low bioavailability is thought to be due to first-pass hepatic and intestinal metabolism. The bioavailability of rectal domperidone is similar to that after oral doses, although peak plasma concentrations are only about one-third that of an oral dose and occur after about an hour, compared with 30 minutes after an oral dose.

Domperidone is more than 90% bound to plasma proteins, and has a terminal elimination half-life of about 7.5 hours. It undergoes rapid and extensive hepatic metabolism. The main metabolic pathways are *N*-dealkylation by cytochrome P450 isoenzyme CYP3A4, and aromatic hydroxylation by CYP3A4, CYP1A2, and CYP2E1. About 30% of an oral dose is excreted in urine within 24 hours, almost entirely as metabolites; the remainder of a dose is excreted in faeces over several days, about 10% as unchanged drug. It does not readily cross the blood-brain barrier.

Small amounts of domperidone are distributed into breast milk; concentrations are 10 to 50% of those in maternal serum.

Preparations

Proprietary Preparations (details are given in Volume B)

Pharmacopoeial Preparations
BP 2014: Domperidone Tablets.

Dosmalfate *(rINN)*

Dosmalfato; Dosmalfatum; F-3616; Дозмальфат.
[μ_7-[(Diosmin heptasulfato)(7-)]]tetracontahydroxytetradecaaluminium.
$C_{28}H_{60}Al_{14}O_{71}S_7$=2134.9
CAS — 122312-55-4.
UNII — P764IU074T.

Profile

Dosmalfate is a cytoprotective drug derived from diosmin (p. 2505.2), that has been used for the treatment of peptic ulcer disease.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Spain***: Diotul†.

Drofenine Hydrochloride *(pINNM)*

Drofenina, hidrocloruro de; Drofénine, Chlorhydrate de; Drofenini Hydrochloridum; Hexahydroadiphenine Hydrochloride; Hidrocloruro de drofenina; Дрофенина Гидрохлорид.
2-(Diethylamino)ethyl α-phenylcyclohexaneacetate hydrochloride.
$C_{20}H_{31}NO_2$,HCl=353.9
CAS — 1679-76-1 (drofenine); 548-66-3 (drofenine hydrochloride).
UNII — MVB31OPW0S.

Pharmacopoeias. In *Swiss*.

Profile

Drofenine hydrochloride is an antimuscarinic available in preparations for the treatment of visceral spasms.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Arg.*: Espasmo Cibalena; *Austria*: Spasmoplus; *Chile*: Espasmo Cibalgina Compuesta†; Espasmo Cibalgina; *Mex.*: Espasmo Cibalgina; *Switz.*: Lunadon†.

Dronabinol *(USAN, rINN)* ⊗

Dronabinolum; NSC-134454; Дронабинол.
(6a*R*,10a*R*)-6a,7,8,10a-Tetrahydro-6,6,9-trimethyl-3-pentyl-6*H*-dibenzo[*b*,*d*]pyran-1-ol.
$C_{21}H_{30}O_2$=314.5
CAS — 1972-08-3.
ATC — A04AD10 (dronabinol); N02BG10 (nabiximols).
ATC Vet — QA04AD10.
UNII — 7J8897W37S.

Pharmacopoeias. In *US*.

USP 36: (Dronabinol). Store at a temperature between 8 degrees and 15 degrees in airtight glass containers in an inert atmosphere. Protect from light.

Uses and Administration

Dronabinol, the major psychoactive constituent of cannabis (p. 2467.1), has antiemetic properties and is used for the control of **nausea and vomiting** associated with cancer chemotherapy (p. 1811.3) in patients who have failed to respond adequately to conventional antiemetics.

The usual initial oral dose of dronabinol is 5 mg/m² given 1 to 3 hours before the first dose of the antineoplastic drug with subsequent doses being given every 2 to 4 hours after chemotherapy to a maximum of 4 to 6 doses daily. If necessary, the dose may be increased by increments of 2.5 mg/m² to a maximum dose of 15 mg/m², if adverse effects permit.

Dronabinol also has appetite-stimulant effects and is used in the treatment of **anorexia** associated with weight loss in patients with AIDS. For this purpose 2.5 mg may be taken twice daily, before lunch and supper, reduced to a single 2.5-mg dose in the evening in patients who tolerate the drug poorly. If necessary, and if adverse effects permit, doses may also be increased up to 20 mg daily in divided doses.

A buccal spray preparation containing cannabis extracts, whose main active ingredients are dronabinol and cannabidiol, is used as adjunctive treatment for the symptomatic relief of **spasticity** and **neuropathic pain** in multiple sclerosis in adults; this combination is also used as adjunctive analgesic treatment in adult patients with advanced cancer (see Nabiximols, p. 2566.3) and is under investigation for several other conditions.

Alzheimer's disease. There are limited data to suggest that dronabinol may decrease agitation in patients with Alzheimer's disease[1] or dementia.[2]

1. Volicer L, *et al.* Effects of dronabinol on anorexia and disturbed behavior in patients with Alzheimer's disease. *Int J Geriatr Psychiatry* 1997; 12: 913–19.
2. Walther S, *et al.* Delta-9-tetrahydrocannabinol for nighttime agitation in severe dementia. *Psychopharmacology (Berl)* 2006; 185: 524–8.

Anorexia. Dronabinol is used for the management of anorexia in patients with HIV-associated wasting (p. 959.1). However, although dronabinol may stimulate appetite and prevent weight loss,[1] it does not appear to produce significant weight gain, and may produce less benefit than megestrol acetate.[2] Benefits were also less than those of megestrol in patients with anorexia associated with malignant disease.[3]

Multiple sclerosis. Anecdotal evidence has suggested that cannabinoids might improve symptoms in patients with multiple sclerosis (p. 996.3); a review[1] considered evidence of efficacy to be lacking. In a large placebo-controlled study, treatment with dronabinol or oral cannabis extract had no benefit on objective assessment of spasticity;[2] however, there were improvements in walking time, and subjective improvements in both spasticity and pain. A subsequent small controlled study found dronabinol to have a modest but clinically relevant effect on central neuropathic pain in patients with multiple sclerosis.[3]

A buccal spray preparation containing cannabis extracts, whose main active ingredients are dronabinol and cannabidiol, is used for the symptomatic relief of spasticity and neuropathic pain in multiple sclerosis in adults.

Tourette's syndrome. Preliminary studies[1,2] indicate that dronabinol may reduce tic severity in Tourette's syndrome (see Tics, p. 1030.1).

1. Müller-Vahl KR, *et al.* Treatment of Tourette's syndrome with Δ⁹-tetrahydrocannabinol (THC): a randomized crossover trial. *Pharmacopsychiatry* 2002; 35: 57–61.
2. Müller-Vahl KR, *et al.* Δ⁹-Tetrahydrocannabinol (THC) is effective in the treatment of tics in Tourette syndrome: a 6-week randomized trial. *J Clin Psychiatry* 2003; 64: 459–65.

Adverse Effects and Precautions

As for Nabilone, p. 1865.3. The most frequent adverse effects of dronabinol include abdominal pain, nausea and vomiting, dizziness, euphoria, paranoid reactions, and somnolence. Seizures and seizure-like activity have been reported; dronabinol should be used with caution in those with a history of seizure disorders, and therapy should be stopped if seizures occur.

Abuse. The abuse liability of dronabinol was rated as being substantially lower than that of cannabis.[1]

1. WHO. WHO expert committee on drug dependence: thirty-third report. *WHO Tech Rep Ser 915* 2003. Available at: http://libdoc.who.int/trs/WHO_TRS_915.pdf (accessed 03/07/08)

Breast feeding. US licensed product information states that dronabinol is concentrated in breast milk and recommends that it should not be used in breast-feeding mothers.

Pharmacokinetics

After oral doses dronabinol is slowly and erratically absorbed from the gastrointestinal tract; the bioavailability of an oral dose is about 10 to 20%, due to extensive first-pass metabolism. Peak plasma concentrations of dronabinol and its 11-hydroxy metabolite occur about 2 to 4 hours after an oral dose. It is widely distributed and is extensively protein bound, with a volume of distribution of about 10 litres/kg. Elimination is biphasic, with an initial half-life of about 4 hours, and a terminal half-life of about 25 to 36 hours.

Dronabinol is extensively metabolised, mainly in the liver by cytochrome P450 isoenzymes; the primary metabolite, 11-hydroxydronabinol is also active. The 11-hydroxy metabolite is converted to other, more polar and acidic compounds which are excreted in faeces via the bile, and in the urine. About 50% of an oral dose is recovered in faeces within 72 hours and 10 to 15% in urine. Many of the metabolites have relatively prolonged half-lives, and accumulation may occur with repeated dosage.

Dronabinol is distributed into breast milk and crosses the placenta.

Ecabet Sodium *(rINN)*

Ecabet sódico; Écabet Sodique; Natrii Ecabetum; 12-Sulphodehydroabietic Acid, Monosodium Salt; TA-2711; Экабет Натрий.
13-Isopropyl-12-sulphopodocarpa-8,11,13-trien-15-oic acid pentahydrate, sodium salt.
$C_{20}H_{27}NaO_5S.5H_2O$=492.6
CAS — 33159-27-2 (ecabet); 86408-72-2 (ecabet sodium).
UNII — 51MO2B2O5B.

Profile

Ecabet sodium is a cytoprotective drug used in the treatment of peptic ulcer disease (p. 1813.2). The suggested oral dose is 1 g of ecabet sodium twice daily.

It is also under investigation as eye drops in the management of dry eye.

Enoxolone Aluminium *(BANM, rINNM)*

Aluminii Enoxolonum; Aluminium Glycyrrhetate; Aluminium Glycyrrhetinate; Enoxolona de aluminio; Enoxolone Aluminum; Énoxolone d'Aluminium; Алюминий Эноксолон.
3β-Hydroxy-11-oxo-olean-12-en-30-oic acid, aluminium salt.
$(C_{30}H_{46}O_4)_3Al$=1439.1
CAS — 4598-66-7.
ATC — D03AX10.
ATC Vet — QD03AX10.

Profile

Enoxolone aluminium is an analogue of carbenoxolone (p. 1825.3) that has been used in preparations for the treatment of peptic ulcer disease and other gastrointestinal disorders. It has also been used in preparations for skin disorders and mouth and throat disorders.

Pulmonary hypertension. *In-utero* exposure to enoxolone was implicated in a fatal case of neonatal pulmonary arterial hypertension; the mother had used a lotion for prurigo that contained enoxolone and the authors supposed it had contributed at least in part to the pulmonary hypertension.[1]

Eseridine Salicylate *(rINNM)*

Eseridina, salicilato de; Éséridine, Salicylate d'; Eseridini Salicylas; Eserine Aminoxide Salicylate; Eserine Oxide Salicylate; Physostigmine Aminoxide Salicylate; Physostigmine *N*-Oxide Salicylate; Salicilato de eseridina; Эзеридина Салицилат.
(4a*S*,9a*S*)-2,3,4,4a,9,9a-Hexahydro-2,4a,9-trimethyl-1,2-oxazino[6,5-*b*]indol-6-ylmethylcarbamate salicylate.
$C_{15}H_{21}N_3O_3.C_7H_6O_3$=429.5
CAS — 25573-43-7 (eseridine); 5995-96-0 (eseridine salicylate).

Profile

Eseridine salicylate, a derivative of physostigmine (p. 2009.3), is an inhibitor of cholinesterase activity that has been given orally for dyspepsia in doses of up to 4.5 mg 3 times daily, taken 30 minutes before meals.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Esomeprazole Magnesium Trihydrate). A white or slightly coloured, slightly hygroscopic powder. Slightly soluble in water; soluble in methyl alcohol; practically insoluble in heptane. Store in airtight containers. Protect from light.

USP 36: (Esomeprazole Magnesium). A white to slightly coloured powder. Slightly soluble in water; soluble in methyl alcohol; practically insoluble in heptane. Store in airtight containers. Protect from light.

Esomeprazole Potassium *(BANM, USAN, rINNM)*

Esomeprazol potásico; Esoméprazole Potassique; Kalii Esomeprazolum; Калия Эзомепразол.

$C_{17}H_{18}KN_3O_3S$=383.5

CAS — 161796-84-5.

ATC — A02BC05.

ATC Vet — QA02BC05.

UNII — F37S7G37O2.

Esomeprazole Sodium *(BANM, USAN, rINNM)*

Esomeprazol sódico; Esoméprazole Sodique; Natrii Esomeprazolum; Натрия Эзомепразол.

$C_{17}H_{18}N_3NaO_3S$=368.4

CAS — 161796-78-7.

ATC — A02BC05.

ATC Vet — QA02BC05.

UNII — L2C9GWQ43H.

Esomeprazole Strontium *(USAN, rINNM)*

Esomeprazol estroncio; Esoméprazole Strontium; FM-0F67; Эзомепразол Стронция.

$(C_{17}H_{18}N_3O_3S)_2Sr.4H_2O$=848.5

CAS — 934714-36-0.

UNII — C5N2SH3803.

Uses and Administration

Esomeprazole is the *S*-isomer of the proton pump inhibitor omeprazole (p. 1867.2) and is used similarly in the treatment of peptic ulcer disease and NSAID-associated ulceration (p. 1813.2), in gastro-oesophageal reflux disease (p. 1807.2), and the Zollinger-Ellison syndrome (p. 1814.3). It is given as the magnesium, sodium, or strontium salts but doses are calculated in terms of esomeprazole. Esomeprazole magnesium 22.2 mg, esomeprazole sodium 21.3 mg, and esomeprazole strontium 24.7 mg are each equivalent to about 20 mg of esomeprazole.

Usual oral doses in **peptic ulcer disease**, for *Helicobacter pylori* eradication as a component of a triple therapy regimen with amoxicillin and clarithromycin, are the equivalent of 20 mg esomeprazole twice daily for 7 days, or 40 mg once daily for 10 days.

Oral doses of 20 mg daily, for 4 to 8 weeks, are used in the treatment of **NSAID-associated ulceration**; a dose of 20 or 40 mg daily may also be used for prophylaxis in patients at risk of such lesions who require continued NSAID treatment.

In the UK, the dose for treatment of severe (erosive) **gastro-oesophageal reflux disease** is 40 mg once daily for 4 weeks, extended for a further 4 weeks if necessary; in the USA, where doses of 20 or 40 mg daily are permitted for initial treatment, a further 4 to 8 weeks of treatment may be considered for patients who do not heal after 4 to 8 weeks. For maintenance, or for symptomatic disease without erosive oesophagitis, doses equivalent to 20 mg of esomeprazole daily may be used in both countries.

For the treatment of **Zollinger-Ellison syndrome**, the recommended initial oral dose of esomeprazole is 40 mg twice daily, which is then adjusted as needed. The majority of patients can be controlled on doses between 80 and 160 mg daily, although daily doses of 240 mg have been given. Doses above 80 mg daily should be given in 2 divided doses. For doses in children, see below.

PARENTERAL DOSAGE.

Similar doses to the above may be given intravenously for gastro-oesophageal reflux disease and NSAID-associated ulceration. Esomeprazole is given as the sodium salt by slow intravenous injection over at least 3 minutes or by intravenous infusion over 10 to 30 minutes.

For the **prevention of rebleeding** of gastric and duodenal ulcers after therapeutic endoscopy, 80 mg esomeprazole can be given as an intravenous infusion over 30 minutes, followed by a continuous intravenous infusion of 8 mg/hour over 72 hours. This parenteral treatment period is then followed by oral therapy; 40 mg is given once daily for 4 weeks.

Doses of esomeprazole may need to be reduced in patients with hepatic impairment (see below).

Administration in children. Esomeprazole is given orally to children for the treatment of gastro-oesophageal reflux disease and erosive oesophagitis,[1,2] and for duodenal ulcers caused by *Helicobacter pylori*.

For gastro-oesophageal reflux disease, children aged from 1 to 11 years and weighing 10 kg and over are given 10 mg once daily for up to 8 weeks.

In erosive oesophagitis, doses are based on body-weight and given once daily for 8 weeks:

- 10 kg up to 20 kg: 10 mg
- ⩾ 20 kg: 10 or 20 mg

For the eradication of *H. pylori* in duodenal ulceration in children over 4 years of age, oral esomeprazole is given with amoxicillin and clarithromycin for 1 week; doses are according to weight:

- < 30 kg: 10 mg twice daily
- ⩾ 30 kg: 20 mg twice daily

Regardless of indication, children from 12 years of age may be given adult doses, see above.

For doses in children with hepatic impairment, see below.

Esomeprazole is unlicensed in children under 1 year of age; however, a pharmacokinetic study in preterm and term neonates with gastro-oesophageal reflux disease found oral esomeprazole 500 micrograms/kg once daily for 7 days reduced oesophageal acid exposure and gastric acidity but had no effect on bolus reflex characteristics, findings that were consistent with those reported in adults. Systemic exposure to esomeprazole was proportionally higher in neonates compared with older infants.[3]

For findings from a review regarding the efficacy and safety of proton pump inhibitors in infants, children, and adolescents, see Administration in Children, under Omeprazole, p. 1867.3.

Administration in hepatic impairment. No dosage adjustment of esomeprazole is considered necessary for patients with mild to moderate hepatic impairment (Child-Pugh Classes A and B, respectively). In severe hepatic impairment (Child-Pugh Class C), US licensed product information recommends that a daily dose of 20 mg, orally or intravenously, should not be exceeded. In the UK, licensed product information specifies a maximum daily intravenous dose of esomeprazole 20 mg in those aged 18 years and over, although when given for prevention of rebleeding of gastric and duodenal ulcers after endoscopy in those with severe hepatic impairment, an initial intravenous infusion of 80 mg over 30 minutes, may be followed by a continuous intravenous infusion of 4 mg/hour over about 72 hours. A maximum daily oral dose of esomeprazole 20 mg is recommended in patients from 12 years of age, and 10 mg in those aged 1 to 11 years.

Administration in renal impairment. Although no dosage adjustment is considered necessary in patients with renal impairment, UK licensed product information advises caution in those with severe renal impairment, as experience in these patients is limited.

Adverse Effects and Precautions

As for Omeprazole, p. 1868.1.

Interactions

As for Omeprazole, p. 1870.3.

References.

1. Andersson T, *et al.* Drug interaction studies with esomeprazole, the (S)-isomer of omeprazole. *Clin Pharmacokinet* 2001; 40: 523–37.

Pharmacokinetics

Esomeprazole is rapidly absorbed after oral doses and peak plasma levels occur after about 1 to 2 hours. It is acid labile and an enteric-coated formulation has been developed. Bioavailability of esomeprazole increases on repeated dosage to about 68 and 89% for doses of 20 and 40 mg respectively. Food delays and decreases the absorption of esomeprazole, but this does not significantly change its effect on intragastric acidity. Esomeprazole is about 97% bound to plasma proteins. It is extensively metabolised in the liver by the cytochrome P450 isoenzyme CYP2C19 to hydroxy and desmethyl metabolites, which have no effect on gastric acid secretion. The remainder is metabolised by the cytochrome *P450* isoenzyme CYP3A4 to esomeprazole sulfone. With repeated dosage, there is a decrease in first-pass metabolism and systemic clearance, probably caused by an inhibition of the CYP2C19 isoenzyme. However, there is no accumulation during once daily use. The plasma elimination half-life is about 1.3 hours. Almost 80% of an oral dose is eliminated as metabolites in the urine, the remainder in the faeces.

2. Sostek MB, *et al.* Effect of timing of dosing in relation to food intake on the pharmacokinetics of esomeprazole. *Br J Clin Pharmacol* 2007; 64: 386–90.

Metabolism. As for omeprazole (p. 1871.2), the cytochrome P450 isoenzyme CYP2C19 is involved in the metabolism of esomeprazole, and individuals who are deficient in this enzyme are poor metabolisers of esomeprazole. However, there is some suggestion that the metabolism of esomeprazole is less dependent on this genotype, as there may be a metabolic shift towards the CYP3A4-mediated pathway.[1]

1. Schwab M, *et al.* Esomeprazole-induced healing of gastroesophageal reflux disease is unrelated to the genotype of CYP2C19: evidence from clinical and pharmacokinetic data. *Clin Pharmacol Ther* 2005; 78: 627–34.

Uses and Administration

Famotidine is a histamine H_2-antagonist with actions and uses similar to those of cimetidine (see p. 1827.2).

Famotidine may be given orally or intravenously.

In the management of benign **gastric** and **duodenal ulceration** (see Peptic Ulcer Disease, p. 1813.2) the dose is 40 mg daily orally at bedtime, for 4 to 8 weeks. A dose of 20 mg twice daily has also been given. A maintenance dose of 20 mg at bedtime may be given to prevent recurrence of duodenal ulceration. In **gastro-oesophageal reflux disease** (p. 1807.2) the recommended oral dose is 20 mg twice daily for 6 to 12 weeks, or up to 40 mg twice daily if there is oesophageal erosion or ulceration. A maintenance dose of 20 mg twice daily may be given to prevent recurrence. For the short-term symptomatic relief of heartburn or non-ulcer **dyspepsia** (p. 1806.3) a dose of 10 mg up to twice daily is suggested. In the **Zollinger-Ellison syndrome** (p. 1814.3) the initial oral dose is 20 mg every 6 hours, increased as necessary; doses up to 800 mg daily have been used.

The usual dose of famotidine by the intravenous route is 20 mg and may be given by injection over at least 2 minutes or as an infusion over 15 to 30 minutes; the dose may be repeated every 12 hours.

Doses of famotidine should be reduced in patients with renal impairment (see below). For doses in children, see below.

Administration. Although famotidine is usually given as a film-coated tablet, an alternative wafer formulation, designed to dissolve on the tongue without the need for water, has also been developed.[1]

Parenteral formulations of famotidine are also available in some countries. Licensed product information recommends intravenous injection over at least 2 minutes or intravenous infusion over 15 to 30 minutes; however, a study that compared rapid intravenous injection (over up to 1 minute) with slow intravenous infusion found rapid injection to be comparable with infusion in terms of safety.[2] Continuous infusion has however been reported by others[3] to be more effective in the prevention of stress ulceration than bolus injection.

3. Baghaie AA, *et al.* Comparison of the effect of intermittent administration and continuous infusion of famotidine on gastric pH in critically ill patients: results of a prospective, randomized, crossover study. *Crit Care Med* 1995; 23: 687–91.

Administration in children. Famotidine is licensed for use in children in some countries, including the USA. It is used to inhibit gastric acid secretion and may be given orally or intravenously.

In the management of **gastro-oesophageal reflux disease**, the following initial oral doses of famotidine are suggested, according to age:

- under 3 months: 500 micrograms/kg once daily
- 3 months up to 1 year: 500 micrograms/kg twice daily
- 1 to 16 years: 500 micrograms/kg twice daily; up to 40 mg twice daily may be given

Famotidine may also be given intravenously to children from 1 to 16 years. An initial dose of 250 micrograms/kg is suggested for gastro-oesophageal reflux disease, given by injection over at least 2 minutes or as an infusion over 15 minutes, and repeated every 12 hours. Up to 40 mg daily may be given.

In the management of **peptic ulcers**, famotidine may be given to children from 1 to 16 years in an initial oral dose of 500 micrograms/kg daily, either in a single dose at night or in 2 divided doses; up to 40 mg daily may be given.

Administration in renal impairment. In patients with renal impairment, famotidine clearance is reduced and the elimination half-life increased, resulting in increased serum-drug concentrations. The half-life of famotidine in healthy subjects is about 3 hours, but in patients with a creatinine clearance (CC) less than 38 mL/min[1] or those with end-stage renal disease[2] it has been reported to be 19.3 hours and 27.2 hours, respectively. A reduced dose has therefore been recommended in patients with renal impairment, although it may not be sufficient to adjust the dose only on the basis of creatinine clearance since famotidine is partly eliminated by tubular secretion, which may also be diminished.[1] Licensed product information recommends reducing the dose by half or increasing the dosage interval to 36 to 48 hours for patients with moderate or severe renal impairment (CC less than 50 mL/min). A chart review[3] in patients with end-stage renal disease suggested that most patients would tolerate a dose of 20 mg daily, although a few might need further adjustment to prevent mental status changes.

Haemodialysis does not effectively remove famotidine from the systemic circulation. The proportion removed depends on the type of membrane used; with a high flux polysulfone membrane about 16% is reported to be removed, but only 6% with a cuprophan membrane.[2] Continuous ambulatory peritoneal dialysis removes about 5% of a dose.[2] Continuous haemofiltration may remove about 16% of a dose[2] and intermittent haemofiltration is reported to remove about 4%[4] or 8%.[2] Dosage supplements of famotidine are not required during or after dialysis or filtration procedures.

Adverse Effects

As for Cimetidine, p. 1828.3. Unlike cimetidine, famotidine is reported to have little or no anti-androgenic effect, although there are isolated reports of gynaecomastia and impotence.

General references.

1. Howden CW, Tytgat GNJ. The tolerability and safety profile of famotidine. *Clin Ther* 1996; 18: 36–54.

Precautions

As for Cimetidine, p. 1830.2.

Hepatic impairment. For a report of increased resistance to H_2-antagonists in patients with liver cirrhosis, see Cimetidine, p. 1830.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies famotidine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pregnancy. For information on the use of H_2-antagonists during pregnancy, see Cimetidine, p. 1830.3.

Interactions

Unlike cimetidine (see p. 1830.3) famotidine does not inhibit cytochrome P450 isoenzymes, and therefore is considered to have little effect on drugs metabolised by this route. However, like other H_2-antagonists its effects on gastric pH may affect the absorption of drugs whose absorption is dependent on an acid gastric pH.

Antacids. For discussion of the effect of antacids on the bioavailability of H_2-antagonists including famotidine, see Cimetidine, p. 1831.1.

Probenecid. For mention of the reduced clearance of famotidine when given with probenecid, see Cimetidine, p. 1831.1.

Sucralfate. For information on the effect of sucralfate on the bioavailability of H_2-antagonists, see Cimetidine, p. 1831.1.

Theophylline. Although famotidine is considered not to interfere with the metabolism of other drugs there is a report of a clinically significant interaction with theophylline—see p. 1236.1.

Pharmacokinetics

Famotidine is readily but incompletely absorbed from the gastrointestinal tract with peak concentrations in plasma occurring 1 to 3 hours after oral doses. The bioavailability of oral famotidine is about 40 to 45% and is not significantly affected by the presence of food.

The elimination half-life from plasma is reported to be about 3 hours and is prolonged in renal impairment (see also Administration in Renal Impairment, p. 1842.2). Famotidine is weakly bound, about 15 to 20%, to plasma proteins. A small proportion of famotidine is metabolised in the liver to famotidine *S*-oxide. About 25 to 30% of an oral dose, and 65 to 70% of an intravenous dose, is excreted unchanged in the urine, primarily by active tubular secretion. Famotidine is also found in breast milk.

Reviews.

1. Echizen H, Ishizaki T. Clinical pharmacokinetics of famotidine. *Clin Pharmacokinet* 1991; 21: 178–94.

Children. Famotidine 300 micrograms/kg intravenously was given to 10 children aged 2 to 7 years, after cardiac surgery and before extubation, to prevent aspiration.[1] This dose (equivalent to about 20 mg in adults) induced a rise in the intragastric pH within 1 hour of being given and the pH remained above 3.5 for about 9 hours. The mean elimination half-life was 3.3 hours, similar to the value in healthy adults and it was considered that doses in children need therefore only be adjusted according to body-weight and renal function. This conclusion was supported by a review of 8 studies in children over 1 year of age.[2] Conversely, in infants aged 5 to 19 days, the mean elimination half-life was prolonged (10.5 hours) secondary to reduced renal clearance.[3] This was confirmed by another study,[4] which indicated that reduced clearance was found in infants under 3 months of age, but that pharmacokinetics in older infants were similar to those previously reported for children and adults.

3. James LP, *et al.* Pharmacokinetics and pharmacodynamics of famotidine in infants. *J Clin Pharmacol* 1998; 38: 1089–95. Correction. *ibid.* 2000; 40: 1298.
4. Wenning LA, *et al.* Pharmacokinetics of famotidine in infants. *Clin Pharmacokinet* 2005; 44: 395–406.

Distribution into breast milk. The peak concentration of famotidine in breast milk, which occurred in 8 women 6 hours after a 40 mg oral dose, was similar to the peak plasma concentration, which occurred 2 hours after the dose.[1]

1. Courtney TP, *et al.* Excretion of famotidine in breast milk. *Br J Clin Pharmacol* 1988; 26: 639P.

Enterohepatic recirculation. Some individuals have a second peak in the plasma concentration of famotidine, which could be due to enterohepatic recirculation. However, a maximum of 0.43% of a dose of famotidine was excreted in the bile of 2 patients after single doses of 20 mg intravenously or 40 mg orally indicating that significant recirculation had not occurred.[1]

Pharmacopoeial Preparations

BP 2014: Famotidine Tablets;
USP 36: Famotidine for Oral Suspension; Famotidine Injection; Famotidine Tablets.

Fig

Carica; Ficus; Higo; Инжир; Фикус.
ATC Herb — HA06AX5004 (Ficus carica: fruit).
UNII — TGD87RII2U.

Pharmacopoeias. In *Br.* and *Swiss.*

BP 2014: (Fig). The sun-dried succulent fruit of *Ficus carica* containing not less than 60.0% of water-soluble extractive. Store in a dry place.

Profile

Fig is a mild laxative and demulcent usually used with other laxatives.

Effects on the skin. Skin reactions and photodermatitis have followed application of home-made decoctions of fig leaves to the skin.[1,2]

1. Ozdamar E, *et al.* An unusual cause of burn injury: fig leaf decoction used as a remedy for a dermatitis of unknown etiology. *J Burn Care Rehabil* 2003; 24: 229–33.

Homoeopathic Preparations. *Fr.*: Poconeol no 79.

Fosaprepitant *(BAN, rINN)*

Fosaprépitant; Fosaprepitantum; Фозапрепитант.
(3-[((2*R*,3*S*)-2-[(1*R*)-1-[3,5-bis(Trifluoromethyl)phenyl]ethoxy)-3-(4-fluorophenyl)morpholin-4-yl)methyl]-5-oxo-4,5-dihydro-1*H*-1,2,4-triazol-1-yl]phosphonic acid.
$C_{23}H_{22}F_7N_4O_6P$=614.4
CAS — 172673-20-0.
UNII — 6L8OF9XRDC.

Fosaprepitant Meglumine *(rINNM)*

Fosaprepitant Dimeglumide (BANM); Fosaprepitant Dimeglumine; Fosaprepitant meglumina; Fosaprépitant Méglumine; Meglumini Fosaprepitantum; MK-0517; Меглумина Фозапрепитант.
1-Deoxy-1-(methylamino)-D-glucitol (3-[((2*R*,3*S*)-2-[(1*R*)-1-[3,5-bis(trifluoromethyl)phenyl]ethoxy)-3-(4-fluorophenyl)-4-morpholinyl)methyl]-2,5-dihydro-5-oxo-1*H*-1,2,4-triazol-1-yl] phosphonate.
$C_{23}H_{22}F_7N_4O_6P$, $2C_7H_{17}NO_5$=1004.8
CAS — 265121-04-8.
UNII — D35FM8T64X.

Stability. US licensed product information states that, once reconstituted and diluted as directed in sodium chloride 0.9%, a solution of fosaprepitant meglumine is stable for 24 hours at room temperature (at or below 25 degrees).

Uses and Administration

Fosaprepitant is a prodrug of the antiemetic aprepitant (p. 1819.2), which is a neurokinin-1 receptor antagonist. Fosaprepitant meglumine is used for the prevention of acute and delayed nausea and vomiting associated with highly emetogenic or moderately emetogenic cancer chemotherapy. Doses are expressed in terms of the base; 188 mg of fosaprepitant meglumine is equivalent to about 115 mg of fosaprepitant. It is given intravenously 30 minutes before the start of chemotherapy, with a corticosteroid such as oral dexamethasone and a 5-HT_3 antagonist:

- *either* as a single intravenous dose equivalent to fosaprepitant 150 mg infused over 20 to 30 minutes on day 1 of the chemotherapy regimen
- *or* as an intravenous dose equivalent to fosaprepitant 115 mg infused over 15 minutes on day 1, followed by an oral dose of aprepitant 80 mg on days 2 and 3

The reconstituted dose of fosaprepitant is diluted in sodium chloride 0.9% to a final concentration of 1 mg/mL.

References.

2. Van Belle SJP, Cocquyt V. Fosaprepitant dimeglumine (MK-0517 or L-785,298), an intravenous neurokinin-1 antagonist for the prevention of chemotherapy induced nausea and vomiting. *Expert Opin Pharmacother* 2008; 9: 3261–70.

Adverse Effects and Precautions

As for Aprepitant, p. 1819.3.

Interactions

As for Aprepitant, p. 1820.1.

Pharmacokinetics

Fosaprepitant is rapidly converted to aprepitant; for the pharmacokinetics of aprepitant, see p. 1820.1.

Bioavailability. A pharmacokinetic study found fosaprepitant 115 mg by intravenous infusion to be bioequivalent to an oral dose of aprepitant 125 mg, suggesting that these doses could be used interchangeably (see Uses and Administration, above).[1]

1. Lasseter KC, *et al.* Tolerability of fosaprepitant and bioequivalency to aprepitant in healthy subjects. *J Clin Pharmacol* 2007; 47: 834–40.

Frangula Bark

Alder Buckthorn Bark; Amieiro Negro; Bourdaine; Faulbaumrinde; Frángula, corteza de; Frangulabark; Frangulae cortex; Kora kruszyny; Krušinová kůra; Kutyabengekéreg; Paatsamankuori; Rhamni Frangulae Cortex; Šaltekšnių žievė; Kopa Крушины.
CAS — 8057-57-6 (frangula extract).
ATC Herb — HA06AB5013 (Rhamnus frangula: *bark*).
UNII — S2D77IH61R.

NOTE. The name Buckthorn Bark has also been used; distinguish Frangula Bark from Buckthorn (p. 1824.2) and from Sea Buckthorn (p. 2611.3).

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Frangula Bark). The dried, whole or fragmented bark of the stems and branches of *Rhamnus frangula* (=*Frangula alnus*). It contains not less than 7.0% of glucofrangulins, expressed as glucofrangulin A ($C_{27}H_{30}O_{14}$=578.5) and calculated with reference to the dried drug. Protect from light.

Profile

Frangula bark is an anthraquinone stimulant laxative with actions and uses similar to those of senna (p. 1885.1).

Homoeopathy

Frangula bark has been used in homoeopathic medicines under the following names: Frangula; Rhamnus frangula; Rhamnus frang; Rham. fr.

Pharmacopoeial Preparations

Ph. Eur.: Frangula Bark Dry Extract, Standardised.

Gefarnate *(BAN, rINN)*

DA-688; DE-099; Gefarnate; Gefarnato; Gefarnatum; Geranyl Farnesylacetate; Гефарнат.

A mixture of stereoisomers of 3,7-dimethylocta-2,6-dienyl 5,9,13-trimethyltetradeca-4,8,12-trienoate.

$C_{27}H_{44}O_2$=400.6

CAS — 51-77-4.

ATC — A02BX07.

ATC Vet — QA02BX07.

UNII — 11SE2Y6ULA.

Profile

Gefarnate is a cytoprotective that has been used in the treatment of peptic ulcer disease and gastritis. An ophthalmic preparation is under investigation for the treatment of corneal and conjunctival epithelial disorders.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *China*: Wycakon-G (慕加强-G); *Jpn*: Gefanil.

Ginger

Gengibre; Gingembre; Gyömbér gyökértörzs; Imbieru šakniastiebiai; Ingefära; Ingwer; Ingwerwurzelstock; Inkivääri; Jengibre; Zázvorový oddenek; Zingib.; Zingiber; Zingiberis rhizoma; Имбирь.

ATC Herb — HM01AW5029 (Zingiber officinale: rhizome); HC01EB5024 (Zingiber officinale: rhizome); HA04WX5004 (Zingiber officinale: rhizome); HA03AW5067 (Zingiber officinale: rhizome); HA09WX5003 (Zingiber officinale: rhizome).

UNII — C5529G5JPQ.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*. *US* also includes the powdered form.

Ph. Eur. 8: (Ginger). The dried, whole or cut rhizome of *Zingiber officinale*, with the cork removed, either completely or from the wide flat surfaces only. Whole or cut, it contains not less than 1.5% of essential oil, calculated with reference to the anhydrous drug. It has a characteristic aromatic odour. Protect from light.

The BP 2014 states that ginger may be known in commerce as unbleached ginger.

USP 36: (Ginger). The scraped, partially scraped, or unscraped rhizome of *Zingiber officinale* (Zingiberaceae), known in commerce as unbleached ginger. It contains not less than 4.5% of alcohol-soluble extractive and not less than 10% of water-soluble extractive. Store at 8 degrees to 15 degrees. Protect from light and moisture.

Profile

Ginger has carminative properties. It is used as a flavouring agent and has been tried for the prophylaxis of motion sickness and nausea and vomiting in pregnancy, although it does not seem to be effective for postoperative nausea and vomiting (p. 1811.3).

Ginger oil is used in aromatherapy.

Homoeopathy

Ginger has been used in homoeopathic medicines under the following names: Zingiber; Zingiber officinale; Zing.

$C_{18}H_{24}N_4O$, HCl=348.9

CAS — 109889-09-0 (granisetron); 107007-99-8 (granisetron hydrochloride).

ATC — A04AA02.

ATC Vet — QA04AA02.

UNII — 318F6L70J8.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Ph. Eur. 8: (Granisetron Hydrochloride). A white or almost white powder. Freely soluble in water; sparingly soluble in dichloromethane; slightly soluble in methyl alcohol. A 1% solution in water has a pH of 4.0 to 6.5.

USP 36: (Granisetron Hydrochloride). A white or almost white powder. Freely soluble in water; slightly soluble in methyl alcohol; sparingly soluble in dichloromethane. A 1% solution in water has a pH of 4.0 to 6.5. Protect from light.

Uses and Administration

Granisetron is a 5-HT_3 antagonist with an antiemetic action similar to that of ondansetron (p. 1872.2). It is used in the management of nausea and vomiting induced by cytotoxic chemotherapy and radiotherapy and for the prevention and treatment of postoperative nausea and vomiting (p. 1811.3). Granisetron is given as the hydrochloride, but doses are expressed in terms of the base. Granisetron hydrochloride 1.1 mg is equivalent to about 1 mg of granisetron base. The efficacy of granisetron may be enhanced by the use of corticosteroids such as dexamethasone or methylprednisolone.

For acute **nausea and vomiting** associated with **chemotherapy** granisetron is used in *prevention* and *treatment* in similar doses.

In the UK, a dose equivalent to 1 or 3 mg of granisetron as a 1 mg/mL solution is given intravenously within 30 minutes before the start of chemotherapy, either diluted in 20 to 50 mL of a suitable infusion solution and given over 5 minutes, or added to 4 times its own volume of infusion solution and given as a bolus over at least 30 seconds. Any further doses should be given at least 10 minutes apart. The recommended oral dose is 1 to 2 mg within one hour before therapy begins, then 2 mg daily as a single dose or in 2 divided doses for up to 1 week after chemotherapy. The total maximum dose by any route in 24 hours is granisetron 9 mg.

In the USA, lower intravenous doses of the equivalent of granisetron 10 micrograms/kg are recommended, beginning within 30 minutes before chemotherapy. Oral doses are similar to those described for the UK above: a single dose of

2 mg may be given up to 1 hour before chemotherapy, or, alternatively, 1 mg can be taken up to 1 hour before chemotherapy with another dose of 1 mg 12 hours later. Granisetron is given only on the days that chemotherapy is administered.

Granisetron can also be delivered transdermally to prevent nausea and vomiting caused by moderately or highly emetogenic chemotherapy. One patch supplying 3.1 mg granisetron per 24 hours is applied to the upper arm 24 to 48 hours before chemotherapy and removed at least 24 hours after chemotherapy ends. The patch can be worn for up to 7 days.

For the *prevention* of nausea and vomiting associated with **radiotherapy** the recommended oral dosage is 2 mg daily taken within 1 hour of irradiation. The drug is also given intravenously for the *treatment and prevention* of nausea and vomiting associated with radiotherapy, in the same doses as those recommended above for emetogenic chemotherapy in the UK.

For doses in children, see below.

For the *prevention* of **postoperative** nausea and vomiting 1 mg is diluted to 5 mL and given before the induction of anaesthesia by slow intravenous injection. For *treatment*, the same dose may be repeated up to a maximum of 3 mg in 24 hours.

Intranasal formulations of granisetron are under investigation.

Administration in children. In the UK and USA, granisetron hydrochloride is licensed for use in children from 2 years of age for the management of acute nausea and vomiting associated with chemotherapy. Similar doses are used for both prevention and treatment.

- An intravenous infusion equivalent to granisetron 10 to 40 micrograms/kg, up to a maximum of 3 mg is given before the start of chemotherapy; doses should be diluted in 10 to 30 mL of infusion fluid, and given over 5 minutes. One additional dose may be given within 24 hours, but at least 10 minutes after the original infusion.
- The *BNFC* suggests that granisetron can also be given to children aged from 1 month; doses are as for those used in older children.

Oral granisetron may be given to children from 12 years of age; the adult dose can be used, see p. 1844.3.

Although not licensed in the UK, the *BNFC* recommends that similar intravenous doses to those given above can be used for both the treatment and prevention of radiotherapy-induced nausea and vomiting in children from 1 month and over.

Pain. For reference to the use of granisetron in various painful syndromes see under Uses and Administration of Ondansetron, p. 1873.1

Adverse Effects and Precautions

As for Ondansetron, p. 1873.2, although no dosage reduction is considered necessary in renal or hepatic impairment.

Carcinogenicity. The manufacturer (*Roche*) has reported an increased incidence of hepatic neoplasms in *rodents* given very high doses of granisetron for prolonged periods, but the clinical relevance of these results is unknown. Although mutagenicity and genotoxicity have not been seen in some tests, others have reported an increased incidence of polyploidy or unscheduled DNA synthesis in exposed cells.

Effects on the cardiovascular system. For a discussion of the effects of 5-HT_3 antagonists on the cardiovascular system, see under Ondansetron, p. 1873.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies granisetron as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Interactions

The metabolism of granisetron is induced by phenobarbital.

Pharmacokinetics

Granisetron is rapidly absorbed after oral doses and peak plasma concentrations occur after about 2 hours. Oral bioavailability is about 60% as a result of first-pass hepatic metabolism. Granisetron has a large volume of distribution of around 3 litres/kg; plasma protein binding is about 65%. The pharmacokinetics exhibit considerable interindividual variation, and the elimination half-life after an intravenous dose is reported to be around 4 to 5 hours in healthy subjects but about 9 to 12 hours in cancer patients. It is metabolised in the liver, primarily by *N*-demethylation, with less than 20% of a dose recovered unchanged in urine, the remainder being excreted in faeces and urine as metabolites. Granisetron clearance is not affected by renal impairment, but is lower in the elderly and in patients with hepatic impairment.

Hydrotalcite *(BAN, rINN)*

Hidrotalcita; Hidrotalsit; Hydrotalcit; Hydrotalcitum; Hydrotalsiitti; Гидротальцит.

Aluminium magnesium carbonate hydroxide hydrate.

$Mg_6Al_2(OH)_{16}CO_3.4H_2O$=604.0

CAS — 12304-65-3.

ATC — A02AD04.

ATC Vet — QA02AD04.

UNII — 17432CG1KU.

NOTE. Compounded preparations of hydrotalcite may be represented by the following names:

- *Co-simalcite x/y (BAN)*—where *x* and *y* are the strengths in milligrams of simeticone and hydrotalcite respectively.

Pharmacopoeias. In *Br.*

BP 2014: (Hydrotalcite). A hydrated form of an aluminium magnesium basic carbonate corresponding to the formula $Al_2Mg_6(OH)_{16}CO_3.4H_2O$. It contains not less than 15.3% and not more than 18.7% of Al_2O_3 and not less than 36.0% and not more than 44.0% of MgO. The ratio of Al_2O_3 to MgO is not less than 0.40 and not more than 0.45. A white or almost white, free-flowing, granular powder. Practically insoluble in water; it dissolves in dilute mineral acids with slight effervescence. A 4% suspension in water has a pH of 8.0 to 10.0.

Profile

Hydrotalcite is an antacid (see p. 1803.1) that is given in oral doses of up to about 1 g.

UNII — 451IF8OGX8.

NOTE. HYO is a code approved by the BP 2014 for use on single unit doses of eye drops containing hyoscine hydrobromide where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Hyoscine Hydrobromide). A white or almost white, efflorescent, crystalline powder or colourless crystals. Freely soluble in water; soluble in alcohol. A 5% solution in water has a pH of 4.0 to 5.5. Store in well-filled airtight containers of small capacity. Protect from light.

USP 36: (Scopolamine Hydrobromide). Colourless or white crystals, or white granular powder. Is odourless and slightly efflorescent in dry air. Soluble 1 in 1.5 of water and 1 in 20 of alcohol; slightly soluble in chloroform; insoluble in ether. pH of a 5% solution in water is between 4.0 and 5.5. Store in airtight containers. Protect from light.

Hyoscine Methobromide (BAN)

Epoxymethamine Bromide; Escopolamina, metilbromuro de; Hyoscine Methylbromide; Methscopolamine Bromide; Metilbromuro de hioscina; Metobromuro de escopolamina; Metobromuro de hioscina; Scopolamine Methobromide; Scopolamine Methylbromide; Гиосцина Метобромид.

(-)-(1*S*,3*s*,5*R*,6*R*,7*S*)-6,7-Epoxy-8-methyl-3-[(*S*)-tropoyloxy]tropanium bromide.

$C_{18}H_{24}BrNO_4$=398.3

CAS — 155-41-9.

ATC — A03BB03; S01FA03.

ATC Vet — QA03BB03; QS01FA03.

UNII — RTN51LK7WL.

Pharmacopoeias. In *US*.

USP 36: (Methscopolamine Bromide). Store in airtight containers. Protect from light.

Hyoscine Methonitrate (BANM)

Escopolamina, metilnitrato de; Hyoscine Methylnitrate; Methscopolamine Nitrate; Methylhyoscini Nitras; Methylscopolamine Nitrate; Methylscopolamini Nitras; Metilnitrato de hioscina; Metonitrato de escopolamina; Metonitrato de hioscina; Metylskopolaminnitrat; Metyylliskopolamiininitraatti; Scopolamine Methonitrate; Scopolamine Methylnitrate; Гиосцина Метонитрат.

(-)-(1*S*,3*s*,5*R*,6*R*,7*S*)-6,7-Epoxy-8-methyl-3-[(*S*)-tropoyloxy]tropanium nitrate.

$C_{18}H_{24}N_2O_7$=380.4

CAS — 6106-46-3.

ATC — A03BB03; S01FA03.

ATC Vet — QA03BB03; QS01FA03.

UNII — K0813KQM3V.

Uses and Administration

Hyoscine is a tertiary amine antimuscarinic with central and peripheral actions (see Action of Antimuscarinics, p. 1310.3). It is a more powerful suppressant of salivation than atropine, and usually slows rather than increases heart rate, especially in low doses. Its central action differs from that of atropine in that it depresses the cerebral cortex and produces drowsiness and amnesia. Hyoscine hydrobromide is also a tertiary amine, whereas hyoscine butylbromide, hyoscine methobromide, and hyoscine methonitrate are quaternary ammonium derivatives.

Hyoscine and hyoscine hydrobromide are used in the management of motion sickness and other forms of nausea and vomiting (below); hyoscine hydrobromide is also given as a premedicant in anaesthesia (below), and to produce mydriasis and cycloplegia (below). Hyoscine butylbromide and other quaternary ammonium derivatives are used in conditions associated with visceral spasms. Hyoscine methobromide has also been employed as an adjunct in the treatment of peptic ulcer disease (below).

Other hyoscine salts or derivatives that have been used include hyoscine borate, hyoscine hydrochloride, and hyoscine oxide hydrobromide.

Anaesthesia. The role of antimuscarinics, including hyoscine, in anaesthesia is discussed under Atropine on p. 1311.1. For the use of hyoscine in the prevention of postoperative nausea and vomiting, see below.

For premedication hyoscine hydrobromide is injected subcutaneously or intramuscularly in doses of 200 to 600 micrograms, usually with papaveretum about half to one hour before induction of general anaesthesia. In the UK, a dose of 15 micrograms/kg is licensed in children (the *BNFC* suggests that this dose is appropriate from 1 to 12 years of age; older children may be given the adult dose). If necessary for acute use, the same doses may be given by intravenous injection.

Anoxic seizures. For mention of the use of transdermal hyoscine as an alternative to atropine in the management of reflex anoxic seizures in children, see p. 1311.3.

Biliary and renal colic. Hyoscine has been used as an adjunct to opioid analgesics for symptomatic relief of biliary or renal colic (see p. 6.3) although the evidence for such use is weak. Hyoscine butylbromide 20 mg is given by intramuscular or slow intravenous injection; this may be repeated after 30 minutes if necessary to a maximum daily dose of 100 mg. See also Palliative Care, below.

References.

Cardiac disorders. Although hyoscine is not one of the conventional therapies for heart failure (p. 1262.3) or myocardial infarction (p. 1257.1), low-dose transdermal hyoscine can increase cardiac vagal activity and thereby reduce the autonomic imbalance seen in patients with these conditions.[1-3] Improved exercise tolerance has been reported after 1 week of treatment with transdermal hyoscine in a small open study in 14 patients with mild to moderate heart failure.[4]

1. Casadei B, *et al.* Low doses of scopolamine increase cardiac vagal tone in the acute phase of myocardial infarction. *Circulation* 1993; 88: 353–7.
2. La Rovere MT, *et al.* Scopolamine improves autonomic balance in advanced congestive heart failure. *Circulation* 1994; 90: 838–43.
3. Venkatesh G, *et al.* Double blind placebo controlled trial of short term transdermal scopolamine on heart rate variability in patients with chronic heart failure. *Heart* 1996; 76: 137–43.
4. De Vecchis R, *et al.* Different impact of carvedilol and transdermal scopolamine on cardiovascular performance of mild-moderate chronic heart failure patients: evidence of useful effects of scopolamine on tolerance to work load. *Minerva Cardioangiol* 2000; 48: 393–401.

Depression. Rapid reductions in severity of depression were seen after intravenous hyoscine hydrobromide 4 micrograms/kg was given to patients with major depressive disorders or bipolar disorders (see Depression, p. 398.1). Repeat doses showed more benefit than single doses. Clinical effects persisted beyond the treatment period, which led the authors to conclude the effects were not due to anticholinergic euphoria. While noting that the optimal schedule and potential long-term use of hyoscine as an antidepressant needed further study, they also concluded that hyoscine could be a relatively safe and well-tolerated intervention for achieving a rapid initial antidepressant response.[1]

1. Furey ML, Drevets WC. Antidepressant efficacy of the antimuscarinic drug scopolamine: a randomized, placebo-controlled clinical trial. *Arch Gen Psychiatry* 2006; 63: 1121–9.

Dysmenorrhoea. Hyoscine as the butylbromide or hydrobromide has been used for its antispasmodic action in the treatment of dysmenorrhoea. (p. 8.2), but the *BNF* considers that antispasmodics do not generally provide significant relief.

Eye disorders. Hyoscine hydrobromide is used in the eye for its mydriatic and cycloplegic actions (p. 2000.2) usually in a concentration of 0.25%. It has a faster onset and shorter duration of action than atropine although the effects may still persist for up to 3 to 7 days. It may be useful for patients who are hypersensitive to atropine.

Hyperhidrosis. Adverse effects of antimuscarinics given orally generally preclude their use by this route for the management of hyperhidrosis (p. 1685.1), but some, such as hyoscine, have been applied topically as alternatives to aluminium salts. Hyoscine hydrobromide applied as a 3% cream was successful in reducing gustatory sweating, consisting of flushing and sweating over the right mandible during eating, in a patient who had previously undergone surgical excision of the right submandibular salivary gland.[1] The use of transdermal or injectable hyoscine was reported[2] to be effective for the control of opioid-associated sweating in 2 patients receiving palliative care (see also below for other uses of hyoscine in palliative care).

1. Bailey BMW, Pearce DE. Gustatory sweating following submandibular salivary gland removal. *Br Dent J* 1985; 158: 17–18.
2. Mercadante S. Hyoscine in opioid-induced sweating. *J Pain Symptom Manage* 1998; 15: 214–15.

Nausea and vomiting. Hyoscine is effective in the prevention of **motion sickness** and is one of the principal drugs used. It may be given orally for short-term protection or by transdermal patch for a prolonged duration of action.

In the UK, a dose of hyoscine hydrobromide is taken 20 to 30 minutes before a journey, followed by the same dose every 6 hours if required up to a maximum of 3 doses in 24 hours. The usual dose in adults is 300 micrograms. Children aged 4 to 10 years may be given 75 to 150 micrograms and those over 10 years, 150 to 300 micrograms. Children aged 3 to 4 years may be given 75 micrograms, repeated once if necessary to a maximum total dose of 150 micrograms in 24 hours. Hyoscine is also given via a transdermal patch which is placed behind the ear and supplies 1 mg over 3 days. The patch is licensed in the UK for adults and children aged 10 years and over and should be applied 5 to 6 hours before travelling or on the preceding evening and removed at the end of the journey.

An intranasal formulation of hyoscine hydrobromide has been investigated for the treatment and prevention of motion sickness.

Transdermal hyoscine has been used in adults and children for the prevention of **postoperative nausea and vomiting.**

Hyoscine hydrobromide has also been given by intravenous, subcutaneous, or intramuscular injection for its antiemetic effect in doses ranging from 200 micrograms to 1 mg in adults.

The other drugs used in the management of motion sickness and postoperative nausea and vomiting are discussed on p. 1811.3.

Palliative care. The *BNF* includes doses for hyoscine in palliative care. *Hyoscine hydrobromide* is used in palliative care for the treatment of bowel colic and to reduce excessive respiratory secretions, although care should be taken to avoid the discomfort of a dry mouth. The following parenteral doses have been suggested for adults:

- 400 micrograms by subcutaneous injection, usually given every 4 hours when required, although hourly use is sometimes necessary

or

- 1.2 to 2 mg by continuous subcutaneous infusion over 24 hours

To reduce excessive respiratory secretions in children, the *BNFC* suggests parenteral doses of:

- 10 micrograms/kg (maximum 600 micrograms) by subcutaneous or intravenous injection every 4 to 8 hours

or

- 40 to 60 micrograms/kg by continuous subcutaneous or intravenous infusion over 24 hours

Oral and sublingual doses have also been suggested for children, according to age:

- 2 to 12 years: 10 micrograms/kg (maximum 300 micrograms) four times daily
- 12 to 18 years: 300 micrograms four times daily

Alternatively, hyoscine hydrobromide may be given as a transdermal patch in the following doses:

- 1 month to 3 years: 250 micrograms (quarter of a patch) every 72 hours
- 3 to 10 years: 500 micrograms (half a patch) every 72 hours
- 10 to 18 years: 1 mg (one patch) every 72 hours

Hyoscine has also been used transdermally in adults for reducing respiratory secretions; one regimen uses 2 to 4 mg (two to four patches) every 72 hours with additional parenteral doses of glycopyrronium bromide (see p. 2520.1).[1]

Hyoscine butylbromide is also used in palliative care; the *BNF* suggests the following doses for adults:

- bowel colic: 60 to 300 mg by continuous subcutaneous infusion over 24 hours
- excessive respiratory secretions: 20 to 120 mg by continuous subcutaneous infusion over 24 hours

or

- bowel colic and excessive respiratory secretions: 20 mg by subcutaneous injection, usually given every 4 hours when required, although hourly use is sometimes necessary

The use of hyoscine in palliative care has been reviewed.[2,3] Hyoscine hydrobromide may be more effective than glycopyrronium bromide in drying secretions, and has a rapid onset of action, but it can produce both sedation and agitation;[4] there is no clear evidence favouring one antimuscarinic over another.[4,5]

5. Wee B, Hillier R. Interventions for noisy breathing in patients near to death. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2008 (accessed 04/06/09).

Smooth muscle spasm. Hyoscine has been used as an antispasmodic (p. 1803.3) to relieve the pain of smooth muscle spasm associated with the gastrointestinal tract and genito-urinary tract. In adults, *hyoscine butylbromide* 20 mg

may be given orally four times daily; children aged 6 to 12 years may be given 10 mg three times daily. It is also used in adults with irritable bowel syndrome (p. 1810.3); the recommended oral starting dose is 10 mg three times daily which may be increased to 20 mg four times daily, if necessary. Hyoscine butylbromide may also be given by intramuscular or slow intravenous injection for acute spasm and as an antispasmodic in diagnostic procedures. Adults may be given a dose of 20 mg, repeated after 30 minutes if necessary, up to a maximum of 100 mg daily. Although hyoscine butylbromide injection is unlicensed in the UK for use in children, the *BNFC* suggests the following doses repeated after 30 minutes if necessary (but more frequently in endoscopy):

- 2 to 6 years: 5 mg (maximum 15 mg daily)
- 6 to 12 years: 5 to 10 mg (maximum 30 mg daily)
- 12 to 18 years: 20 mg (maximum 80 mg daily)

As an adjunct in the treatment of peptic ulcer disease; *hyoscine methobromide* has been licensed in the USA in a dose of 2.5 mg half an hour before meals and 2.5 to 5 mg at bedtime.

Urinary incontinence. Antimuscarinics have been used in the management of urge incontinence (p. 2349.2) but the incidence of adverse effects can be high. Results of a small study[1] suggested that transdermal hyoscine might be of benefit in females with detrusor instability.

Vertigo. Hyoscine has a long history of use in the management of vertigo, although other drugs are now preferred (p. 612.3).

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p. 1312.1 and p. 1312.2. In contrast to atropine, hyoscine produces central depression at therapeutic doses and symptoms include drowsiness and fatigue. Toxic doses of hyoscine produce stimulation of the CNS in a similar manner to atropine. However, hyoscine does not stimulate the medullary centres and therefore does not produce the increases in respiration rate or blood pressure seen with atropine. Hyoscine may produce CNS stimulation rather than depression at therapeutic doses if used in the presence of pain without opioid analgesics; symptoms include excitement, restlessness, hallucinations, or delirium.

Patients who experience drowsiness should not drive or operate machinery. Caution has been advised in elderly patients and in patients with impaired liver, or kidney function, as adverse CNS effects have been stated to be more likely in these patients. There have been rare reports of an increase in frequency of seizures in epileptic patients.

The quaternary derivatives, such as the butylbromide, methobromide, or methonitrate, do not readily cross the blood-brain barrier, so central effects are rare.

Abuse. Hyoscine has been used by criminals to incapacitate and produce anterograde amnesia in their victims in crimes such as drug-facilitated rape ('date rape'), robbery, and kidnapping. In some countries in South America there has been a particular problem with the use of powders or extracts of plants containing hyoscine for such crimes. A powder, known locally as burundanga, prepared from the borrachero or borracchio tree (also referred to as cacao sabanero) has been blown into the victim's face or given in drinks, chocolate, or chewing gum.

Breast feeding. The American Academy of Pediatrics[1] states that there have been no reports of any clinical effect on the infant associated with the use of hyoscine by breast-feeding mothers, and that therefore it may be considered to be usually compatible with breast feeding.

Effects on body temperature. Central anticholinergic syndrome was thought to be responsible for hyperthermia and consequent multi-organ failure in an adolescent with cerebral palsy who was receiving symptomatic treatment with transdermal hyoscine.[1] Although the condition was rare in children it should be considered in those being given antimuscarinics if fever developed, particularly in the absence of sweating.

1. Frampton A, Spinks J. Hyperthermia associated with central anticholinergic syndrome caused by a transdermal hyoscine patch in a child with cerebral palsy. *Emerg Med J* 2005; 22: 678–9.

Effects on the eyes. *ANISOCORIA.* Although bilateral mydriasis has occurred with the use of transdermal hyoscine, development of a unilateral fixed dilated pupil (anisocoria) may be due to contamination of a finger with hyoscine in handling the device, and then rubbing the eye.[1-6] Similarly, anisocoria has been attributed[7] to ocular contamination after handling broken hyoscine methobromide tablets.

Effects on the oesophagus. A patient developed pain on swallowing after 4 days of treatment with hyoscine. Endoscopy showed oesophageal ulceration, which healed completely after 8 weeks of esomeprazole treatment.[1]

1. Philcox S, Keegan A. A case of hyoscine-related oesophagitis. *Med J Aust* 2007; 186: 650–1.

Effects on the skin. Contact dermatitis occurred in 16 men being treated for seasickness with transdermal hyoscine for 6 weeks to 15 months.[1]

1. Gordon CR, *et al.* Allergic contact dermatitis caused by transdermal hyoscine. *BMJ* 1989; 298: 1220–1.

Migraine. A small case-control study[1] suggested that hyoscine could trigger or exacerbate migraine in patients with a history of the condition.

1. Ikeda K, *et al.* Scopolamine-induced migraine like headache. *Intern Med* 2009; 48: 681–5.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies hyoscine butylbromide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pregnancy. A report[1] of hyoscine toxicity in a neonate born to a mother who had received a total of 1.8 mg of hyoscine in divided doses with pethidine and levorphanol before delivery. The neonate was lethargic, barrel chested, and had a heart rate of 200 beats/minute. Symptoms subsided when physostigmine 100 micrograms was given intramuscularly.

1. Evens RP, Leopold JC. Scopolamine toxicity in a newborn. *Pediatrics* 1980; 66: 329–30.

Withdrawal. A withdrawal syndrome of dizziness and nausea[1,2] can occur in patients who have used transdermal hyoscine patches for several days; hypersalivation and diarrhoea has also been described.[3] In reported cases, transdermal hyoscine had been used continuously for 7 or 10 days to prevent motion sickness. Symptoms usually begin 2 or 3 days after the last patch has been removed, and may last for a few days.

3. Feder RE. Transdermal scopolamine withdrawal syndrome. *Clin Neuropharmacol* 1999; 22: 120.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

The sedative effect of hyoscine may be enhanced by alcohol or other CNS depressants.

Pharmacokinetics

Hyoscine is readily absorbed from the gastrointestinal tract after oral doses of the hydrobromide. It is almost entirely metabolised, probably in the liver; only a small proportion of an oral dose is excreted unchanged in the urine. It crosses the blood-brain barrier and has been stated to cross the placenta. Hyoscine is also well absorbed after application to the skin.

The quaternary derivatives, such as the butylbromide or methobromide, are poorly absorbed from the gastrointestinal tract and do not readily pass the blood-brain barrier.

Pharmacopoeial Preparations

BP 2014: Hyoscine Butylbromide Injection; Hyoscine Butylbromide Tablets; Hyoscine Eye Drops; Hyoscine Injection; Hyoscine Tablets;

USP 36: Methscopolamine Bromide Tablets; Scopolamine Hydrobromide Injection; Scopolamine Hydrobromide Ophthalmic Ointment; Scopolamine Hydrobromide Ophthalmic Solution; Scopolamine Hydrobromide Tablets.

Hyoscyamine *(BAN)*

Hiosciamina; Hyoscyamin; (-)-Hyoscyamine; *l*-Hyoscyamine; Hyoscyaminum; Hyoskyamiini; Гиосциамин.

(-)-(1*R*,3*r*,5*S*)-Tropan-3-yl (*S*)-tropate.

$C_{17}H_{23}NO_3$=289.4

CAS — 101-31-5.

ATC — A03BA03.

ATC Vet — QA03BA03.

UNII — PX44XO846X.

Description. Hyoscyamine is an alkaloid obtained from various solanaceous plants. It is the laevo-isomer of atropine into which it can be converted by heating or by the action of alkali.

Pharmacopoeias. In *US.*

USP 36: (Hyoscyamine). A white crystalline powder. M.p. 106 degrees to 109 degrees. Slightly soluble in water and in benzene; freely soluble in alcohol, in chloroform, and in dilute acids; sparingly soluble in ether. Its solutions are alkaline to litmus. Store in airtight containers. Protect from light.

Hyoscyamine Hydrobromide *(BANM)*

Bromidrato de Hiosciamina; Hiosciamina, hidrobromuro de; Hyoscyamine Bromhydrate; Гиосциамина Гидробромид.

$C_{17}H_{23}NO_3$,HBr=370.3

CAS — 306-03-6.

ATC — A03BA03.

ATC Vet — QA03BA03.

UNII — JWT5OP9S79.

Pharmacopoeias. In *US.*

USP 36: (Hyoscyamine Hydrobromide). White, odourless crystals or crystalline powder. M.p. not less than 149 degrees. Freely soluble in water; soluble 1 in 2.5 of alcohol, 1 in 1.7 of chloroform, and 1 in 2300 of ether. pH of a 5% solution in water is about 5.4. Store in airtight containers. Protect from light.

Hyoscyamine Sulfate *(BANM)*

Hiosciamina, sulfato de; Hiosciamino sulfatas; Hioscyjaminy siarczan; Hioszciamin-szulfát; Hyoscyamin sulfát dihydrát; Hyoscyamine, sulfate d'; Hyoscyamine Sulphate; Hyoscyamini sulfas; Hyoscyamini Sulfas Dihydricus; Hyoscyaminsulfat; Hyoscyaminum Sulfuricum; Hyoskyamiinisulfaatti; Iosciamina Solfato; Гиосциамина Сульфат.

$(C_{17}H_{23}NO_3)_2,H_2SO_4,2H_2O$=712.9

CAS — 620-61-1 (anhydrous hyoscyamine sulfate); 6835-16-1 (hyoscyamine sulfate dihydrate).

ATC — A03BA03.

ATC Vet — QA03BA03.

UNII — F2R8V82B84.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Hyoscyamine Sulfate). A white or almost white, crystalline powder or colourless needles. Very soluble in water; sparingly soluble or soluble in alcohol. A 2% solution in water has a pH of 4.5 to 6.2. Store in airtight containers. Protect from light.

USP 36: (Hyoscyamine Sulfate). A white or almost white, crystalline powder or colourless needles. It is deliquescent and affected by light. Soluble 1 in 0.5 of water and 1 in 5 of alcohol; practically insoluble in ether. pH of a 1% solution in water is about 5.3.

Uses and Administration

Hyoscyamine is a tertiary amine antimuscarinic with the actions of atropine (which is racemic hyoscyamine, see p. 1312.1); hyoscyamine, the laevo-isomer, has about twice the potency of atropine since the dextro-isomer has only very weak antimuscarinic activity. Hyoscyamine is used mainly in the relief of conditions associated with visceral spasm. It has also been given for rhinitis and was formerly used in the treatment of parkinsonism.

Hyoscyamine is given in usual oral doses of 150 to 300 micrograms up to four times daily, but it is more usually employed as the sulfate; the hydrobromide is also used. Suggested doses of hyoscyamine sulfate are 125 to 250 micrograms orally or sublingually every four hours as needed, up to a maximum of 1.5 mg in 24 hours. Modified-release oral preparations of hyoscyamine sulfate are available in some countries; dosage is specific to a particular formulation. Hyoscyamine sulfate has also been given by injection.

Homoeopathy

Hyoscyamine hydrobromide has been used in homoeopathic medicines under the following names: Hyoscyaminum hydrobromatum.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p. 1312.1 and p. 1312.2.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Denm.*: Egazil; *Hong Kong*: Levsin; *Norw.*: Egazil; *Swed.*: Egazil; *USA*: Anaspaz†; Cystospaz†; Donnamar; ED-SPAZ; Gastrosed; HyoMax; IB-Stat†; Levbid; Levsin; Levsinex†; Mar-Spas; Neosol†; NuLev; Oscimin; Symax.

Multi-ingredient Preparations. *Austral.*: Donnagel; Donnalix; Donnatab; *Braz.*: Neogrein; Ormigrein; Tropinal; *Indon.*: Aludonna; Feminax†; *S.Afr.*: Donnatal†; Millerspas†; *USA*: Alkabel; Antispasmodic Elixir; Atrosept; Bellacane; Bellahist-D; Bellatal; Darpaz†; Digex NF; Digext†; Donnatal; Hyophen; Hyosophen; MHP-A; MSP-Blu; PB-Hyos; PhenazoForte Plus; Phenazopyridine Plus; Phosphasal; Prosed/DS; Pyrelle HB†; Pyridium Plus; Quadrapax; Se-Donna PB HYOS; Servira; Stahist; Susano; Trellium Plus†; UAA; Urelief Plus; Urelle; Uretron; Urimar-T; Urimax; Uriseptic; Uritact; Uro Blue; Urogesic Blue; Uryl; Ustell; Uticap; Utira; Utrona-C.

Pharmacopoeial Preparations

USP 36: Hyoscyamine Sulfate Elixir; Hyoscyamine Sulfate Injection; Hyoscyamine Sulfate Oral Solution; Hyoscyamine Sulfate Tablets; Hyoscyamine Tablets.

Ilaprazole *(rINN)*

Gilaprazole; Ilaprazol; Ilaprazolum; IY-81149; Илапразол.

2-[(*RS*)-[(4-Methoxy-3-methylpyridin-2-yl)methyl]sulfinyl]-5-(1*H*-pyrrol-1-yl)-1*H*-benzimidazole.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *China*: Yi Li An (意丽安).

Indisetron Hydrochloride *(rINNM)*

Hidrocloruro de indisetrón; Indisétron, Chlorhydrate d'; Indisetron Dihydrochloride; Indisetroni Hydrochloridum; N-3389; Индисетрона Гидрохлорид.

N-(3,9-Dimethyl-*endo*-3,9-diazabicyclo[3.3.1]non-7-yl)-1*H*-indazole-3-carboxamide dihydrochloride.

$C_{17}H_{23}N_5O$,2HCl=386.3

CAS — 141549-75-9 (indisetron); 160472-97-9 (indisetron dihydrochloride).

UNII — NBN3HB12DW.

Profile

Indisetron is a 5-HT_3-receptor antagonist with general properties similar to those of ondansetron (p. 1872.1); it is also stated to be an antagonist at 5-HT_4 receptors. Indisetron hydrochloride is used as an antiemetic in the management of nausea and vomiting associated with chemotherapy.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Sinseron.

Irsogladine Maleate *(rINNM)*

Irsogladina, maleato de; Irsogladine, Maléate d'; Irsogladini Maleas; Maleato de irsogladina; MN-1695; Ирсогладина Малеат.

2,4-Diamino-6-(2,5-dichlorophenyl)-*S*-triazine maleate.

$C_9H_7Cl_2N_5.C_4H_4O_4$=372.2

CAS — 57381-26-7 (irsogladine); 84504-69-8 (irsogladine maleate).

Profile

Irsogladine maleate is a cytoprotective drug that is used in the treatment of peptic ulcer disease (p. 1813.2) in a usual oral dose of 4 mg daily. It has also been investigated for mucositis and mouth ulceration.

References.

Single-ingredient Preparations. *China*: Gaslon N (盖世龙); Hengzhi (恒至); Ke Ma Nuo (科玛诺); Yi Ge Ding (一格定); *Jpn*: Gaslon N.

Isopropamide Iodide *(BAN, rINN)*

Ioduro de isopropamida; Isopropamida, ioduro de; Isopropamide, Iodure d'; Isopropamidi Iodidum; Изопропамида Йодид.

(3-Carbamoyl-3,3-diphenylpropyl)di-isopropylmethylammonium iodide.

$C_{23}H_{33}IN_2O$=480.4

CAS — 7492-32-2 (isopropamide); 71-81-8 (isopropamide iodide).

ATC — A03AB09.

ATC Vet — QA03AB09.

UNII — E0KNA372SZ.

Pharmacopoeias. In *US.*

USP 36: (Isopropamide Iodide). A white to pale yellow crystalline powder. Soluble 1 in 50 of water, 1 in 10 of alcohol, and 1 in 5 of chloroform; very slightly soluble in ether and in benzene. Protect from light.

Profile

Isopropamide iodide is a quaternary ammonium antimuscarinic with peripheral effects similar to those of atropine (p. 1312.1). It has been used as an adjunct in the treatment of peptic ulcer disease, in the relief of gastrointestinal and

urinary-tract disorders associated with smooth muscle spasm, in rhinitis, and for the relief of symptoms of colds.

Isopropamide bromide has been used similarly.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Gr.*: Raspon.

Multi-ingredient Preparations. *India*: Gastabid; *Ital.*: Influmed C; Influmed; Raffreddoremed; Valtrax; *Mex.*: Stelabid.

Pharmacopoeial Preparations
USP 36: Isopropamide Iodide Tablets.

Ispaghula

Egyiptomi útifűmag (ispaghula seed); Egyiptomi útifűmaghéj (ispaghula husk); Ispaghul; graine d' (ispaghula seed); Ispaghul (graine d'), tégument de la (ispaghula husk); Ispagula; Ispagula Kabuğu; Ispagulafrö (ispaghula seed); Ispagulafröskal (ispaghula husk); Ispagulansiemen (ispaghula seed); Ispagulansiemenkuori (ispaghula husk); Kepek; Kiaušininių gysločių sėklų luobelės (ispaghula husk); Kiaušininių gysločių sėklos (ispaghula seed); Łupina nasienna babki jajowatej (ispaghula husk); Nasienie babki jajowatej (ispaghula seed); Osemení jitrocele vejčitého (ispaghula husk); Plantaginis ovatae semen (ispaghula seed); Plantaginis ovatae seminis tegumentum (ispaghula husk); Psilio; Semeno jitrocele vejčitého (ispaghula seed); Zaragatona; Шелуха Исфарулы (ispaghula husk).

ATC Herb — HA06AC5010 (Plantago ovata: *seed husk*).

UNII — UD50RBY30F (Plantago ovata *seed*); *0SHC53407G* (*psyllium husk*); *NU5XN4136K* (Plantago ovata *seed coat*).

Pharmacopoeias. Monographs for the husk and seed are included in *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Ispaghula Husk; Plantaginis Ovatae Seminis Tegumentum). The episperm and collapsed adjacent layers removed from the seeds of *Plantago ovata* (*P. ispaghula*). The powdered drug loses not more than 12.0% of its weight on drying. Protect from light.

Ph. Eur. 8: (Ispaghula Seed; Plantaginis Ovatae Semen). The dried ripe seeds of *Plantago ovata* (*P. ispaghula*). The powdered drug loses not more than 10.0% of its weight on drying. Protect from light.

USP 36: (Psyllium Husk). The cleaned, dried seed coat (epidermis), in whole or in powdered form, separated by winnowing and threshing from the seeds of *Plantago ovata* (known in commerce as Blond Psyllium, Indian Psyllium, or Ispaghula), or from *Plantago arenaria* (*Plantago psyllium*), known in commerce as Spanish or French Psyllium.

USP 36: (Plantago Seed). The cleaned, dried, ripe seed of *Plantago ovata*, or of *Plantago psyllium*, or of *Plantago indica* (*P. arenaria*).

Psyllium Hemicellulose *(USAN)*

CAS — 9034-32-6.
UNII — Y2HNG56689.

Pharmacopoeias. In *US*.

USP 36: (Psyllium Hemicellulose). The alkali soluble fraction of the husk from *Plantago ovata* consisting of highly substituted arabinoxylan polysaccharides. These polysaccharides are linear chains of xylose units to which are attached single units of arabinose and additional xylose. Rhamnose, galactose, glucose, and rhamnosyluronic acid residues are also present as minor constituents. It contains not less than 75.0% of dietary soluble fibre, calculated on the dried basis. Store in airtight containers at a temperature of 25 degrees, excursions permitted between 15 degrees and 30 degrees.

Psyllium Seed

Blešníkové semeno; Bolhafúmag; Flea Seed; Flohsamen; Loppfrö; Nasienie plesznika; Psilio, semilla de; Psyllii semen; Psyllium, graine de; Psylliumínsiemen; Smiltyninių gysločių sėklos.

ATC — A06AC01.

ATC Vet — QA06AC01.

ATC Herb — HA06AC5008 (Plantago afra: *seed*); *HA07BW5004* (Plantago ovata: *seed*); *HA06AC5009* (Plantago ovata: *seed*); *HA07BW5003* (Plantago afra: *seed*).

UNII — 9C60Y73166.

Pharmacopoeias. In *Eur.* (see p. vii). Also in *US* under the title of Plantago Seed.

Ph. Eur. 8: (Psyllium Seed). The ripe, whole, dry seeds of *Plantago afra* (*P. psyllium*) or *Plantago indica* (*P. arenaria*). It loses not more than 14.0% of its weight on drying. Protect from light and moisture.

USP 36: (Plantago Seed). The cleaned, dried, ripe seed of *Plantago ovata*, or of *Plantago psyllium*, or of *Plantago indica* (*P. arenaria*) (see also Ispaghula, above).

Uses and Administration

Ispaghula seed, ispaghula husk, and psyllium seed are bulk laxatives (p. 1804.1). They absorb water in the gastrointestinal tract to form a mucilaginous mass which increases the volume of faeces and hence promotes peristalsis. They are used in the treatment of constipation (p. 1804.3), especially in diverticular disease (p. 1806.2) and irritable bowel syndrome (p. 1810.3), and when excessive straining at stool must be avoided, for example after anorectal surgery or in the management of haemorrhoids. The ability to absorb water and increase faecal mass means that they may also be used in the management of diarrhoea (p. 1805.2) and for adjusting faecal consistency in patients with colostomies.

The usual oral dose is about 3.5 g one to three times daily, although higher doses have been given. It should be taken immediately after mixing in at least 150 mL water or fruit juice. The full effect may not be achieved for up to 3 days. For doses in children, see below.

Ispaghula is also given for mild to moderate hypercholesterolaemia as an adjunct to a lipid-lowering diet. The recommended dose is about 7.5 to 10 g daily.

Administration in children. Ispaghula husk can be given orally to treat constipation in children; doses vary slightly according to the preparation used. A typical preparation (*Fybogel; Reckitt Benckiser, UK*), which contains ispaghula husk 1.75 g per level 5-mL spoonful, recommends children aged 12 years and under be given ½ to 1 level 5-mL spoonful dissolved in water twice daily. The *BNFC* recommends the same dose, but restricts the use of ispaghula husk to children aged 6 years and over. Children aged 12 years and over are usually given adult doses, see above.

Hyperlipidaemias. Preparations of ispaghula have been reported[1-4] to lower serum-cholesterol concentrations in patients with mild to moderate hypercholesterolaemia. They have also been given with reduced doses of a bile-acid binding resin in the treatment of hyperlipidaemia,[5] which is reported to be effective and better tolerated than full doses of the resin alone. Similarly, psyllium supplementation with 10 mg of simvastatin was found to be as effective in lowering cholesterol as 20 mg of simvastatin alone.[6] However, ispaghula or psyllium should be regarded as adjuncts to dietary modification rather than substitutes for it. For a discussion of the hyperlipidaemias and their management, see p. 1248.1.

Adverse Effects and Precautions

Large quantities of ispaghula and other bulk laxatives may temporarily increase flatulence and abdominal distension; hypersensitivity reactions have been reported. There is a risk of intestinal or oesophageal obstruction and faecal impaction, especially if such compounds are taken with insufficient fluid. Therefore, they should always be taken with at least 150 mL of water or other liquid. Ispaghula and bulk laxatives should not be taken immediately before going to bed because reduced gastric motility may impair intestinal passage and cause obstruction. They should be avoided by patients who have difficulty swallowing.

Bulk laxatives should not be given to patients with pre-existing faecal impaction, intestinal obstruction, or colonic atony.

Hypersensitivity. Hypersensitivity reactions associated with the ingestion or inhalation of ispaghula or psyllium have been reported.[1-9] Symptoms have included rash, rhinitis, urticaria, bronchospasm, and anaphylactic shock; in one case, anaphylaxis was fatal.[9] In most patients, sensitisation was thought to have occurred during occupational exposure.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies ispaghula as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 10/10/11)

Interactions

Ispaghula and other bulk-forming laxatives may delay or reduce the gastrointestinal absorption of other drugs such as cardiac glycosides, coumarin derivatives, lithium, or vitamins (such as vitamin B_{12}) and minerals (such as calcium, iron, or zinc). Intervals of 30 minutes to 1 hour are recommended between ispaghula and other drugs or food, although some recommend as much as 3 hours between bulk-forming laxatives and other drugs. The dose of insulin may need to be reduced in diabetic patients taking ispaghula.

Lithium. For reference to ispaghula possibly reducing the absorption of lithium, see Gastrointestinal Drugs, p. 432.2.

USP 36: Psyllium Hydrophilic Mucilloid for Oral Suspension.

Itopride Hydrochloride *(rINNM)*

HC-803; Hidrocloruro de itoprida; HSR-803; Itoprida, hidrocloruro de; Itopride, Chlorhydrate d'; Itopridi Hydrochloridum; Итоприда Гидрохлорид.
N-[*p*-[2-(Dimethylamino)ethoxy]benzyl]veratramide hydrochloride.
$C_{20}H_{26}N_2O_4,HCl$=394.9
CAS — 122898-67-3 (itopride).
UNII — 2H9NV66W0I.

Profile

Itopride hydrochloride is a substituted benzamide with general properties similar to those of metoclopramide (p. 1862.2) that has been used for its prokinetic and antiemetic actions in oral doses of 50 mg three times daily before meals.

References.

UNII — 24H4NWX5CO.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.* Some pharmacopoeias do not differentiate between the heavy and light varieties.

Ph. Eur. 8: (Kaolin, Heavy). A purified, natural, hydrated aluminium silicate of variable composition. It is a fine, white or greyish-white, unctuous powder. Practically insoluble in water and in organic solvents.

BP 2014: (Light Kaolin). A native hydrated aluminium silicate, freed from most of its impurities by elutriation, and dried. It contains a suitable dispersing agent. It is a light, white, odourless or almost odourless, unctuous powder free from gritty particles. Practically insoluble in water and in mineral acids.

The BP 2014 directs that when Kaolin or Light Kaolin is prescribed or demanded, Light Kaolin shall be dispensed or supplied, unless it is ascertained that Light Kaolin (Natural) is required.

BP 2014: (Light Kaolin (Natural)). It is Light Kaolin which does not contain a dispersing agent. It is a light, white, odourless or almost odourless, unctuous powder free from gritty particles. Practically insoluble in water and in mineral acids.

The BP 2014 directs that when Kaolin or Light Kaolin is prescribed or demanded, Light Kaolin shall be dispensed or supplied, unless it is ascertained that Light Kaolin (Natural) is required.

USP 36: (Kaolin). A native hydrated aluminium silicate, powdered and freed from gritty particles by elutriation. It is a soft, white or yellowish-white powder or lumps with an earthy or clay-like taste and when moistened with water assumes a darker colour and develops a marked clay-like odour. Insoluble in water, in cold dilute acids, and in solutions of alkali hydroxides.

Profile

Light kaolin and light kaolin (natural) are adsorbent antidiarrhoeal agents that have been used as adjuncts to rehydration therapy in the management of diarrhoea (p. 1805.2). Up to about 24 g daily may be taken orally in divided doses. Kaolin is often combined with other antidiarrhoeals, especially pectin.

Kaolin can form insoluble complexes with some drugs in the gastrointestinal tract and reduce their absorption; oral doses should not be taken at the same time.

Externally, light kaolin is used as a dusting powder. Kaolin is liable to be heavily contaminated with bacteria, and when used in dusting powders, it should be sterilised.

Heavy kaolin is used in the preparation of kaolin poultice, which is applied topically with the intention of reducing inflammation and alleviating pain (see Rubefacients and Topical Analgesia, p. 6.3).

Light kaolin is also used as a food additive.

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Fr.*: Elusanes Calmodiger†; *UK*: Childrens Diarrhoea Mixture; Entrocalm.

Multi-ingredient Preparations. *Arg.*: Anusol-A; Argeal; Cleanance; Opocarbon; *Austral.*: Diarcalm†; Donnagel; *Belg.*: Alopate; Neutroses; Restofit; *Braz.*: Gastrobene; Kaomagma; *Chile*: Argeal; Furazolidona; Normaderm Concentrado Activo; *Fr.*: Argeal; Gastropax; Kaobrol; Kaologeais†; Kaomuth; Karayal; Keracnyl; Neutroses; Supro; *Gr.*: Enteromyk; Fissan-Pate; Kaopectate; Polypictine; *Hong Kong*: Diapectin†; Kaopectin; Pectolin†; Uni-Kaotin; *Hung.*: Bolus Adstringens; Bolus Laxans; Pasta Cool; *Indon.*: Diaend; Envios; Kaopectate†; Neo Diaform; Neo Kaocitin; Neo Kaolana; Neo Kaominal; Opidiar; *Israel*: Kaopectin; Zincod; *Ital.*: Katoxyn; Keromicil; Neutrose S Pellegrino; Streptomagma; *Mex.*: Ameban; Caopectar†; Colfur†; Colistin Magma†; Coralzul; Depofin; Dia-Par Compuesto; Dibapec Compuesto†; Estibal; Exofur; Facetin-D; Farpectol; Furoxona CP; Isocar; K-Omistron; Kaomycin†; Kaopectate†; Kapecfuran; Kediar; Lactopectin†; Neokap; Neoxil; Nineka; Olam†; Optazol; Quimefuran; Suyodil; Treda; Yodozona; *S.Afr.*: Adco-Biskapect†; Betapect; Bipectinol†; Bolus Eucalypti Comp†; Chloropect; Collodene†; Enterolyte; Gastropect; Kaostatex; Pectin-K†; Pectrolyte; SB Diarrhoea Mixture†; *Singapore*: Axcel Kaopec; Beakopectin; Bio-Taches Masque†; Diapectin; Kaomix; Pectolin; *Switz.*: Cicafissan; Creme vulneraire; Neo-Decongestine; Neutroses; Padma-Lax; Padmed Laxan; Phlogantin†; *Thai.*: Alkamine†; Alumag; Alupep; Cenopect†; Coccila; Coccila; Conmag; Diaropect; Difuran; Diocin; Disento PF; Disento; Droximag-P; Puramed; Furasian; Furopectal; Furopectin; Kaolin Mixture w/ Pectin; Kaolin Mixture; Kaopectal; Kaptate; Patarlin; Profura; Siemag; Suratin; *UAE*: Kaptin; *UK*: Collis Browne's; De Witt's Antacid; Junior Kao-C; KLN; Moorland; Opazimes; *USA*: K-C; Kao-Paverin; Kao-Spen; Kaodene Non-Narcotic; Mexsana; *Venez.*: Argeal; Klincosal; Niosilin.

Homoeopathic Preparations. *Ger.*: Phonix Silybum spag; Phonix Solidago spag; Phonix Thuja-Lachesis spag; Phonix Urtica-Arsenicum spag; *Neth.*: Phonix Hydrargyrum; *UK*: Bolus Eucalypti Comp.

Pharmacopoeial Preparations
BP 2014: Kaolin and Morphine Mixture; Kaolin Mixture; Kaolin Poultice.

Lactitol *(BAN, rINN)*

E966; β-Galactosido-sorbitol; Lactit; Lactitolum; Lactobiosit; Lactositol; Laktitol; Laktitoli; Laktitolis; Лактитол.
4-*O*-(β-D-Galactopyranosyl)-D-glucitol.
$C_{12}H_{24}O_{11}$=344.3
CAS — 585-86-4.
ATC — A06AD12.
ATC Vet — QA06AD12.
UNII — L2B0WJF7ZY (lactitol); UH2K6W1Y64 (lactitol monohydrate).

Pharmacopoeias. In *USNF*. *Eur.* (see p. vii) includes the monohydrate.

Ph. Eur. 8: (Lactitol Monohydrate). A white or almost white crystalline powder. Very soluble in water; slightly soluble in alcohol; practically insoluble in dichloromethane.

USNF 31: (Lactitol). It may be the anhydrous form, the monohydrate, or the dihydrate. White or light brown odourless, crystals. It has a mild, sweet taste, and no aftertaste.

Profile

Lactitol is a disaccharide analogue of lactulose (below) and has similar actions and uses.

Lactitol monohydrate is used as an oral powder or solution in the management of hepatic encephalopathy (p. 1808.2) and in constipation (p. 1804.3). Lactitol monohydrate 1.05 g is equivalent to about 1 g of anhydrous lactitol.

In the treatment of **hepatic encephalopathy**, lactitol monohydrate is given in usual oral doses of 500 to 700 mg/kg daily in 3 divided doses at meal times. The dose is subsequently adjusted to produce 2 soft stools daily.

In the treatment of **constipation**, lactitol monohydrate is given in an initial dose of 20 g daily as a single dose with the morning or evening meal, subsequently adjusted to produce one stool daily. A dose of 10 g daily may be sufficient for many patients.

Doses should be mixed with food or liquid, and 1 to 2 glasses of liquid should be drunk with the meal.

Lactitol is a permitted sweetener in foods.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies lactitol as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Austria*: Importal; *Belg.*: Importal; Normolaxil†; Portolac†; *Braz.*: Sigmalac; *China*: Kang Xin (康欣); *Fin.*: Importal Ex-Lax†; Lalax†; *Fr.*: Importal; *Ger.*: Importal†; *Gr.*: Importal; *India*: Encelax; Eva-Q; Lactihep; *Israel*: Novolax; *Ital.*: Portolac; *Jpn*: Portolac; *Neth.*: Importal; *NZ*: Importal; *Port.*: Importal; *Rus.*: Exportale (Экспортал); *Spain*: Emportal; Oponaf; *Swed.*: Importal; *Switz.*: Importal; *Thai.*: Importal†; *Turk.*: Importal.

Multi-ingredient Preparations. *India*: Lactifiber; *Ital.*: Levoplus.

Lactulose *(BAN, USAN, rINN)*

Lactulosa; Lactulosum; Laktuliozė; Laktuloosi; Laktulos; Laktulosa; Laktuloz; Laktulóz; Лактулоза.
4-*O*-β-D-Galactopyranosyl-D-fructose.
$C_{12}H_{22}O_{11}$=342.3
CAS — 4618-18-2.
ATC — A06AD11.
ATC Vet — QA06AD11.
UNII — 9U7D5QHSAE.

Pharmacopoeias. In *Eur.* (see p. vii) and *Jpn*. *Chin.* only contains specifications for a solution. *US* only contains specifications for a solution and a concentrated liquid.

Ph. Eur. 8: (Lactulose). A white or almost white, crystalline powder. Freely soluble in water; sparingly soluble in methyl alcohol; practically insoluble in toluene.

Ph. Eur. 8: (Lactulose, Liquid; Lactulose Solution BP 2014). An aqueous solution of lactulose. It contains not less than 62.0% w/v of lactulose; it may contain other sugars including lactose, epilactose, galactose, tagatose, and fructose. It may contain a suitable antimicrobial preservative. It is a clear, colourless or pale brownish-yellow, viscous liquid. Miscible with water. It may be a supersaturated solution or may contain crystals that disappear on heating. A 10.0% solution in water has a pH of 3.0 to 7.0.

USP 36: (Lactulose Concentrate). A colourless to amber syrupy liquid that may exhibit some precipitation and

darkening on standing. Miscible with water. Store in airtight containers preferably at a temperature between 2 degrees and 30 degrees.

Uses and Administration

Lactulose is a synthetic disaccharide osmotic laxative (p. 1804.1) used in the treatment of constipation (p. 1804.3) and in hepatic encephalopathy (p. 1808.2). Lactulose is broken down by colonic bacteria mainly into lactic acid. This exerts a local osmotic effect in the colon resulting in increased faecal bulk and stimulation of peristalsis. It may take up to 48 hours before an effect is obtained. When larger doses are given for hepatic encephalopathy the pH in the colon is reduced significantly and the absorption of ammonium ions and other toxic nitrogenous compounds is decreased, leading to a fall in blood-ammonia concentration and an improvement in mental function.

Lactulose is usually given orally as a solution containing about 3.35 g of lactulose per 5 mL, with other sugars such as galactose and lactose; an oral powder formulation is also available in some countries. In the treatment of **constipation**, the usual initial dose is 10 to 20 g (15 to 30 mL) given daily in a single dose or in 2 divided doses; doses up to 45 mL daily of the solution (or up to 40 g of the reconstituted oral powder formulation) have been given. The dose is gradually adjusted according to the patient's needs. For doses in children, see below.

In **hepatic encephalopathy**, an oral dose of 60 to 100 g (90 to 150 mL) is given daily in 3 divided doses. The dose is subsequently adjusted to produce 2 or 3 soft stools each day. Lactulose solution 200 g (300 mL) mixed with 700 mL of water or sodium chloride 0.9% has been used as a retention enema; the enema is retained for 30 to 60 minutes, repeated every 4 to 6 hours until the patient is able to take oral medication.

Administration in children. In the UK, children may be given the following oral doses of lactulose 3.35 g per 5 mL solution for constipation; doses may be adjusted according to response:

- 1 month to 1 year: 2.5 mL twice daily
- 1 to 5 years: 5 mL twice daily
- 5 to 10 years: 10 mL twice daily
- 10 to 18 years: 15 mL twice daily

Diagnosis and testing. *THE SUGAR ABSORPTION TEST.* In healthy individuals lactulose is largely unabsorbed from the gastrointestinal tract, but in, for example, coeliac disease there is increased permeability to disaccharides such as lactulose and a paradoxical decrease in the absorption of monosaccharides. This led to the development of the differential sugar absorption test in which 2 sugars are given simultaneously by mouth and the urinary recovery of each is determined; mannitol is commonly used as the monosaccharide component and lactulose as the disaccharide. Alternatives include mannitol plus cellobiose and rhamnose plus lactulose. This absorption test is useful in the investigation of intestinal disease.[1]

The lack of a standardised test solution has hampered comparison of test results. Although hyperosmolar solutions are better at determining intestinal damage,[2] some have preferred to use low osmolar solutions because of the risk of inducing osmotic diarrhoea, especially in children.

A study found the sugar absorption test to be strongly predictive of an organic cause of chronic diarrhoea; it may be useful in improving the selection of patients who need further evaluation.[3]

THE LACTULOSE BREATH TEST (hydrogen breath test). Lactulose is converted by bacteria in the large bowel to short chain fatty acids with the production of small quantities of hydrogen gas. The hydrogen is rapidly absorbed and is exhaled in the breath and measurement of its production is used to measure orocaecal transit time and carbohydrate malabsorption. However, even small doses of lactulose shortens transit time, which may limit the value of this test.[4]

The test is also diagnostic for bacterial overgrowth in the small intestine, which is increased in irritable bowel syndrome. Although hydrogen is produced in most subjects, methane is also produced in up to 50% of healthy subjects, and data suggest there may be clinical implications to different gas profiles. A study found that the presence of methane was associated with constipation, and with constipation-predominant irritable bowel syndrome. Methane production was infrequent in diarrhoea-predominant irritable bowel syndrome and virtually absent in inflammatory bowel disease. Diarrhoea and inflammatory bowel disease were associated with hydrogen production. Whether the type of bacterial flora causally determines symptoms is as yet unknown.[5] The diagnostic value of the test in irritable bowel syndrome has, however, been questioned.[6]

Adverse Effects

Lactulose may cause abdominal discomfort associated with flatulence or cramps. Nausea and vomiting have occasionally been reported after high doses. Some consider the taste to be unpleasant; this can be minimised by dilution in water, fruit juice, or milk, or by mixing the dose with food. Prolonged use or excessive dosage may result in diarrhoea with excessive loss of water and electrolytes, particularly potassium. Hypernatraemia has been reported.

Lactic acidosis. Severe lactic acidosis developed in a patient with adynamic ileus who was being given lactulose for hepatic encephalopathy.[1]

1. Mann NS, *et al.* Lactulose and severe lactic acidosis. *Ann Intern Med* 1985; 103: 637.

Precautions

Lactulose should not be given to patients with galactosaemia or intestinal obstruction. It should not be used in patients on a low galactose diet and care should be taken in patients with lactose intolerance or in diabetic patients because of the presence of some free galactose and lactose.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies lactulose as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pharmacokinetics

Taken orally, lactulose passes essentially unchanged into the large intestine where it is metabolised by saccharolytic bacteria with the formation of simple organic acids, mainly lactic acid and small amounts of acetic and formic acids. The small amount of absorbed lactulose is subsequently excreted unchanged in the urine.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Genocolan; Lactulon; Lafelax; Medixin; Tenualax; *Austral.*: Actilax; Duphalac; Genlac†; Lac-Dol; Lactocur; *Austria*: Bifteral†; Duphalac; Laevolac; *Belg.*: Bifiteral; Duphalac; *Braz.*: Colonac; Duphalac; Farlac; Lactuliv; Lactulona; Normolax; Pentalac; *Canad.*: Euro-Lac; Gen-Lac†; *Chile*: Axant; Dicelax; Dismam; Duphalac; *China*: Danilax (丹尼莱克); Duphalac (杜密克); Laevolac (拉韦); Lidong (利动); *Cz.*: Duphalac; Lactecon†; Lactorin; *Denm.*: Favolax†; Medilax; *Fin.*: Duphalac; Lactecon†; Laxorin; Levolac; *Fr.*: Duphalac; Laxaron; *Ger.*: Bifinorma†; Bifiteral; Eugalac†; Lactuflor; LactuGel; Lactulade; Lactuverlan†; Tulotract†; *Gr.*: Duphalac; Neosoldan; Purgolac; Purselect; *Hong Kong*: Danilax; Dhactulose; Duphalac; Laevolac; Martulose†; *Hung.*: Duphalac; Laevolac; *India*: Bowelac; Bowlease; Canphalac-Sol; Daffolac; Duphalac; Evacuate; Evict; Eziluk; Fresky; Gush; Lace; Laclouse; Lacrest; Lactucos; Lactulax; Lactulin; Lactusan; Laxan; Laxatin; Laxicare Soft; Laxil; Laxitose; Laxobus; Laxolin; Laxose; Livintact-EV; Livoluk; Looz; Loozit; Loozylax; MTLac; Normalac; Nostipan; Novalak; *Indon.*: Constipen; Dulcolactol; Duphalac; Lacons; Lactulax; Lantulos; Laxadilac†; Opilax; Pralax; Solac; *Irl.*: Duphalac; Gerelax†; Lactugal†; Laevolac; Laxose; *Israel*: Avilac; Gerelax; Laevolac; Normase; *Ital.*: Dia-Colon; Duphalac; Epalat EPS†; Epalfen; Laevolac; Lattulac; Normase; Osmolac; Verelait; *Jpn*: Monilac; *Malaysia*: Dhactulose; Duphalac; Lactul; *Mex.*: Duphalac; Lactulax; Quimtulac; Regulact; *Neth.*: Duphalac; Epalfen†; Kruidvat Laxeerdrank; Laevolac; Laxeerdrank; Laxeersiroop; Legendal; *Norw.*: Duphalac; Levolac; *NZ*: Duphalac; Laevolac†; *Philipp.*: Duphalac; Lactul; Lilac; Rilax; *Pol.*: Duphalac; Lactulol; Normalac; Normase†; *Port.*: Colsanac; Duphalac; Laevolac; Obstipar†; *Rus.*: Duphalac (Дюфалак); Gudlac (Гудлак); Livoluk-PB (Ливолюк-ПБ); Normase (Нормазе); Portalac (Порталак); Romfalak (Ромфалак); *S.Afr.*: Aculax; Adco-Liquilax; Duphalac; Lacson; Laxette; *Singapore*: Dhactulose; Duphalac; Lactus; *Spain*: Belmalax†; Duphalac; *Swed.*: Duphalac; Laktipex; *Switz.*: Duphalac; Gatinar; Legendal; Rudolac; *Thai.*: Duphalac; Hepalac; Laevolac; Losalac; Safex; *Turk.*: Duphalac; Lactulac; Laevolac; Laktol†; Osmolak; *UAE*: Soflax; *UK*: Duphalac; Lactugal; Lemlax; Regulose; *Ukr.*: Bioflorax (Биофлоракс)†; Duphalac (Дуфалак); Lactuvit (Лактувит); Laxarin (Лаксарин); Medulac (Медулак); Normase (Нормазе); Normolact (Нормолакт); *USA*: Cephulac; Chronulac†; Constilac†; Constulose; Duphalac†; Enulose; Generlac; Kristalose; *Venez.*: Lactulona; Moderan.

USP 36: Lactulose Solution.

Lafutidine *(rINN)*

FRG-8813; Lafutidina; Lafutidinum; Лафутидин.
(±)-2-(Furfurylsulfinyl)-*N*-[(*Z*)-4-[[4-(piperidinomethyl)-2-pyridyl]oxy]-2-butenyl]acetamide.
$C_{22}H_{29}N_3O_4S$=431.6
CAS — 118288-08-7.
ATC — A02BA08.
ATC Vet — QA02BA08.
UNII — 495407ADLC.

Profile

Lafutidine, like cimetidine (p. 1827.1), is a histamine H_2-antagonist. It is used in the management of peptic ulcer disease and gastritis. Lafutidine is given orally; a usual dose for peptic ulcers is 10 mg twice daily, and for gastritis, 10 mg daily in the evening. Care is required in patients with renal or hepatic impairment.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *China*: He Ke Di Si (赫克迪思); Lemeiting (乐美汀); Ning Wei Shu (宁维舒); Nuo Fei (诺非); Shun Ru (顺儒); Weisida (卫斯大); *Jpn*: Protecadin; Stogar†.

Lansoprazole *(BAN, USAN, rINN)*

A-65006; AG-1749; CG-4801; Lansopratsoli; Lansoprazol; Lansoprazolum; Лансопразол.
2-{[3-Methyl-4-(2,2,2-trifluoroethoxy)-2-pyridyl]methyl}sulphinylbenzimidazole.
$C_{16}H_{14}F_3N_3O_2S$=369.4
CAS — 103577-45-3.
ATC — A02BC03.
ATC Vet — QA02BC03.
UNII — 0K5C5T2QPG.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Lansoprazole). A white or brownish powder. Practically insoluble in water; soluble in anhydrous alcohol; very slightly soluble in acetonitrile. It exhibits polymorphism. Store in airtight containers. Protect from light.

USP 36: (Lansoprazole). A white to brownish-white powder. Practically insoluble in water; freely soluble in dimethylformamide. Store in airtight containers at a temperature not exceeding 40 degrees. Protect from light.

Uses and Administration

Lansoprazole is a proton pump inhibitor with actions and uses similar to those of omeprazole (p. 1867.2). It is used in the treatment of peptic ulcer disease and in other conditions where inhibition of gastric acid secretion may be beneficial.

Lansoprazole is given orally as capsules, dispersible tablets, or suspension containing enteric-coated granules. Once daily regimens are taken before food in the morning. Lansoprazole has also been given intravenously.

For the relief of acid-related **dyspepsia** (p. 1806.3) intermittent courses of lansoprazole may be given in oral doses of 15 or 30 mg once daily, for 2 to 4 weeks.

In the treatment of **gastro-oesophageal reflux disease** (p. 1807.2) the usual oral dose is 15 to 30 mg once daily for 4 to 8 weeks; thereafter maintenance therapy can be continued with 15 or 30 mg once daily according to response.

Lansoprazole is given orally for the treatment of **peptic ulcer disease** (p. 1813.2); in the UK usual doses are 30 mg once daily. Treatment is continued for 2 to 4 weeks for duodenal and 4 to 8 weeks for gastric ulcer. In the USA, a dose of 15 mg daily for 4 weeks is recommended for duodenal ulcer, and 30 mg once daily is given for up to 8 weeks for gastric ulceration. When appropriate, 15 mg daily may be used as maintenance therapy for the prevention of relapse of duodenal ulcer. Lansoprazole may be combined with antibacterials in 7- to 14-day **triple therapy** regimens for the eradication of *Helicobacter pylori*. Effective regimens include lansoprazole 30 mg twice daily combined with clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily, or combined with clarithromycin 250 mg twice daily and metronidazole 400 mg twice daily; lansoprazole with amoxicillin and metronidazole has also been used. **Dual therapy** with lansoprazole 30 mg three times daily and amoxicillin for 14 days is also used, but may be less effective. In patients with **NSAID-associated ulceration** a dose of 30 mg daily for 4 to 8 weeks is recommended; 15 to 30 mg daily may be used as prophylaxis for patients who require continued NSAID treatment.

In the treatment of pathological hypersecretory states such as the **Zollinger-Ellison syndrome** (p. 1814.3) the initial oral dose is 60 mg once daily, adjusted as required. Doses of up to 90 mg twice daily have been used. Daily doses greater than 120 mg should be given in divided doses.

For doses in children and in hepatic impairment, see below.

General references. For general reviews of proton pump inhibitors, see Omeprazole, p. 1867.3.

3. Preston JW, *et al.* Lansoprazole for maintenance of remission of erosive oesophagitis. *Drugs* 2002; 62: 1173–84.
4. Dando TM, Plosker GL. Intravenous lansoprazole: in erosive oesophagitis. *Drugs* 2004; 64: 2085–9.
5. Croom KF, Scott LJ. Lansoprazole: in the treatment of gastro-oesophageal reflux disease in children and adolescents. *Drugs* 2005; 65: 2129–35.

Administration. Lansoprazole *capsules* should be swallowed whole and not crushed or chewed. Lansoprazole *dispersible tablets* should be placed on the tongue and allowed to disintegrate and the resultant granules swallowed; alternatively, the tablets may be swallowed whole with a glass of water. The tablets should not be crushed or chewed. The tablets may also be dispersed in a small amount of water and given via an oral syringe, or via a nasogastric tube. Lansoprazole *granules for oral suspension* should be reconstituted in a little water and swallowed immediately. Where the suspension formulation is not available, the contents of the capsules (enteric-coated granules) can be sprinkled on a small amount of soft food (such as yogurt or apple sauce) or mixed with a little fruit juice and swallowed. For dosage via a nasogastric tube, the contents of a capsule may be mixed with 40 mL of apple juice; additional apple juice may be used to flush the tube.

Administration in children. In the USA, children may be given lansoprazole for the short-term treatment of erosive oesophagitis and symptomatic gastro-oesophageal reflux disease. In children aged 1 to 11 years, the following oral doses may be given once daily for up to 12 weeks, according to body-weight:

- 30 kg or less: 15 mg
- over 30 kg: 30 mg

Doses of up to 30 mg twice daily have been used in children who remain symptomatic after 2 or more weeks of treatment.

In children aged from 12 to 17 years, oral lansoprazole 30 mg once daily for up to 8 weeks may be given for erosive oesophagitis, and 15 mg once daily for up to 8 weeks may be given for symptomatic non-erosive gastro-oesophageal reflux disease.

Although not licensed for children in the UK, the *BNFC* recommends lansoprazole in the treatment of gastro-oesophageal reflux disease, acid-related dyspepsia, duodenal and benign gastric ulcer including those complicating NSAID therapy, and fat malabsorption despite pancreatic enzyme replacement therapy in cystic fibrosis; comparable oral doses may be given once daily in the morning:

- up to 30 kg: 0.5 to 1 mg/kg (maximum 15 mg)
- over 30 kg: 15 to 30 mg

Studies of oral lansoprazole in infants with gastro-oesophageal reflux disease have produced conflicting results. Lansoprazole reduced symptoms in one study compared with treatment with a hydrolysed formula feed,[1] whereas another study found lansoprazole to be no more effective than placebo; a higher incidence of adverse effects was also reported with lansoprazole therapy.[2] For findings from a review (including these references) regarding the efficacy and safety of proton pump inhibitors in infants, children, and adolescents, see Administration in Children, under Omeprazole, p. 1867.3.

1. Khoshoo V, Dhume P. Clinical response to 2 dosing regimens of lansoprazole in infants with gastroesophageal reflux. *J Pediatr Gastroenterol Nutr* 2008; 46: 352–4.
2. Orenstein SR, *et al.* Multicenter, double-blind, randomized, placebo-controlled trial assessing the efficacy and safety of proton pump inhibitor lansoprazole in infants with symptoms of gastroesophageal reflux disease. *J Pediatr* 2009; 154: 514–20.

Administration in hepatic impairment. Exposure to lansoprazole is increased in patients with hepatic impairment. UK licensed product information suggests that patients with moderate to severe liver disease should be kept under supervision, and the oral daily dose reduced by 50%.

Adverse Effects and Precautions

As for Omeprazole, p. 1868.1.

Reviews.

1. Preston JW, *et al.* Safety profile of lansoprazole: the US clinical trial experience. *Drug Safety* 1999; 20: 195–205.

Effects on the blood. For a report of thrombocytopenia with lansoprazole, see under Omeprazole, p. 1868.2.

Effects on electrolytes. For mention of a fall in electrolytes during treatment with proton pump inhibitors including lansoprazole, see Omeprazole, p. 1868.3.

Effects on the endocrine system. For cases of gynaecomastia associated with lansoprazole, see p. 1868.3.

Effects on the gastrointestinal tract. Glossitis (associated in some cases with black tongue or stomatitis) has been reported in a few patients taking lansoprazole as part of a triple therapy regimen for *Helicobacter pylori* elimination in peptic ulcer disease.[1] Discoloured tongue has been reported in a patient taking lansoprazole alone.[2]

An increase in gastritis occurred in patients infected with *Helicobacter pylori* when given long-term lansoprazole therapy.[3] For further discussion of the link between *H. pylori*, gastritis, and proton pump inhibitor use, see Gastrointestinal Tumours, p. 1869.3.

For a suggestion that the incidence of diarrhoea may be greater with lansoprazole than omeprazole see Incidence of Adverse Effects, p. 1868.2. Cases of microscopic colitis have been reported with use of lansoprazole.[4] UK licensed product information states that stopping therapy should be considered in the case of severe and/or persistent diarrhoea.

4. Hilmer SN, *et al.* Microscopic colitis associated with exposure to lansoprazole. *Med J Aust* 2006; 184: 185–6.

Effects on the musculoskeletal system. For reference to a case of eosinophilia and myalgia related to lansoprazole therapy, see p. 1869.1.

Effects on the skin. For mention of skin reactions to lansoprazole, see p. 1869.2.

Hypersensitivity. For a suggestion that lansoprazole may be tolerated in patients sensitive to omeprazole and pantoprazole see p. 1870.1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies lansoprazole as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Interactions

As for Omeprazole, p. 1870.3. Antacids and sucralfate may reduce the bioavailability of lansoprazole, and should not be taken within 1 hour of a dose of lansoprazole.

For reference to a lack of effect of lansoprazole on diazepam, see Gastrointestinal Drugs, p. 1069.3, and for a clinically insignificant effect on theophylline clearance, see p. 1236.1. For reference to glossitis occurring when lansoprazole was used with some antibacterials, see Effects on the Gastrointestinal Tract, above.

Pharmacokinetics

Lansoprazole is rapidly absorbed after oral doses and peak plasma concentrations occur after about 1.5 to 2 hours. Bioavailability is reported to be 80% or more even with the first dose, although the drug must be given in an enteric-coated form since lansoprazole is unstable at acid pH. Food slows the absorption of lansoprazole and reduces the bioavailability by about 50%. Lansoprazole is about 97% bound to plasma protein. It is extensively metabolised in the liver, primarily by cytochrome P450 isoenzyme CYP2C19 to form 5-hydroxyl-lansoprazole and by CYP3A4 to form lansoprazole sulfone. Metabolites are excreted mainly in faeces via the bile; only about 15 to 30% of a dose is excreted in urine. The plasma elimination half-life is around 1 to 2 hours but the duration of action is much longer. Clearance is decreased in elderly patients, and in hepatic impairment.

Metabolism. As for omeprazole (p. 1871.2), the cytochrome P450 isoenzyme CYP2C19 (*S*-mephenytoin hydroxylase) is involved in the hydroxylation of lansoprazole, and individuals who are deficient in this enzyme are poor metabolisers of lansoprazole.[1,2] There is some suggestion that the effect of this genetic polymorphism on lansoprazole may be less than the effect on omeprazole.[3]

CAS — 851199-60-5.

ATC — A06AX04.

ATC Vet — QA06AX04.

UNII — NSF067KU1M.

Uses and Administration

Linaclotide is a 14-amino acid synthetic peptide structurally related to the endogenous guanylin peptide family. Both linaclotide and its active metabolite bind as agonists to the guanylate cyclase-C receptor on the luminal surface of the intestinal epithelium. It is used in the treatment of constipation-predominant irritable bowel syndrome (p. 1810.3) and chronic idiopathic constipation (p. 1804.3). Oral doses are taken on an empty stomach, at least 30 minutes before the first meal of the day.

For constipation-predominant irritable bowel syndrome linaclotide 290 micrograms is taken orally once daily. If there is no improvement in symptoms after 4 weeks, continued treatment should be reconsidered.

For chronic idiopathic constipation linaclotide 145 micrograms is taken orally once daily.

5. Lee N, Wald A. Linaclotide: evidence for its potential use in irritable bowel syndrome and chronic constipation. *Core Evid* 2012; **7**: 39–47.

Adverse Effects and Precautions

The most commonly reported adverse effect of linaclotide is diarrhoea, and treatment may need to be withheld for severe diarrhoea or prolonged episodes lasting longer than 1 week. Other gastrointestinal effects include abdominal pain or distention, flatulence, vomiting, and dyspepsia. Headache, fatigue, viral gastroenteritis, upper respiratory-tract infections, and sinusitis have also been reported.

Linaclotide is not recommended for children or adolescents as it has not been studied in this population. Guanylate cyclase-C receptors are known to be over-expressed in infancy and children younger than 2 years may be particularly sensitive to linaclotide effects. Linaclotide is also not recommended in those with inflammatory bowel disease due to a lack of data. It should not be used in patients with known or suspected gastrointestinal obstruction.

Pharmacokinetics

Linaclotide has low bioavailability after oral dosing and is virtually undetectable in the plasma. It is broken down within the gastrointestinal tract by proteolysis to its main des-tyrosine active metabolite MM-419447, and then further degraded or reduced to smaller peptides and amino acids. About 4% of a dose is excreted in the faeces as the active metabolite.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Neth.*: Constella; *UK*: Constella; *USA*: Linzess.

Liquorice

Alcaçuz; Édesgyökér; Gancao; Glycyrrhiza; Korzeń lukrecji; Lakritsijuuri; Lakritsrot; Lékořicový kořen; Licorice; Liquiritiae Radix; Liquorice Root; Orozuz; Raiz de Regaliz; Raíz de regaliz; Regaliz; Réglisse, racine de; Saldymedžių šaknys; Süssholzwurzel; Лакрица.

ATC Herb — HR05WA5014 (Glycyrrhiza glabra: root); HA02WA5001 (Glycyrrhiza glabra: root).

UNII — 61ZBX54883 (liquorice); 2788Z9758H (Glycyrrhiza glabra root).

Description. The dried rhizome and roots of *Glycyrrhiza glabra* var. *typica* are known in commerce as Spanish Liquorice, those of *G. glabra* var. *glandulifera* as Russian Liquorice, and those of *G. glabra* var. β-*violacea* as Persian Liquorice.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*. *Eur.* (see p. vii) also includes Liquorice Dry Extract for Flavouring Purposes. *US* also includes Powdered Licorice and Powdered Licorice Extract. *Br.* also includes Liquorice Root for use in Traditional Chinese Medicine and Processed Liquorice Root for use in Traditional Chinese Medicine.

Ph. Eur. 8: (Liquorice Root; Liquorice BP 2014). The dried unpeeled or peeled, whole or cut root and stolons of *Glycyrrhiza glabra* and/or *G. inflata* and/or *G. uralensis*. It contains not less than 4% of 18β-glycyrrhizic acid. Protect from light.

USP 36: (Licorice). The roots, rhizomes, and stolons of *Glycyrrhiza glabra* or *G. uralensis*. It contains not less than 2.5% of glycyrrhizic acid, calculated on the dried basis. Store in a cool, dry place.

BP 2014: (Liquorice Root for use in TCM). It is the dried unpeeled root and rhizome of *Glycyrrhiza uralensis*, *G. inflata*, or *G. glabra*, or a mixture of these. For use in traditional Chinese medicines. It contains not less than 2.0% of glycyrrhizic acid calculated with reference to the dried material. Protect from moisture.

BP 2014: (Processed Liquorice Root for use in TCM). Liquorice Root for use in TCM which has been cleaned, softened, sliced transversely or longitudinally to form uniform pieces, and dried. It contains not less than 2.0% of glycyrrhizic acid calculated with reference to the dried material. Protect from moisture.

Uses and Administration

Liquorice is used as a flavouring and sweetening agent. It has demulcent and expectorant properties and has been used in cough preparations. It has ulcer-healing properties that may result from stimulation of mucus synthesis. It contains constituents that produce mineralocorticoid effects (see below). Liquorice may also possess some antispasmodic and laxative properties.

Deglycyrrhizinised liquorice has a reduced mineralocorticoid activity and has been used, usually with antacids, for the treatment of peptic ulcer disease (p. 1813.2).

Reviews.
1. Fiore C, *et al.* A history of the therapeutic use of liquorice in Europe. *J Ethnopharmacol* 2005; **99**: 317–24.

Adverse Effects and Precautions

Liquorice has mineralocorticoid-like actions manifesting as sodium and water retention and hypokalaemia (see below).

Deglycyrrhizinised liquorice is not usually associated with such adverse effects.

Mineralocorticoid effects. Mineralocorticoid effects have been reported after excessive or prolonged ingestion of liquorice. The liquorice may be ingested in confectionery (including liquorice-flavoured chewing gum), tea, soft drinks, herbal medicines, cough mixtures, or by chewing tobacco. The enzyme 11-β-hydroxysteroid dehydrogenase (cortisol oxidase) converts cortisol to cortisone, preventing cortisol gaining access to non-specific mineralocorticoid receptors. This enzyme is inhibited by glycyrrhetinic acid (produced by the hydrolysis of glycyrrhizic acid, a natural constituent of liquorice), resulting in increased concentrations of cortisol in the body, enhancing its physiological effects.[1-3]

Clinical manifestations include consequences of sodium retention such as hypertension,[4-10] and hypokalaemia, which can result in neuromuscular disturbances ranging from muscle weakness,[11] myoclonus,[12] and myopathy[10] to paralysis[13-15] and rhabdomyolysis.[15-18] Arrhythmias[16,19] and fatal cardiac arrest[20] have also been reported.

Increased amounts of cortisol in vascular smooth muscle may cause vasoconstriction. Vasospasm of vessels supplying the optic nerve may have caused transient visual disturbances reported after liquorice ingestion.[2] Liquorice has also been reported to cause symptoms including recurrent thunderclap headaches with intermittent loss of vision, severe transient hypertension, and seizures; reversible angiographic abnormalities and bilateral lobar haemorrhages suggested reversible cerebral vasoconstriction, whereas brain oedema was consistent with posterior reversible encephalopathy.[21]

Other reported effects of liquorice include growth retardation in a boy with Addison's disease;[22] liquorice was thought to have potentiated the effect of hydrocortisone.

Endocrine effects of liquorice have been reviewed.[23] Conflicting effects on testosterone and prolactin have been reported. Components of liquorice root (which has been tried for menopausal symptoms) have both oestrogenic and anti-oestrogenic activity, and it has reportedly caused gynaecomastia.

Individuals vary markedly in their susceptibility to liquorice-induced adverse effects.[1] Those consuming 400 mg glycyrrhetinic acid daily generally have adverse effects, but a regular daily intake of no more than 100 mg of glycyrrhetinic acid (about 50 g of liquorice sweets) has produced adverse effects in some who appear more sensitive to its effects. Some consider a daily intake of 10 mg glycyrrhetinic acid to be a safe daily dose for adults; the amount of salt consumed needs to be considered as even a low dose of liquorice may induce sodium overload in those consuming high amounts of sodium chloride.[3]

Pregnancy. Studies in Finnish women indicated that heavy consumption of liquorice (equivalent to ≥ 500 mg/week of glycyrrhizic acid) during pregnancy was associated with an increased risk of preterm delivery.[1,2] Consumption of large amounts of liquorice was a social habit noted to occur in some northern European countries.

Pharmacopoeial Preparations
Ph. Eur.: Liquorice Ethanolic Liquid Extract, Standardised;
USP 36: Licorice Fluidextract.

Loperamide Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de loperamida; Loperamid Hidroklorür; Loperamid hydrochlorid; Loperamida, hidrocloruro de; Lopéramide, chlorhydrate de; Loperamid-hidroklorid; Loperamidhydrochlorid; Loperamidhydroklorid; Loperamidi Hydrochloridum; Loperamidihydroklóridi; Loperamido hidrochloridas; R-18553; Лоперамида Гидрохлорид.

4-(4-*p*-Chlorophenyl-4-hydroxypiperidino)-*NN*-dimethyl-2,2-diphenylbutyramide hydrochloride.

$C_{29}H_{33}ClN_2O_2,HCl$=513.5

CAS — 53179-11-6 (loperamide); 34552-83-5 (loperamide hydrochloride).

ATC — A07DA03.

ATC Vet — QA07DA03.

UNII — 77T135393C.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, and *US*.

Ph. Eur. 8: (Loperamide Hydrochloride). A white or almost white powder. It exhibits polymorphism. Slightly soluble in water; freely soluble in alcohol and in methyl alcohol. Protect from light.

USP 36: (Loperamide Hydrochloride). A white to slightly yellow powder. Slightly soluble in water and in dilute acids; freely soluble in chloroform and in methyl alcohol; very slightly soluble in isopropyl alcohol.

Loperamide Oxide *(BAN, rINN)*

Loperamid oxid; Loperamida, óxido de; Lopéramide Oxyde; Lopéramide, oxyde de; Loperamidi Oxidum; Loperamidioksidi; Loperamido oksidas; Loperamidoxid; Loperamidum Oxidum; Óxido de loperamida; R-58425; Лоперамида Оксид.

$C_{29}H_{33}ClN_2O_3$=493.0

CAS — 106900-12-3.

ATC — A07DA05.

ATC Vet — QA07DA05.

UNII — H3VOT77DE1.

Pharmacopoeias. *Eur.* (see p. vii) includes the monohydrate.

Ph. Eur. 8: (Loperamide Oxide Monohydrate; Loperamidi Oxidum Monohydricum). A white or almost white, slightly hygroscopic, powder. Practically insoluble in water; freely soluble in alcohol and in dichloromethane. Store in airtight containers. Protect from light.

Uses and Administration

Loperamide is a synthetic derivative of pethidine that inhibits gut motility and may also reduce gastrointestinal secretions. It is given orally as an antidiarrhoeal drug as an adjunct in the management of acute and chronic diarrhoeas and may also be used in the management of colostomies or ileostomies to reduce the volume of discharge.

In **acute diarrhoea** the usual initial dose is loperamide hydrochloride 4 mg followed by 2 mg after each loose stool to a maximum of 16 mg daily; the usual daily dose is 6 to 8 mg.

In **chronic diarrhoea** the usual initial dose is 4 to 8 mg daily in divided doses subsequently adjusted as necessary; doses of 16 mg daily should not be exceeded. If no improvement has been seen after treatment with 16 mg daily for at least 10 days, further use is unlikely to be of benefit.

For doses in children, see below

Loperamide is also given as the prodrug, **loperamide oxide**, which is converted to loperamide in the gastrointestinal tract. It has been given for acute diarrhoea in doses of 2 to 4 mg initially followed by 1 mg after each loose stool, to a maximum of 8 mg daily.

Administration in children. Loperamide can be used in children as an adjunct in the symptomatic treatment of acute and chronic diarrhoeas, and in the management of colostomies or ileostomies to reduce the volume of discharge.

In **acute diarrhoea** dose regimens vary according to country. In the UK, it is licensed for children from 4 years of age; recommended oral doses of loperamide hydrochloride are:

- 4 to 8 years: 1 mg three or four times daily for up to 3 days
- over 8 years: 2 mg four times daily for up to 5 days

The *BNFC* suggests using adult doses (see above) in children from 12 years of age.

In the USA, loperamide is licensed for children from 2 years of age. The recommended initial oral dose for children aged 2 to 5 years is 1 mg three times daily.

For restrictions on the use of loperamide in children and the view that antidiarrhoeal drugs should not be used at all in children with acute diarrhoea, see Diarrhoea, below.

Although not licensed for use in children for **chronic diarrhoea**, in the UK the *BNFC* allows for the following oral doses:

- 1 month to 1 year: 100 to 200 micrograms/kg twice daily, given 30 minutes before feeds; up to a maximum of 2 mg/kg daily in divided doses may be required
- 1 to 12 years: 100 to 200 micrograms/kg (maximum dose 2 mg) three to four times daily; up to 1.25 mg/kg daily in divided doses may be required, to a maximum of 16 mg daily
- 12 to 18 years: adult doses can be given

Diarrhoea. The mainstay of treatment for acute diarrhoea (p. 1805.2) is rehydration therapy. Antidiarrhoeals may have a role for symptomatic relief in adults with acute diarrhoea, and loperamide is often chosen in such circumstances,[1] but WHO does not recommend the use of *any* antidiarrhoeal drug in children with diarrhoea. Similarly, in the UK the *BNFC* states that antimotility drugs are not recommended for acute diarrhoea in children under 12 years of age. There have been problems regarding the use of antidiarrhoeals such as loperamide in young children in developing countries. Manufacturers have considered that a lower age limit is acceptable in those countries than is recommended in the UK or USA; even that lower limit is not always observed in practice and there have been reports of serious toxicity in very young children.[3] In response to such reports the manufacturers withdrew concentrated drops of loperamide worldwide and the syrup from countries where the WHO had a programme for control of diarrhoeal diseases,[3] but tablets and capsules remain available. In some countries the use of antidiarrhoeals is now restricted by law.

In the UK, NICE states that loperamide is the antidiarrhoeal of first choice in adults with faecal incontinence;[4] it can be used long-term in doses from 500 micrograms to 16 mg daily as needed. Loperamide should be started at a very low dose which can be increased as needed, and then adjusted in response to stool consistency. It should not be given to those with hard or

infrequent stools, those with acute diarrhoea of unknown cause, or with acute ulcerative colitis. Patients who are unable to tolerate loperamide may be offered codeine phosphate (p. 40.2) or co-phenotrope (see Diphenoxylate Hydrochloride, p. 1835.3).

For mention of the use of loperamide in the management of diarrhoea caused by chemotherapy, see p. 731.3.

Adverse Effects and Treatment

Abdominal pain or bloating, nausea, constipation, dry mouth, dizziness, fatigue, and hypersensitivity reactions including skin rashes have been reported. Loperamide has been associated with paralytic ileus, particularly in infants and young children, and deaths have been reported. Depression of the CNS, to which children or those with hepatic impairment may be more sensitive, may be seen in overdosage; constipation and urinary retention also occur. Naloxone hydrochloride (see p. 1563.3) has been recommended for treatment of severe overdosage.

Toxicity. Toxic megacolon has been reported[1,2] after use of loperamide. Severe effects reported in young children have included loss of consciousness[3,4] and delirium.[5] Several cases of paralytic ileus have also occurred in children,[6,7] some of which were fatal.[6]

Precautions

Loperamide should not be used when inhibition of peristalsis is to be avoided, in particular where ileus or constipation occur, and should be avoided in patients with abdominal distension, acute inflammatory bowel disease, or antibiotic-associated colitis. Loperamide should not be used alone in patients with dysentery.

Loperamide should be used with caution in patients with hepatic impairment because of its considerable first-pass metabolism in the liver. It should also be used with caution in young children because of a greater variability of response in this age group; it is not recommended for use in infants (but see Administration in Children, p. 1854.3).

Breast feeding. Loperamide is distributed into breast milk in small amounts.[1] The American Academy of Pediatrics[2] states that there have been no reports of any clinical effect on the infant associated with the use of loperamide by breast-feeding mothers, and that therefore it may be considered to be usually compatible with breast feeding.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies loperamide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 06/10/11)

Pregnancy. A study[1] in 105 women who had used loperamide during pregnancy (89 in the first trimester) found no increase in major congenital defects compared with controls. However, another study[2] of loperamide use in early pregnancy in 638 women reported an increased risk of congenital malformations; the adjusted odds ratio was 1.41 (with a 95% confidence interval of 1.03-1.93) based on 43 affected children. The authors warned that the results could have arisen by chance and further studies were needed to verify the effect.

Interactions

Loperamide may increase the gastrointestinal absorption of desmopressin (p. 2357.1).

Antifungals. A pharmacokinetic study in 12 healthy subjects found that *itraconazole* significantly increased peak plasma concentrations and area under the concentration-time curve of loperamide, and also prolonged the half-life of loperamide. Itraconazole also inhibited metabolism of loperamide to *N*-desmethylloperamide, suggesting that metabolism of loperamide in humans concurs with *in-vitro* data (see Metabolism, below). Use of itraconazole with gemfibrozil (see Cardiovascular Drugs, below) synergistically increased exposure to loperamide.[1]

1. Niemi M, *et al.* Itraconazole, gemfibrozil and their combination markedly raise the plasma concentrations of loperamide. *Eur J Clin Pharmacol* 2006; 62: 463–72.

Antivirals. In a single-dose study,[1] oral *ritonavir* significantly increased the bioavailability of loperamide, possibly through inhibition of the cytochrome P450 isoenzyme CYP3A4, and not necessarily as originally supposed through P-glycoprotein inhibition. No serious adverse effects occurred. Licensed information for one UK preparation of loperamide (*Imodium; Janssen-Cilag, UK*) states that the clinical relevance of the pharmacokinetic interaction with P-glycoprotein inhibitors such as ritonavir is unknown.

For the effect of loperamide on *saquinavir*, and the corresponding effect of the antiviral on loperamide concentrations, see Gastrointestinal Drugs, under Interactions of Indinavir, p. 988.1.

1. Tayrouz Y, *et al.* Ritonavir increases loperamide plasma concentrations without evidence for P-glycoprotein involvement. *Clin Pharmacol Ther* 2001; 70: 405–14.

Cardiovascular drugs. A pharmacokinetic study in 12 healthy subjects found that *gemfibrozil* significantly increased peak plasma concentrations and area under the concentration-time curve of loperamide, and also prolonged the half-life of loperamide. Gemfibrozil also inhibited metabolism of loperamide to *N*-desmethylloperamide, suggesting that metabolism of loperamide in humans concurs with *in-vitro* data (see Metabolism, below). Use of gemfibrozil with itraconazole (see Antifungals, above) synergistically increased exposure to loperamide.[1]

1. Niemi M, *et al.* Itraconazole, gemfibrozil and their combination markedly raise the plasma concentrations of loperamide. *Eur J Clin Pharmacol* 2006; 62: 463–72.

Co-trimoxazole. Use with co-trimoxazole increases the bioavailability of loperamide,[1] apparently by inhibiting its first-pass metabolism.

1. Kamali F, Huang ML. Increased systemic availability of loperamide after oral administration of loperamide and loperamide oxide with cotrimoxazole. *Br J Clin Pharmacol* 1996; 41: 125–8.

Quinidine. A small study[1] found that giving quinidine with loperamide caused respiratory depression in 8 healthy subjects; when given with placebo, loperamide produced no respiratory depression. The authors supposed that inhibition of P-glycoprotein by quinidine had increased entry of loperamide into the CNS.

1. Sadeque AJM, *et al.* Increased drug delivery to the brain by P-glycoprotein inhibition. *Clin Pharmacol Ther* 2000; 68: 231–7.

Pharmacokinetics

About 40% of a dose of loperamide is reported to be absorbed from the gastrointestinal tract to undergo first-pass metabolism in the liver and excretion in the faeces via the bile as inactive conjugate; there is slight urinary excretion. Little intact drug reaches the systemic circulation. The elimination half-life is reported to be about 10 hours.

Metabolism. Loperamide is metabolised to desmethylloperamide through *N*-demethylation. An *in-vitro* study established that this occurs mainly via cytochrome P450 isoenzymes CYP2C8 and CYP3A4; CYP2B6 and CYP2D6 also play a role. Loperamide is also a substrate of P-glycoprotein.[1]

1. Kim K-A, *et al.* Identification of cytochrome P450 isoforms involved in the metabolism of loperamide in human liver microsomes. *Eur J Clin Pharmacol* 2004; 60: 575–81.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Colifilm; Contem; Custey; Dotalsec; Elcoman; Excelentia Antidiarreico; Ionet; Lansek A; Lefa Enteril L; Minicam; Nodiar; Normasec; Plexol; Florinoc; Regulane; Suprasec; Viltar; *Austral.*: Chemists Own Diarrhoea Relief; Diareze; Gastro-Stop; Harmonise; Imodium; Lopedium; *Austria*: Enterobene; Imodium; Normakut; *Belg.*: Imodium; Transityl; *Braz.*: Diafuran; Diasec; Imosec; Loperin; Magnostase; *Canad.*: Diarr-Eze; Diarrhea Relief; Imodium; Loperacap; *Chile*: Capent; Coliper; Lopediar†; Salvacoll; *China*: Pu Xie Ding (腹泻啶); Imodium (易蒙停); Luobaomai (罗宝迈); Ya Bang (雅邦); *Cz.*: Dissenten†; Imodium; Loperon; *Denm.*: Imodium; Imolope; Propiden; *Fin.*: Imocur; Imodium Pro†; Imodium; Lopacut; Lopex; *Fr.*: Altocel; Arestal; Diaretyl; Diastrolib; Dyspagon; Ercestop; Imodium; Imodiumcaps; Imodiumlingual; Indiaral; Peracel; *Ger.*: Imodium; Lop-Dia†; Lopedium†; Loperhoe; *Gr.*: Imodium; Neo-Enteroseptol; Neo-Septol; *Hong Kong*: Diacure†; Diatabs Reformulated; Imodium; Imodonl; Lopa; Loper; Loperamil; Loperax; Loperium†; Lopil†; Mar-Loper†; NT-Diorea†; Reximide†; Synodium†; Uni-Motil†; Vidaperamide†; *Hung.*: Enterobene; Imodium; Lopedium; *India*: Andial; Diarlop Plus; Diarlop; Eldoper; Imodium; Lofact; Lomin; Lopamide; Loperam; Loperiv; Lopona; Roko; *Indon.*: Alphamid†; Amerol; Antidia†; Colidium; Diadium; Diasec; Diaston; Imodan; Imodium; Imomed†; Imoret†; Imosa; Inamid; Lexadium; Licodium; Lodia; Loremid; Motilex; Normotil; Normudal; Opox; Oramide†; Primodium; Renamid; Rhomuz; Xepare; Zeroform; *Irl.*: Arret; Diareze†; Diarrest RF†; Imodium; *Israel*: Imodium; Loperid; Lopi-Care; Loprex; Rekamide; Shilshul X; Stopit; *Ital.*: Diarstene; Diarstop; Diarzero; Dissenten; Imodium; Lopemid; *Malaysia*: Beamodium; Imodium; Loperax†; Loperium; Lopermide; Loramide; Reximide; Vaconil; *Mex.*: Acanol; Acqta; Apo-Pera; Biolid; Cryoperacid; Deroser; Diaperol; Exclefin; Hurplex; Imodium; Lomidal; Lomotil; Lop; Nodiamex; Permidal; Pramidal; Rediarin; Top-Dal; Valfam; *Neth.*: Arestal; Diacure; Diarem†; Diarreeremmer; Imodium; Kruidvat Diarreeremmer; Trekpleister Diarreeremmer; *Norw.*: Imodium; *NZ*: Diamide; Dicap†; Imodium; Nodia; *Philipp.*: Bryper; Diamide; Diaperyl; Diastop; Diatabs (Reformulated); Gastromed; Imodium; LBX; Lomotil; Lormide; Permid†; Tymedon; *Pol.*: Imodium; Laremid; Stoperan; *Port.*: Dyspagon†; Fulcalrex†; Pulcralex†; Imodium; Lopitum; Loprex†; Loride; *Rus.*: Diara (Диара); Imodium (Имодиум); Lopedium (Лопедиум); Superilop (Суперилоп); *S.Afr.*: Betaperamide; Gastron; Imodium; Lenide-T†; Lopedium; Loperastat; Norimode; Prodium; *Singapore*: Colodium; Diatrol; Eldoper; Imodium; Loperamil; Loperax; Lopermide; Loramide; Lorpa; Reximide; SP-Emoloc; Vacontil; *Spain*: Diarfin; Elissan; Fortasec; Imodium; Loperan; Loperkey; Protector†; Salvacolina; Taguinol†; *Swed.*: Dimor; Imodium; Lopacut; Primodium; Travellof†; *Switz.*: Binaldan; Imodium; Lopimed; Lopisol; *Thai.*: Diara; Diarent; Diarine; Diarodil; Dicotil; Entermid; Imodium; Imonox; Impelium; KB Peramide; Leon; Lomide; Lomy; Lopela; Lopercin; Loperdium; Loperiat†; Lopermide†; Lopil; Mantil; Miderlar; Operium; Patardium; Perasian; Ropa; Ropermide; SBOB; Setonox; Tedium; *Turk.*: Diadef; Lopermid; *UK*: Arret; Boots Diarrhoea Relief; Diah-Limit; Diaquitte; Diareze; Diocalm Ultra; Diocaps; Entrocalm; Imodium; Norimode; Normaloe; *Ukr.*: Imodium (Имодиум); Lopedium (Лопедиум); Stoperan (Стоперан); *USA*: Imodium; K-Pek II; Kao-Paverin; Neo-Diaral; Pepto Diarrhea Control; *Venez.*: Glucitol; Imodium; Loperam.

Pharmacopoeial Preparations

BP 2014: Loperamide Capsules;
USP 36: Loperamide Hydrochloride Capsules; Loperamide Hydrochloride Oral Solution; Loperamide Hydrochloride Tablets.

Loxiglumide *(rINN)*

CR-1505; CR-2017 (dexloxiglumide); Loxiglumida; Loxiglumidum; Локсиглумид.

(±)-4-(3,4-Dichlorobenzamido)-*N*-(3-methoxypropyl)-*N*-pentylglutaramic acid.

$C_{21}H_{30}Cl_2N_2O_5$=461.4

CAS — 107097-80-3 (loxiglumide); 119817-90-2 (dexloxiglumide).

UNII — 77MPX3N42I.

Profile

Loxiglumide is a specific cholecystokinin antagonist related to proglumide (see p. 1880.1), and has been investigated in

biliary and gastrointestinal dyskinesias, constipation and irritable bowel syndrome, and pancreatitis.

The *R*-isomer of loxiglumide, dexloxiglumide is also under investigation for constipation-predominant irritable bowel syndrome.

Lubiprostone *(USAN, rINN)*

Lubiprostona; Lubiprostonum; RU-0211; SPI-0211; Лубипростон.

(-)-7-[(2*R*,4a*R*,5*R*,7a*R*)-2-(1,1-Difluoropentyl)-2-hydroxy-6-oxooctahydrocyclopenta[*b*]pyran-5-yl]heptanoic acid.

$C_{20}H_{32}F_2O_5$=390.5

CAS — 136790-76-6; 333963-40-9.

ATC — A06AX03.

ATC Vet — QA06AX03.

UNII — 7662KG2R6K.

Uses and Administration

Lubiprostone is a chloride-channel activator that acts locally in the gut to increase intestinal fluid secretion, which increases motility. It is used in the treatment of chronic idiopathic constipation (p. 1804.3) in a dose of 24 micrograms twice daily, taken orally with food. It is also used in women for the treatment of constipation-predominant irritable bowel syndrome (p. 1810.3) in a dose of 8 micrograms twice daily, taken orally with food.

Adverse Effects and Precautions

The most common adverse effect of lubiprostone is nausea, which is dose-dependent and may be severe in some patients. Symptoms can be reduced by taking lubiprostone with food. Diarrhoea also occurs commonly, and other gastrointestinal effects include abdominal distension and pain, flatulence, and vomiting. Other reported adverse effects include headache, dizziness, fatigue, dyspnoea, chest discomfort, and peripheral oedema. Intestinal functional disorder, constipation, cough, dysgeusia, eructation, decreased appetite, gastro-oesophageal reflux disease, gastritis, increased weight, and rectal haemorrhage have been reported rarely, as have muscle cramps, joint swelling, myalgia, fibromyalgia, hyperhidrosis, pain (including pharyngolaryngeal pain), anxiety, influenza, syncope, tremor, dry mouth, increased liver enzyme values, erythema, palpitations, urinary-tract infection, and depression.

Lubiprostone is contra-indicated in patients with a history of mechanical gastrointestinal obstruction.

Pharmacokinetics

A negligible amount of lubiprostone is absorbed after an oral dose. It is rapidly and extensively metabolised by carbonyl reductase, probably in the stomach and jejunum.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Amitiza; *Switz.*: Amitiza; *UK*: Amitiza; *USA*: Amitiza.

Magaldrate *(BAN, USAN, rINN)*

Aluminum Magnesium Hydroxide Sulfate; AY-5710; Hidroxidosulfato de aluminio y magnesio hidratado; Magaldraatti; Magaldrat; Magáldrát; Magaldratas; Magaldrato; Magaldratum; Маралдрат.

$Al_5Mg_{10}(OH)_{31}(SO_4)_2.xH_2O$=1097.3 (anhydrous)

CAS — 74978-16-8.

ATC — A02AD02.

ATC Vet — QA02AD02.

UNII — 0MFM55849I (anhydrous magaldrate); 6V88E24N5T (magaldrate hydrate).

NOTE. Magaldrate was formerly described as Aluminium Magnesium Hydroxide ($AlMg_2(OH)_7$ monohydrate, *CAS—1317-26-6*).

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Magaldrate). A combination of aluminium and magnesium hydroxides (see p. 1817.2 and p. 1857.2 respectively) and sulfates. It contains the equivalent of 90 to 105% of $Al_5Mg_{10}(OH)_{31}(SO_4)_2$, calculated with reference to the dried substance. It contains a variable amount of water. A white or almost white crystalline powder. Practically insoluble in water and in alcohol; soluble in dilute mineral acids. It loses between 10 and 20% of its weight on drying at 200 degrees for 4 hours.

USP 36: (Magaldrate). A combination of aluminium and magnesium hydroxides and sulfates. It contains the equivalent of 90 to 105% of $Al_5Mg_{10}(OH)_{31}(SO_4)_2$, calculated on the dried basis. A white odourless crystalline powder. Insoluble in water and in alcohol; soluble in dilute solutions of mineral acids. It loses between 10 and 20% of its weight on drying at 200 degrees for 4 hours.

Profile

Magaldrate is an antacid (see p. 1803.1) that is given in oral doses of up to about 2 g.

Magnesium Carbonate

Bázisos magnézium-karbonát; E504; Magnesii Carbonas; Magnesii Subcarbonas; Magnesio, carbonato de; Magnésium, carbonate de; Magnesiumsubkarbonaatti; Magnesiumsubkarbonat; Magnezu węglan; Magnezyum Karbonat; Magnio subkarbonatas; Uhličitan hořečnatý zásaditý; Магния Карбонат.

CAS — 546-93-0 (anhydrous magnesium carbonate); 23389-33-5 (hydrated normal magnesium carbonate); 39409-82-0 (hydrated basic magnesium carbonate).

ATC — A02AA01; A06AD01.

ATC Vet — QA02AA01; QA06AD01.

UNII — 0E53J927NA.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, *US*, and *Viet.* Some pharmacopoeias include a single monograph that permits both the light and heavy varieties while some have 2 separate monographs for the 2 varieties.

Ph. Eur. 8: (Magnesium Carbonate, Heavy; Magnesii Subcarbonas Ponderosus). A hydrated basic magnesium carbonate containing the equivalent of 40 to 45% of MgO. A white or almost white powder. Practically insoluble in water; dissolves in dilute acids with strong effervescence.

Ph. Eur. 8: (Magnesium Carbonate, Light; Magnesii Subcarbonas Levis). A hydrated basic magnesium carbonate containing the equivalent of 40 to 45% of MgO. A white or almost white powder. Practically insoluble in water; dissolves in dilute acids with strong effervescence.

USP 36: (Magnesium Carbonate). A basic hydrated magnesium carbonate or a normal hydrated magnesium carbonate containing the equivalent of 40.0 to 43.5% of MgO. It is an odourless, bulky white powder or light, white, friable masses. Practically insoluble in water; insoluble in alcohol; dissolves in dilute acids with effervescence.

Profile

Magnesium carbonate is an antacid with general properties similar to those of magnesium hydroxide (p. 1857.2) that is given in oral doses of up to about 500 mg. When given orally, it reacts with gastric acid to form soluble magnesium chloride and carbon dioxide in the stomach; the carbon dioxide may cause flatulence and eructation. Magnesium carbonate is often given with aluminium-containing antacids such as aluminium hydroxide, which counteract its laxative effect.

Magnesium carbonate may be used as a magnesium supplement. It is also used as a food additive, and as a binder and diluent in tablet-making.

Preparations

Proprietary Preparations (details are given in Volume B)

Pharmacopoeial Preparations
BP 2014: Aromatic Magnesium Carbonate Mixture; Chewable Calcium Carbonate and Heavy Magnesium Carbonate Tablets; Compound Magnesium Trisilicate Oral Powder; Kaolin Mixture; Magnesium Sulphate Mixture; Magnesium Trisilicate Mixture;
USP 36: Alumina and Magnesium Carbonate Oral Suspension; Alumina and Magnesium Carbonate Tablets; Alumina, Magnesium Carbonate, and Magnesium Oxide Tablets; Calcium and Magnesium Carbonates Oral Suspension; Calcium and Magnesium Carbonates Tablets; Magnesium Carbonate and Citric Acid for Oral Solution; Magnesium Carbonate and Sodium Bicarbonate for Oral Suspension; Magnesium Carbonate, Citric Acid, and Potassium Citrate for Oral Solution; Magnesium Citrate Oral Solution.

Magnesium Citrate

Magnesii citras; Magnesio, citrato de; Magnésium, citrate de; Магний Цитрат.

$C_{12}H_{10}Mg_3O_{14}$=451.1

CAS — 3344-18-1 (anhydrous magnesium citrate); 153531-96-5 (magnesium citrate nonahydrate); 144-23-0 (dibasic magnesium citrate).

ATC — A06AD19; A12CC04; B05CB03.

ATC Vet — QA06AD19; QA12CC04; QB05CB03.

UNII — RHO26O1T9V.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Magnesium Citrate, Anhydrous). A white or almost white, fine, slightly hygroscopic powder. Soluble in water; practically insoluble in alcohol. It dissolves in dilute hydrochloric acid. Store in non-metallic, airtight containers.

Ph. Eur. 8: (Magnesium Citrate Dodecahydrate). A white or almost white, fine powder. Sparingly soluble in water; practically insoluble in alcohol; dissolves in dilute hydrochloric acid. A 5% solution in water has a pH of 6.0 to 8.5.

Ph. Eur. 8: (Magnesium Citrate Nonahydrate). A white or almost white, fine powder. Sparingly soluble in water; practically insoluble in alcohol; dissolves in dilute hydrochloric acid. A 5% solution in water has a pH of 6.0 to 8.5.

USP 36: (Magnesium Citrate). A 5% suspension in water has a pH of 5.0 to 9.0. Store in airtight containers.

Profile

Magnesium citrate is an osmotic laxative (p. 1804.1) used as a bowel evacuant before investigational procedures or surgery of the colon. Dosages have ranged from about 11 to 25 g of magnesium citrate. In the UK, an aqueous solution containing magnesium citrate is prepared from a sachet (*Citramag; Sanochemia, UK*) containing about 11.6 g of magnesium carbonate and about 17.8 g of anhydrous citric acid by mixing with 200 mL of hot water. After the solution has cooled, one dose (the contents of one sachet) is taken orally at 8 a.m. the day before the procedure, and a second dose between 2 and 4 p.m. For doses in children, see below. A high fluid intake and low residue diet are needed with such bowel preparations. Magnesium citrate is also used with sodium picosulfate, see p. 1887.2.

Magnesium citrate is given as a magnesium supplement in oral doses of up to about 1.9 g daily.

Dibasic magnesium citrate (magnesium hydrogen citrate) has also been used.

For the general properties of magnesium salts, see p. 1786.3.

References.
1. Hoy SM, *et al.* Sodium picosulfate/magnesium citrate: a review of its use as a colorectal cleanser. *Drugs* 2009; 69: 123–36.

Administration in children. The *BNFC* recommends the following oral doses of magnesium citrate (*Citramag; Sanochemia, UK*) for use as a bowel cleanser in children, to be taken on the day before the procedure:

- 5 to 10 years: of a sachet at 8 a.m. and of a sachet between 2 and 4 p.m.
- 10 to 18 years: ½ to 1 sachet at 8 a.m. and ½ to 1 sachet between 2 and 4 p.m.

For reconstitution directions, see above.

Migraine. For mention of the use of magnesium supplementation, including magnesium citrate, for the prophylaxis of migraine, see p. 1788.3.

Pharmacopoeial Preparations
USP 36: Magnesium Citrate for Oral Solution.

Magnesium Hydroxide

E528; Hydroxid hořečnatý; Magnesii hydroxidum; Magnesio, hidróxido de; Magnésium-Hydrate; Magnésium, hydroxyde de; Magneslumhydroksidi; Magnesiumhydroxid; Magnézium-hidroxid; Magnezyum Hidroksit; Magnio hidroksidas; Магния Гидроксид.

$Mg(OH)_2$=58.32

CAS — 1309-42-8.

ATC — A02AA04; G04BX01.

ATC Vet — QA02AA04; QG04BX01.

UNII — NBZ3QY004S.

NOTE. Compounded preparations of magnesium hydroxide may be represented by the following names:

- Co-magaldrox *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of magnesium hydroxide and aluminium hydroxide respectively.

Pharmacopoeias. In *Eur.* (see p. vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 8: (Magnesium Hydroxide). A fine white or almost white amorphous powder. Practically insoluble in water; dissolves in dilute acids. A solution in water is alkaline to phenolphthalein.

USP 36: (Magnesium Hydroxide). A bulky white powder. Practically insoluble in water, in alcohol, in chloroform, and in ether; soluble in dilute acids. Store in airtight containers.

Uses and Administration

Magnesium hydroxide is an antacid (see p. 1803.1) that is given in oral doses of up to about 1 g. It is often given with aluminium-containing antacids such as aluminium hydroxide which counteract its laxative effect.

Magnesium hydroxide is also given as an osmotic laxative (p. 1804.1) in oral doses of about 2 to 5 g.

Magnesium hydroxide has also been used as a food additive and as a magnesium supplement in deficiency states.

Adverse Effects, Treatment, and Precautions

As for magnesium salts in general, see p. 1789.3. Magnesium hydroxide may cause diarrhoea, an effect that is dose-dependent. Hypermagnesaemia may occur, usually in patients with renal impairment.

Hypermagnesaemia. There have been reports of hypermagnesaemia in infants given magnesium-containing antacids,[1-3] and in an adult patient with normal renal function but bowel obstruction.[4]

1. Brand JM, Greer FR. Hypermagnesemia and intestinal perforation following antacid administration in a premature infant. *Pediatrics* 1990; 85: 121–4.
2. Alison LH, Bulugahapitiya D. Laxative induced magnesium poisoning in a 6 week old infant. *BMJ* 1990; 300: 125.
3. Sullivan JE, Berman BW. Hypermagnesemia with lethargy and hypotonia due to administration of magnesium hydroxide to a 4-week-old infant. *Arch Pediatr Adolesc Med* 2000; 154: 1272–4.
4. Laughlin SA, McKinney PE. Antacid-induced hypermagnesemia in a patient with normal renal function and bowel obstruction. *Ann Pharmacother* 1998; 32: 312–15.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies magnesium hydroxide as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Interactions

As outlined on p. 1803.1, antacids, including magnesium salts, interact with many other drugs both by alterations in gastric pH and emptying, and by formation of complexes that are not absorbed. Interactions can be minimised by giving the antacid and any other medications 2 to 3 hours apart.

Pharmacokinetics

Magnesium hydroxide, given orally, reacts relatively rapidly with hydrochloric acid in the stomach to form magnesium chloride and water. About 30% of the magnesium ions are absorbed from the small intestine, as described for Magnesium Salts, p. 1790.2.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Leche de Magnesia Phillips; Magnesia San Pellegrino; *Braz.*: Leite de Magnesia de Phillips; Mylanta Plus; *Canad.*: Milk of Magnesia; Phillips' Magnesia Tablets; Phillips' Milk of Magnesia; *Chile*: Leche de Magnesia Phillips; Magnesia Pasteur; Tabletas Antiacidas; *Denm.*: Magnesia; *Fin.*: Emgesan; Magnesiamaito; *Fr.*: Magnesie San Pellegrino; *Gr.*: Milk of Magnesia; *Hong Kong*: Pedia-Lax; *Hung.*: Antagel M; *India*: Dey's Milk of Magnesia; Tricaine-MPS; *Indon.*: Laxasium; *Irl.*: Milk of Magnesia; *Israel*: Magnesia S Pellegrino; Milk of Magnesia; *Ital.*: Citrato Espresso S. ATC — A02AA02; A06AD02; A12CC10.

ATC Vet — QA02AA02; QA06AD02; QA12CC10.

UNII — 3A3U0GI71G.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.* Some pharmacopoeias include a single monograph that permits both the light and heavy varieties while some have 2 separate monographs for the 2 varieties.

Ph. Eur. 8: (Magnesium Oxide, Heavy; Magnesii Oxidum Ponderosum). A fine, white or almost white powder. 15 g has an apparent volume before settling of not more than 60 mL. Practically insoluble in water; dissolves in dilute acids with at most slight effervescence.

Ph. Eur. 8: (Magnesium Oxide, Light; Magnesii Oxidum Leve). A fine, white or almost white, amorphous powder. 15 g has an apparent volume before settling of at least 100 mL. Practically insoluble in water; dissolves in dilute acids with at most slight effervescence.

USP 36: (Magnesium Oxide). A very bulky, white powder, or a relatively dense, white powder, or a granulated powder. Practically insoluble in water; insoluble in alcohol; soluble in dilute acids. Store in airtight containers.

Profile

Magnesium oxide is an antacid with general properties similar to those of magnesium hydroxide (above). It is given in usual oral doses of about 400 mg. It is often given with aluminium-containing antacids such as aluminium hydroxide, which counteract its laxative effect.

Magnesium oxide has been used for its osmotic laxative properties in bowel preparation; oral doses of 3.5 g are given for this purpose, combined with bisacodyl or sodium picosulfate.

Magnesium oxide is also used as a magnesium supplement in deficiency states in oral doses of up to 800 mg (20 mmol) daily. It is also used as a food additive.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies magnesium oxide as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

Magnesium Trisilicate

E553(a); Magnesii trisilicas; Magnesio, trisilicato de; Magnésium, trisilicate de; Magnesiumtrisilicat; Magnesiumtrisilikaatti; Magnesiumtrisilikat; Magnézium-trisziliká; Magnezyum Trisilikat; Magnio trisilikatas; Trikřemičitan hořečnatý; Магния Трисиликат.

CAS — 14987-04-3 (anhydrous magnesium trisilicate); 39365-87-2 (magnesium trisilicate hydrate).

UNII — C2EIC501T.

Description. Magnesium trisilicate is a hydrated magnesium silicate. The code E553(a) has been applied to both magnesium silicate and to magnesium trisilicate.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *US*, and *Viet.*

Ph. Eur. 8: (Magnesium Trisilicate). It has a variable composition corresponding approximately to the formula $Mg_2Si_3O_8.xH_2O$ containing not less than 29% of magnesium oxide and not less than the equivalent of 65% of silicon dioxide, both calculated with reference to the ignited substance. A white or almost white powder. Practically insoluble in water and in alcohol.

USP 36: (Magnesium Trisilicate). A compound of magnesium oxide and silicon dioxide with varying proportions of water. It contains not less than 20% of magnesium oxide and not less than 45% of silicon dioxide. A fine, white, odourless, powder, free from grittiness. Insoluble in water and in alcohol. It is readily decomposed by mineral acids.

Profile

Magnesium trisilicate is a hydrated magnesium silicate. It is an antacid with general properties similar to those of magnesium hydroxide (p. 1857.2). It may be given in typical oral doses of up to about 500 mg as required, although higher doses have been given. When given orally it reacts more slowly with hydrochloric acid in the stomach than magnesium hydroxide. Magnesium trisilicate is often given with aluminium-containing antacids such as aluminium hydroxide, which counteract its laxative effect.

Magnesium trisilicate is also used as a food additive and as a pharmaceutical excipient.

Effects on the kidneys. The formation of renal calculi containing silica is unusual, but has been reported in a small number of patients. In most of these cases, stone formation was attributed to the prolonged, and sometimes excessive, intake of antacids that contained magnesium trisilicate.[1,2]

Mebeverine Hydrochloride

(BANM, USAN, rINNM)

CSAG-144; Hidrocloruro de mebeverina; Mebeverina, hidrocloruro de; Mébévérine, Chlorhydrate de; Mebeverini Hydrochloridum; Мебеверина Гидрохлорид.

4-[Ethyl(4-methoxy-α-methylphenethyl)amino]butyl veratrate hydrochloride.

$C_{25}H_{35}NO_5HCl$=466.0

CAS — 3625-06-7 (mebeverine); 2753-45-9 (mebeverine hydrochloride).

ATC — A03AA04.

ATC Vet — QA03AA04.

UNII — 15VZSAL4JN.

Pharmacopoeias. In *Br.*

BP 2014: (Mebeverine Hydrochloride). A white or almost white crystalline powder. Very soluble in water; freely soluble in alcohol; practically insoluble in ether. A 2% solution in water has a pH of 4.5 to 6.5. Store in airtight containers at a temperature not exceeding 30 degrees. Protect from light.

Uses and Administration

Mebeverine hydrochloride is an antispasmodic with a direct action on the smooth muscle of the gastrointestinal tract. It is used in conditions such as irritable bowel syndrome (p. 1810.3) in a usual oral dose of 135 mg three times daily before meals; 100 mg three times daily has also been used. A modified-release preparation is also available, taken as 200 mg twice daily. The embonate is also used for oral liquid preparations in a dose equivalent to 150 mg of the hydrochloride three times daily.

For doses in children, see below.

Administration in children. Mebeverine is used in children for the symptomatic relief of gastrointestinal smooth muscle spasm. The *BNFC* suggests the following oral doses, expressed as mebeverine hydrochloride, given three times daily, preferably 20 minutes before meals:

- 3 to 4 years: 25 mg
- 4 to 8 years: 50 mg
- 8 to 10 years: 100 mg
- 10 to 18 years: adult doses may be given, see above

A modified-release formulation is also available; children from 12 years of age may be given adult doses, see above.

Adverse Effects and Precautions

Although adverse effects appear rare, gastrointestinal disturbances, dizziness, headache, insomnia, anorexia, and decreased heart rate have been reported in patients receiving mebeverine. Cases of hypersensitivity, including erythematous rash, urticaria, and angioedema, have also been reported. Mebeverine should be avoided in patients with paralytic ileus. Based on theoretical concerns, it should be used with care in patients with marked hepatic or renal impairment, and those with cardiac disorders such as heart block.

Cystic fibrosis. A 24-year-old man with cystic fibrosis, given mebeverine hydrochloride for lower abdominal pain and constipation, was found to have a perforated stercoral ulcer with generalised peritonitis.[1] It was suggested that mebeverine produced colonic stasis, which predisposed the patient to ulceration,[1] but the manufacturers[2] considered that the development of constipation and distal intestinal syndrome (meconium ileus equivalent) in this patient precipitated the development of stercoral ulceration. It was recommended[1] that antispasmodics such as mebeverine should not be used for the symptomatic treatment of distal intestinal syndrome in cystic fibrosis.

2. Whitehead AM. Perforation of colon in distal intestinal syndrome of cystic fibrosis. *Lancet* 1990; **336**: 446.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies mebeverine as

probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pharmacokinetics

Mebeverine is rapidly absorbed after oral doses with peak plasma concentrations occurring in 1 to 3 hours. It is 75% bound to albumin in plasma. Mebeverine is completely metabolised by hydrolysis to veratric acid and mebeverine alcohol, the latter of which may then be conjugated. The metabolites are excreted in the urine.

3-Benziloyloxy-1,1-dimethylpiperidinium bromide.
$C_{21}H_{26}BrNO_3$=420.3
CAS — 25990-43-6 (mepenzolate); 76-90-4 (mepenzolate bromide).
ATC — A03AB12.
ATC Vet — QA03AB12.
UNII — APX8D32IX1.

Pharmacopoeias. In *Jpn.*

Profile

Mepenzolate bromide is a quaternary ammonium antimuscarinic with peripheral actions similar to those of atropine (p. 1312.1). It has been used in the relief of gastrointestinal disorders associated with smooth muscle spasm and as an adjunct in the treatment of peptic ulcer disease. Up to 200 mg daily may be given orally in divided doses.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies mepenzolate as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Trancolon; *USA*: Cantil.

Multi-ingredient Preparations. *Jpn*: Trancolon P.

Mesalazine *(BAN, rINN)*

5-Aminosalicylic Acid; 5-ASA; Fisalamine; Mesalamine (USAN); Mesalatsiini; Mesalazin; Mesalazina; Mesalazinas; Mésalazine; Mesalazinum; Месалазин.
5-Amino-2-salicylic acid.
$C_7H_7NO_3$=153.1.
CAS — 89-57-6.
ATC — A07EC02.
ATC Vet — QA07EC02.
UNII — 4Q81I59GXC.

NOTE. Distinguish from 4-aminosalicylic acid (Aminosalicylic Acid, p. 215.2) which is used in the treatment of tuberculosis.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Mesalazine). An almost white or light grey or light pink powder or crystals. Very slightly soluble in water; practically insoluble in alcohol. It dissolves in dilute solutions of alkali hydroxides and in dilute hydrochloric acid. Store in airtight containers. Protect from light.

USP 36: (Mesalamine). Light tan to pink needle-shaped crystals, odourless or with a slight characteristic odour. The colour may darken on exposure to air. Slightly soluble in water; very slightly soluble in dehydrated alcohol, in acetone, and in methyl alcohol; practically insoluble in butyl alcohol, in chloroform, in dichloromethane, in ether, in ethyl acetate, in *n*-hexane, and in propyl alcohol; soluble in dilute hydrochloric acid and in dilute alkali hydroxides. A 2.5% suspension in water has a pH of 3.5 to 4.5. Store in airtight containers. Protect from light.

Uses and Administration

Mesalazine is an anti-inflammatory drug structurally related to the salicylates and active in inflammatory bowel disease (p. 1808.3); it is considered to be the active moiety of sulfasalazine (p. 1890.1). Mesalazine is thought to act locally on the inflamed intestinal tissue, rather than systemically. Although its precise mechanism of action is uncertain, it may be due to inhibition of prostaglandin and leukotriene synthesis in the gastrointestinal mucosa.

Mesalazine is given orally or rectally in the treatment of *acute attacks* of mild to moderate ulcerative colitis, or the *maintenance of remission* of ulcerative colitis. Some products are also used for the *maintenance of remission* of Crohn's ileocolitis.

There are several differently formulated oral preparations of mesalazine available, and dosage recommendations vary. Recommended doses for some UK preparations are as follows:

- *Asacol 400 mg* tablets (*Warner Chilcott, UK*), *Ipocol* tablets (*Sandoz, UK*), *Mesren* tablets (*IVAX, UK*): acute attack, initially 2.4 g daily in divided doses; maintenance of remission, 1.2 to 2.4 g daily in divided doses.
- *Asacol 800 mg* tablets (*Warner Chilcott, UK*): mild acute exacerbations, 2.4 g daily in divided doses; moderate acute exacerbations, 4.8 g daily in divided doses; maintenance of remission, up to 2.4 g daily in divided doses
- *Mezavant* tablets (*Shire, UK*): acute attack, initially 2.4 to 4.8 g once daily; maintenance of remission, 2.4 g once daily
- *Pentasa* tablets (*Ferring, UK*): acute attack, initially up to 4 g daily in 2 or 3 divided doses; maintenance of remission, adjusted individually from an initial dose of 2 g once daily.
- *Pentasa* granules (*Ferring, UK*): acute attack, initially, up to 4 g daily in 2 to 4 divided doses; maintenance of remission, 2 g once daily.
- *Salofalk* tablets (*Falk, UK*): acute attack, initially 1.5 to 3 g daily in 3 divided doses; maintenance of remission, 1.5 g daily in 3 divided doses.
- *Salofalk* granules (*Falk, UK*): acute attack, initially 1.5 to 3 g daily, either once daily, or in 3 divided doses; maintenance of remission, 1.5 g daily in 3 divided doses.

Mesalazine may be given rectally, particularly when disease affects the sigmoid colon and rectum. Various formulations are available and the dose is usually given at night, but preparations do vary. Recommended doses for some UK preparations are as follows:

- *Asacol* suppositories (*Warner Chilcott, UK*): 0.75 to 1.5 g daily in divided doses
- *Asacol* foam enema (*Warner Chilcott, UK*): 1 g daily for disease affecting the rectosigmoid region; 2 g daily for disease involving the descending colon
- *Pentasa* suppositories and suspension enema (*Ferring, UK*): 1 g daily
- *Salofalk* suppositories (*Falk, UK*): 0.5 to 1 g given 2 or 3 times daily
- *Salofalk* foam enema and suspension enema (*Falk, UK*): 2 g daily

Similar preparations are available in other countries, and in the USA a suspension enema containing 4 g of mesalazine has been used.

For doses in children, see below.

Administration. Because the release characteristics of different formulations of mesalazine vary, they should not be regarded as interchangeable.[1] This applies even to those formulations where the dosage is apparently similar.[2] However, a study in healthy subjects established that an oral once-daily regimen was bioequivalent to a twice-daily regimen of the same product (*Pentasa (Ferring, France)*),[3] and another study using a different product (*Salofalk granules (Falk, Germany)*) found that 8 weeks of once-daily dosing had similar safety and efficacy to a three-times daily regimen for inducing remission in patients with active ulcerative colitis.[4]

Administration in children. Mesalazine may be given orally or rectally to children in the treatment of *acute attacks* of mild to moderate ulcerative colitis, or the *maintenance of remission* of ulcerative colitis.

There are several differently formulated oral preparations of mesalazine available, and dosage recommendations vary. The *BNFC* suggests the following oral doses for some UK preparations when used in children:

- *Asacol 400 mg* tablets (*Warner Chilcott, UK*): children aged 12 to 18 years may be given similar doses to adults, see above.
- *Ipocol* tablets (*Sandoz, UK*): children aged 6 to 18 years and weighing 40 kg or more may be given similar doses to adults.
- *Pentasa* tablets and granules (*Ferring, UK*) and *Salofalk* tablets and granules (*Falk, UK*): children aged 5 to 18 years and under 40 kg: acute attack, 30 to 60 mg/kg daily in 3 divided doses; maintenance of remission, 15 to 30 mg/kg daily in 2 or 3 divided doses. Children aged 5 to 18 years and over 40 kg may be given similar doses to adults.

In addition, *Salofalk* granules may be given to children under 40 kg in a dose of 30 to 50 mg/kg once daily (preferably in the morning) for an acute attack.

Mesalazine may also be given rectally to children, particularly when disease affects the sigmoid colon and rectum. Various formulations are available and the dose is usually given at night, but preparations do vary. The *BNFC* suggests that children aged 12 to 18 years may be given similar doses to adults.

Diverticular disease. In a study involving 218 patients with a history of recurrent attacks of acute diverticulitis (p. 1806.2), half were assigned to treatment with oral

rifaximin 400 mg twice daily for 7 days, and half received rifaximin plus a modified-release formulation of mesalazine 800 mg three times daily, again for 7 days. Courses were then repeated, with rifaximin at the same dose and mesalazine at 800 mg twice daily, for 7 days in each month, and patients followed for 12 months. The combination of rifaximin and mesalazine was significantly more effective in reducing symptomatic episodes and normalisation of bowel habit than rifaximin alone: 89 of 107 patients given the combination were symptom-free at 12 months, compared with 44 of 105 given just the antibacterial.[1] Similarly, the same group found that in patients with uncomplicated diverticular disease given 10 days of treatment with rifaximin and mesalazine (*Pentacol; Sofar, Ital.*) in the doses above, followed by mesalazine 1.6 g daily for 8 weeks, 70 of 86 completing the study were completely asymptomatic, suggesting that daily mesalazine alone was an effective maintenance therapy, although longer-term studies were needed.[2] Mesalazine has also been investigated in combination with a probiotic preparation of lactic-acid-producing organisms.[3]

Adverse Effects and Precautions

Mesalazine may cause headache and gastrointestinal disturbances, such as nausea, diarrhoea, and abdominal pain. Hypersensitivity reactions may occasionally occur. Some patients may experience exacerbation of symptoms of colitis. There are some reports of myocarditis, pericarditis, pancreatitis, interstitial nephritis, nephrotic syndrome, allergic lung reaction, increased liver enzyme values, hepatitis, lupus-like syndrome, skin reactions, alopecia, peripheral neuropathy, myalgia, and arthralgia. There have been rare reports of blood disorders including aplastic anaemia, agranulocytosis, leucopenia, neutropenia, thrombocytopenia, and methaemoglobinaemia.

Mesalazine should not be given to patients with severe renal or hepatic impairment, or salicylate hypersensitivity. It should be used with caution in the elderly, and in mild to moderate renal or hepatic impairment, active peptic ulceration, or sulfasalazine allergy.

If a blood dyscrasia is suspected treatment should be stopped immediately and a blood count performed. Patients or their carers should be told how to recognise signs of blood toxicity and should be advised to seek immediate medical attention if symptoms such as fever, sore throat, mouth ulcers, bruising, or bleeding develop. It is recommended that renal function is monitored before and during therapy (see Effects on the Kidneys, below).

Many of the adverse effects associated with sulfasalazine (sulfapyridine linked to mesalazine) therapy have been attributed to the sulfapyridine moiety and most patients unable to tolerate sulfasalazine because of hypersensitivity or adverse reactions can be transferred to mesalazine without adverse effects occurring.[1-4] However, a small number of patients also have adverse effects while taking mesalazine and these are often very similar to those seen with sulfasalazine.[1-4] They may include nausea, abdominal discomfort or pain, exacerbation of diarrhoea, headache, fever, and rashes. Mesalazine is not generally associated with sulfasalazine's adverse effects on sperm (although there has been a case of reversible male infertility attributed to mesalazine—see under Sulfasalazine, p. 1891.2). An analysis of adverse reactions reported to the UK CSM between 1991 and 1998 found no evidence of a significant difference in the frequency of serious adverse effects for mesalazine and sulfasalazine in the treatment of inflammatory bowel disease.[5] Reports of pancreatitis and interstitial nephritis were more common with mesalazine (but see Effects on the Kidneys, below). However, it has been pointed out that 80% of patients intolerant to sulfasalazine will tolerate mesalazine without problems.[6]

Mesalazine therapy should be started cautiously in patients with a history of sulfasalazine hypersensitivity and it should be withdrawn if signs of sensitivity develop or if there is diarrhoea or rectal bleeding. It has been suggested[2] that patients with a history of sulfasalazine hypersensitivity should be given test doses of mesalazine before starting a full course.

Breast feeding. The concentrations of mesalazine in maternal plasma and breast milk in a woman taking 500 mg three times daily, were 410 and 110 nanograms/mL respectively.[1] Although it was considered that the amount of mesalazine distributed into breast milk was small and that it was safe during breast feeding,[2,3] maternal use of mesalazine 500 mg suppositories twice daily has been associated with watery diarrhoea in a breast-fed infant[2] and for this reason the American Academy of Pediatrics considers that mesalazine should be given with caution to breast-feeding mothers.[4]

Effects on the blood. Although uncommon, mesalazine-associated adverse effects on the blood have been reported, including thrombocytopenia,[1,2] neutropenia,[3] severe aplastic anaemia,[4,5] and pancytopenia.[6] In July 1995 the UK CSM stated that it had been notified of 49 haematological reactions suspected of being associated with mesalazine,[7] including 5 reports of aplastic anaemia, 1 of agranulocytosis, 11 of leucopenia, and 17 of thrombocytopenia. There had been 3 fatalities. They recommended a blood count and immediate withdrawal of the drug if a dyscrasia was suspected. Intensive immunosuppressive treatment has been used in the management of mesalazine-associated aplastic anaemia.[5,8]

Effects on the cardiovascular system. Myocarditis associated with chest pain and ECG abnormalities has been reported[1,2] in 2 patients taking mesalazine; 1 patient died in cardiogenic shock.[2] It has been suggested that mesalazine or sulfasalazine should be replaced by glucocorticoids if cardiac symptoms arise during treatment.[2] Pericarditis[3,4] with fever, rash, dyspnoea, pleural and pericardial effusions, and arthritis, has been described, and is considered to constitute a drug-induced lupus-like syndrome. Constrictive pericarditis with an absence of other lupus-like symptoms developed in a patient taking mesalazine for inflammatory bowel disease.[5] Based on reported cases of mesalazine-induced pericarditis, symptoms of this potentially life-threatening adverse effect have tended to arise 2 to 4 weeks after starting mesalazine, although symptom onset may be delayed by concurrent corticosteroid treatment.[6] Mesalazine cardiotoxicity presenting as an acute coronary syndrome, without myocarditis or pericarditis, has also been reported.[7]

Effects on fertility. For a report of reversible male infertility occurring with mesalazine, see under Sulfasalazine, p. 1891.2.

Effects on the hair. For a report of accelerated loss of scalp hair in 2 patients receiving mesalazine enemas, see under Sulfasalazine, p. 1891.3.

Effects on the kidneys. Between February 1988 and December 1990 the UK CSM[1] received 9 reports of serious nephrotoxic reactions associated with the use of *Asacol*, a modified-release mesalazine preparation. The reactions included 4 cases of interstitial nephritis, 3 of severe renal failure, and 2 cases of nephrotic syndrome. A subsequent case report[2] indicated that by September 1998 the number of such reports for mesalazine totalled 104, including 35 cases of interstitial nephritis. The authors considered that monitoring of renal function was required in patients receiving mesalazine. A protocol for such monitoring was subsequently suggested,[3] and a similar protocol has been adopted in UK licensing information for mesalazine, with serum creatinine being estimated:

- before treatment
- every 3 months for the first year
- every 6 months for the next 4 years
- annually thereafter

The nephrotic syndrome[4] and interstitial nephritis[5] have also been reported with sulfasalazine, and interstitial nephritis with olsalazine (see p. 1867.1). A large UK epidemiologic study found no difference in risk of renal disease between mesalazine and sulfasalazine. The study also concluded that the risk of renal disease associated with mesalazine and related compounds is low and may be partly attributable to the underlying disease.[6] Overall nephrotoxicity has been estimated to occur in about 1 in 4000 UK patients per year taking aminosalicylate-based therapy.[7]

6. Van Staa TP, *et al.* Experience of 5-aminosalicylate nephrotoxicity in the United Kingdom. *Aliment Pharmacol Ther* 2003; 21: 1217–24.

Effects on the liver. A case of chronic hepatitis and liver fibrosis has been reported after prolonged use of mesalazine.[1] The authors considered that mesalazine should be stopped when liver dysfunction occurred.

1. Deltenre P, *et al.* Mesalazine (5-aminosalicylic acid) induced chronic hepatitis. *Gut* 1999; 44: 886–8.

Effects on the nervous system. Peripheral neuropathy,[1] mainly affecting the legs, has occurred during mesalazine treatment. The symptoms resolved on stopping the drug. Mononeuritis multiplex was part of the presentation of an eosinophilic reaction attributed to mesalazine in an asthmatic patient;[2] Churg-Strauss syndrome developed after withdrawal of mesalazine, but the patient subsequently recovered without sequelae.

2. Morice AH, *et al.* Mesalazine activation of eosinophil. *Lancet* 1997; 350: 1105.

Effects on the pancreas. Pancreatitis has been reported as an adverse effect of mesalazine.[1-4] In 2 patients,[1,2] with abdominal pain and raised amylase activity, this reaction to mesalazine was confirmed by rechallenge and symptoms resolved on mesalazine withdrawal. By February 1994 the UK CSM had received 15 reports[3] of pancreatitis associated with mesalazine therapy. However, a case control study suggested that inflammatory bowel disease, rather than the use of mesalazine, may be associated with an increased risk of acute pancreatitis (see under Sulfasalazine, p. 1891.3)

Effects on the respiratory system. Pulmonary complications have been rarely reported with mesalazine. There have though been cases of interstitial lung disease, with features of hypersensitivity pneumonia.[1-3] Symptoms have included dyspnoea, cough, fever, and pleuritic chest pain, with the onset of symptoms varying from a few days to several years after starting mesalazine therapy. Although pulmonary complications can also be associated with inflammatory bowel disease itself, there has been a report[4] of eosinophilic pleural effusion in a patient who was given mesalazine in the absence of an established diagnosis of inflammatory bowel disease.

Pulmonary complications have also been reported with sulfasalazine (p. 1891.3), and pulmonary symptoms may also manifest as part of a broader lupus-like syndrome (see Effects on the Cardiovascular System, p. 1860.2).

4. Trisolini R, *et al.* Eosinophilic pleural effusion due to mesalamine: report of a rare occurrence. *Sarcoidosis Vasc Diffuse Lung Dis* 2000; 17: 288–91.

Lupus. A lupus-like syndrome has been reported in 4 patients receiving mesalazine who developed antinuclear antibody (ANA)-positivity with at least one clinical feature of lupus, such as arthropathy, skin rashes, or acute inflammation unrelated to the underlying condition.[1] In all 4 cases symptoms resolved upon stopping mesalazine. For similar reports, see Effects on the Cardiovascular System, p. 1860.2.

1. Kirkpatrick AW, *et al.* Lupus-like syndrome caused by 5-aminosalicylic acid in patients with inflammatory bowel disease. *Can J Gastroenterol* 1999; 13: 159–62.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies mesalazine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Pregnancy. Renal insufficiency in a neonate whose mother received oral mesalazine 2 to 4 g daily during the second trimester of pregnancy was suggested to be due to the drug,[1] although the proposed mechanism, inhibition of prostaglandin synthesis in the neonatal kidney, has been questioned.[2] A subsequent case-control study[3] found that use of oral mesalazine in 165 pregnant women with inflammatory bowel disease was not associated with a greater incidence of malformations. However, women treated with mesalazine were more likely to have preterm deliveries and newborns with decreased birth-weights, although the disease may have been a factor in this finding. A commentator on this study,[4] considered that active inflammatory bowel disease was a greater risk to pregnancy than drug treatment. In a further cohort of 123 pregnancies,[5] oral mesalazine at doses of 3 g daily or less did not increase the risk of fetal malformations or affect pregnancy outcome. The researchers concluded that further information was required on doses higher than 3 g daily. In another study,[6] all of 19 pregnancies in women receiving rectal mesalazine were full-term with no fetal abnormalities. A Danish cohort study[7] found an increased risk of still-birth and preterm birth in women who had been prescribed mesalazine or olsalazine during pregnancy, but no significant increased risk of malformations. The risk of still-birth was greatest in women with ulcerative colitis who were prescribed corticosteroids and either mesalazine or olsalazine, and the risk of preterm birth was greatest in women with ulcerative colitis who were prescribed either mesalazine or olsalazine alone. The authors acknowledged that it was difficult to distinguish between the increase in risk due to disease state, and the increase in risk due to medication.[7] For a discussion of sulfasalazine in pregnancy, see p. 1892.1.

Interactions

Preparations formulated to release mesalazine in the colon should not be given with drugs, such as lactulose, that lower colonic pH as they may prevent the release of mesalazine (but see Gastrointestinal Drugs below).

Anticoagulants. For reference to a case of mesalazine reducing the effect of *warfarin*, see Gastrointestinal Drugs, p. 1534.1.

Antineoplastics. For mention of 5-aminosalicylates such as mesalazine inhibiting the metabolism of thiopurine antineoplastics, and increasing their toxicity, see Gastrointestinal Drugs, p. 822.1.

Gastrointestinal drugs. Although it has been suggested that *lactulose* could delay the intestinal release of mesalazine from modified-release preparations, a study found no evidence that lactulose influenced the release or disposition of mesalazine.[1] Similarly, *omeprazole* did not appear to increase the likelihood of premature mesalazine release.

1. Hussain FN, *et al.* Mesalazine release from a pH dependent formulation: effects of omeprazole and lactulose co-administration. *Br J Clin Pharmacol* 1998; 46: 173–5.

Pharmacokinetics

If given orally as conventional formulations, mesalazine would be extensively absorbed from the upper gastrointestinal tract, with little of the drug reaching the colon. Oral preparations are therefore generally formulated to release the drug in the terminal ileum and colon, where it is thought to exert a mainly local action. The specific release characteristics differ somewhat between formulations and this, together with interindividual variation, makes comparison of pharmacokinetic data between studies difficult. Even with modified-release preparations some 30 to 50% of an oral dose is thought to be lost to absorption in healthy subjects. Absorption from rectal dosage forms has also varied widely, with factors such as the dose, the formulation, and the pH also playing a role, but mean absorption of around 10 to 30% of a rectal dose has been reported.

The absorbed portion of mesalazine is almost completely acetylated in the gut wall and in the liver to acetyl-5-aminosalicylic acid. The rate of acetylation, and hence the concentration of parent drug and metabolite in the systemic circulation, may be dose dependent and subject to saturation. The acetylated metabolite is excreted mainly in urine by tubular secretion, with traces of the parent compound.

The plasma half-life of mesalazine is reported to be about 40 minutes and it is 40 to 50% bound to plasma proteins; the acetylated metabolite has a plasma half-life of 70 minutes and is about 80% bound to plasma proteins.

Only negligible quantities of mesalazine cross the placenta. Amounts distributed into breast milk are very small.

CAS — 5818-17-7 (methanthelinium); 53-46-3 (methanthelinium bromide).

ATC — A03AB07.

ATC Vet — QA03AB07.

UNII — 090519SAPF.

Profile

Methanthelinium bromide is a quaternary ammonium antimuscarinic with peripheral effects similar to those of atropine (p. 1312.1). It has been used as an adjunct in the treatment of peptic ulcer disease, in gastrointestinal disorders associated with smooth muscle spasm, and in the management of urinary incontinence. A usual oral dose in gastrointestinal disorders is 50 mg three times daily.

$C_{21}H_{26}BrNO_4$=436.3

CAS — 83387-25-1 (methylnaltrexone); 73232-52-7 (methylnaltrexone bromide).

ATC — A06AH01.

ATC Vet — QA06AH01.

UNII — RFO6IL3D3M.

Uses and Administration

Methylnaltrexone bromide is a selective peripherally acting antagonist of opioid μ-receptors that is used for the treatment of opioid-induced constipation in patients receiving palliative care for advanced illness, when response

The symbol † denotes a preparation no longer actively marketed

to usual laxative therapy is insufficient. It is also being studied for treatment of opioid-induced constipation in patients with chronic pain, as well as for opioid-induced urinary retention and postoperative ileus.

For the treatment of opioid-induced constipation methylnaltrexone bromide may be given by subcutaneous injection in the following doses according to body-weight:

- less than 38 kg: 150 micrograms/kg
- 38 to 62 kg: 8 mg
- 62 to 114 kg: 12 mg
- more than 114 kg: 150 micrograms/kg

Doses are usually given once every 48 hours as needed, but no more frequently than once in 24 hours. For doses in renal impairment, see Administration in Renal Impairment, below.

An oral formulation is under investigation.

Administration in renal impairment. Renal impairment reduces the clearance of methylnaltrexone and increases exposure, and although the usual dose (see Uses and Administration, p. 1861.3) may be given to those with mild or moderate impairment (creatinine clearance 30 mL/minute and above), dose reductions are advised in those with severe impairment (creatinine clearance less than 30 mL/minute). UK licensed product information recommends the following subcutaneous doses, usually given once every 48 hours as needed (but no more often than once in 24 hours), according to weight:

- 62 to 114 kg: 8 mg
- less than 62 kg or above 114 kg: 75 micrograms/kg

Methylnaltrexone is not recommended in those with end-stage renal impairment requiring dialysis due to a lack of data.

Similarly, US licensed product information recommends halving the usual dose in severe renal impairment.

Adverse Effects and Precautions

The most common adverse effects in patients treated with methylnaltrexone bromide are gastrointestinal disorders such as abdominal pain, nausea, flatulence, and diarrhoea. If severe or persistent diarrhoea occurs, therapy should be stopped. Dizziness, hyperhidrosis, and injection site reactions are also reported commonly with methylnaltrexone.

Gastrointestinal perforation has been reported rarely and methylnaltrexone should not be used in patients with gastrointestinal obstruction or acute surgical abdomen. Caution is advised in patients with lesions that affect the structural integrity of the gastrointestinal tract such as cancer or peptic ulcer. Caution is also recommended in those with a peritoneal catheter, colostomy, active diverticular disease, or faecal impaction as methylnaltrexone use has not been studied in these patients.

Methylnaltrexone is not recommended in patients with severe hepatic impairment or with end-stage renal disease requiring dialysis, due to a lack of data.

Pharmacokinetics

After subcutaneous injection methylnaltrexone bromide is absorbed rapidly, with peak plasma concentrations occurring at about 0.5 hours. It is only minimally bound to plasma proteins. Methylnaltrexone is eliminated mostly as unchanged drug; metabolites include methylnaltrexone sulfate and methyl-6-naltrexol isomers. Methyl-6-naltrexol isomers have less antagonist activity than methylnaltrexone bromide; methylnaltrexone sulfate is inactive. N-demethylation of methylnaltrexone to naltrexone is not significant. About half of the dose is excreted in the urine and less in the faeces. The terminal half-life is about 8 hours.

$C_{14}H_{22}ClN_3O_2$,HCl,H_2O=354.3

CAS — 7232-21-5 (anhydrous metoclopramide hydrochloride); 54143-57-6 (metoclopramide hydrochloride monohydrate); 2576-84-3 (anhydrous metoclopramide dihydrochloride).

ATC — A03FA01.

ATC Vet — QA03FA01.

UNII — 7B1QZY5SWZ (anhydrous metoclopramide hydrochloride); W1792A2RVD (metoclopramide hydrochloride monohydrate).

Pharmacopoeias. In *Eur.* (see p. vii), *Int.*, and *US.*

Ph. Eur. 8: (Metoclopramide Hydrochloride). A white or almost white, crystalline powder or crystals. Very soluble in water; freely soluble in alcohol; sparingly soluble in dichloromethane. A 10% solution in water has a pH of 4.5 to 6.0. Protect from light.

USP 36: (Metoclopramide Hydrochloride). A white or practically white, odourless or practically odourless, crystalline powder. Very soluble in water; freely soluble in alcohol; sparingly soluble in chloroform; practically insoluble in ether. Store in airtight containers. Protect from light.

Incompatibility. Proprietary preparations of metoclopramide hydrochloride are stated to be incompatible with cephalothin sodium, chloramphenicol sodium, and sodium bicarbonate.

Cisplatin, cyclophosphamide, doxorubicin hydrochloride, morphine hydrochloride, or diamorphine hydrochloride are stated to be compatible with metoclopramide hydrochloride but compatibility is dependent upon factors such as the particular formulation, drug concentration, and temperature.

Uses and Administration

Metoclopramide hydrochloride is a substituted benzamide used for its prokinetic and antiemetic properties. It stimulates the motility of the upper gastrointestinal tract without affecting gastric, biliary, or pancreatic secretion and increases gastric peristalsis, leading to accelerated gastric emptying and intestinal transit time. The resting tone of the gastro-oesophageal sphincter is increased and the pyloric sphincter is relaxed. Metoclopramide possesses parasympathomimetic activity as well as being a dopamine-receptor antagonist with a direct effect on the chemoreceptor trigger zone. It may have serotonin-receptor ($5\text{-}HT_3$) antagonist properties.

Metoclopramide is used in disorders of decreased gastrointestinal motility (p. 1805.2) such as gastroparesis or ileus; in gastro-oesophageal reflux disease (p. 1807.2) and dyspepsia (p. 1806.3); and in nausea and vomiting (p. 1811.3) associated with various gastrointestinal disorders, with migraine, after surgery, and with cancer therapy. It may be used to stimulate gastric emptying during radiographic examinations, to facilitate intubation of the small bowel, and in the management of aspiration syndromes (p. 1804.2).

In order to reduce the risks of neurological and other adverse effects, the EMA has restricted metoclopramide use to a maximum of 5 days and does not recommend its use for chronic conditions such as gastroparesis, dyspepsia, and gastro-oesophageal reflux disease, or as an adjunct in surgical or radiological procedures. The FDA also advises against chronic use unless the benefit of treatment outweighs the risk. The use of metoclopramide is restricted in children and young adults under 20 years of age (see Administration in Children, below).

It is usually given as the hydrochloride monohydrate with doses expressed as the anhydrous hydrochloride. In the USA, the strength of preparations of the hydrochloride monohydrate is usually expressed in terms of the base. Metoclopramide hydrochloride 10.5 mg is equivalent to about 10.0 mg of the anhydrous substance, which is equivalent to about 8.9 mg of the anhydrous base.

For most purposes the total daily dose should not exceed 500 micrograms/kg; dosage reduction is recommended in renal and perhaps hepatic impairment (see Administration in Hepatic or Renal Impairment, below).

- In the UK, the recommended dose, given orally, intramuscularly, or by slow intravenous injection (over at least 3 minutes), is 10 mg (expressed as anhydrous metoclopramide hydrochloride) three times daily.
- In the USA, the usual oral dose is 10 to 15 mg (expressed as the base) up to four times daily.
- Single doses of 10 to 20 mg (expressed as anhydrous base or anhydrous hydrochloride) may be given orally, intravenously, or intramuscularly when required, such as before a diagnostic procedure.

An intranasal formulation of metoclopramide is available in some countries.

The base, and salts including the dihydrochloride and the glycyrrhizate have also been used.

High-dose therapy. High doses of metoclopramide have been used, often with other drugs such as dexamethasone, in the treatment of the nausea and vomiting associated with cancer chemotherapy. In the UK, the loading dose of metoclopramide before cancer therapy is 2 to 4 mg/kg given as a continuous intravenous infusion over 15 to 20 minutes; it is followed by a maintenance dose of 3 to 5 mg/kg, again as a continuous intravenous infusion, given over 8 to 12 hours. Alternatively, initial doses of up to 2 mg/kg by intravenous infusion over at least 15 minutes may be given before cancer therapy and repeated every 2 hours. The total dosage by either continuous or intermittent infusion should not normally exceed 10 mg/kg in 24 hours. In the USA, dosing is started about 30 minutes before cancer chemotherapy; an initial dose of 2 mg/kg for highly emetogenic chemotherapy, or 1 mg/kg for less emetogenic chemotherapy, is given by intravenous infusion over at least 15 minutes. This dose is repeated every 2 hours for 2 doses, then every 3 hours for 3 doses.

Administration. INTRANASAL References.

1. Ormrod D, Goa KL. Intranasal metoclopramide. *Drugs* 1999; 58: 315–22. Commentaries. *ibid.*: 323–4.

Administration in children. In the EU the use of metoclopramide in children and young adults is restricted to a second-line option for prevention of delayed chemotherapy-induced nausea and vomiting and treatment of established postoperative nausea and vomiting. It may be used for up to 5 days in children aged 1 year and over. Usual oral and parenteral (intramuscular or intravenous) doses for all indications in the UK are:

- for those aged 15 to 19 years and weighing 60 kg and over: 10 mg three times daily
- 15 to 19 years (30 to 59 kg): 5 mg three times daily
- 9 to 14 years (30 kg and over): 5 mg three times daily
- 5 to 9 years (20 to 29 kg): 2.5 mg three times daily
- 3 to 5 years (15 to 19 kg): 2 mg two or three times daily
- 1 to 3 years (10 to 14 kg): 1 mg two or three times daily

An alternative dose for postoperative nausea and vomiting in those aged 1 to 20 years is 150 micrograms/kg given by slow intravenous injection. Further doses can be given 6 hours apart to a maximum of 500 micrograms/kg in 24 hours.

Where body-weight is below that specified for a given age group, the dose should reflect the weight rather than the age, so that a lower dose is chosen.

In the USA metoclopramide is licensed for use in children only to facilitate small bowel intubation in those resistant to conventional methods. A single intravenous dose, based on age, is recommended as follows:

- over 14 years: 10 mg
- 6 to 14 years: 2.5 to 5 mg
- under 6 years: 100 micrograms/kg

Administration in hepatic or renal impairment. Total clearance of metoclopramide is significantly reduced in patients with renal impairment[1-3] and the elimination half-life is prolonged to up to 19 hours.[2] This may be due to impaired metabolism[1,2] or to an alteration in enterohepatic circulation of metoclopramide.[1] Accumulation of metoclopramide could therefore occur in renal impairment with a possible increased risk of adverse effects. Dosage reductions of at least 50% have therefore been

recommended in patients with moderate to severe renal impairment.[1,2] US licensed product information recommends this dose reduction in those patients whose creatinine clearance is below 40 mL/minute; UK information advises dose reduction in significant renal impairment, but gives no guidance on appropriate doses.

Patients undergoing haemodialysis do not require dosage supplements since relatively little metoclopramide is cleared by this process.[2,3]

UK licensed product information also recommends that the dose of metoclopramide should be reduced in patients with clinically significant **hepatic impairment**, although again no recommendations on the size of the reduction are given; caution is advised in liver disease, due to loss of conjugation. The US product information notes that metoclopramide undergoes minimal hepatic metabolism and has been used safely in some patients with advanced liver disease (whose renal function was normal), and it makes no such recommendation for reduction of dose. Decreases in clearance and increases in half-life and area under the plasma concentration-time curve have been reported in patients with cirrhosis given metoclopramide.[4,5]

Blood disorders. Responses to treatment with metoclopramide have been reported in patients with Diamond-Blackfan anaemia, probably through induction of prolactin release, although the mechanism by which prolactin affects erythropoiesis is unclear.[1,2] In a pilot study, 3 out of 9 evaluable patients responded after 12 to 15 weeks of therapy; high serum ferritin, pituitary dysfunction, male sex, and younger age may have contributed to the poor response to metoclopramide in other patients.[1] In another case, response was seen by the fourth week of treatment; at the time of the report, the patient had remained asymptomatic and transfusion independent for 8 months.[2]

Gastroenteritis. For mention of the use of antiemetics such as metoclopramide to reduce vomiting in acute gastroenteritis, see Ondansetron, p. 1873.1.

Hiccup. Metoclopramide has been used in the management of intractable hiccup. For a discussion of hiccup and its management see p. 1046.3.

Lactation induction. Metoclopramide has been used[1,2] in doses of 10 mg three times daily for its dopamine antagonist properties to stimulate lactation in women who wish to breast feed and in whom mechanical stimulation of the nipple alone is inadequate, including mothers of adopted babies or babies born to surrogates.[3,4] However, pharmacological lactation induction should be viewed as adjunctive to mechanical methods and the duration of therapy should probably be limited to 7 to 14 days.[1,2] In addition, the efficacy of metoclopramide in stimulating lactation in women with preterm deliveries has been questioned by a controlled study.[5] Young women are at increased risk of extrapyramidal effects from metoclopramide—see under Adverse Effects, p. 1864.1. There has also been concern about the presence of the drug in breast milk. For a discussion of lactation inhibition and induction, see p. 2130.1.

Migraine. Metoclopramide is used in the treatment of migraine (p. 670.3) to alleviate nausea and vomiting and gastric stasis, which commonly develop as a migraine attack progresses and can lead to poor absorption of oral antimigraine preparations. It may also be given to counteract nausea and vomiting from the use of ergotamine. Metoclopramide is included in some combination analgesic preparations for the treatment of acute attacks of migraine. In one study, oral lysine aspirin with metoclopramide was as effective as oral sumatriptan in the treatment of migraine.[1] However, a review of combinations of oral metoclopramide plus an analgesic for migraine suggested that they were likely to be less effective than triptan monotherapy, although they might be an option for patients in whom triptans are contra-indicated or who could not tolerate triptans.[2] Metoclopramide with sumatriptan may be effective in patients unresponsive to a triptan alone.[3]

Parenteral metoclopramide has also been shown to be an effective treatment for acute migraine; it reduces pain, and to some extent nausea (although other antiemetics may be more effective), and a systematic review concluded that it should be considered a first-line treatment for migraine in the emergency department.[4] A later study found intravenous metoclopramide (with intermittent doses of diphenhydramine) to be comparable to subcutaneous sumatriptan in terms of pain relief at both 2 and 24 hours after treatment.[5]

Orthostatic hypotension. Metoclopramide has been tried in the management of some patients with orthostatic hypotension, as mentioned on p. 1634.3.

Tourette's syndrome. A small, short-term study in children and adolescents with Tourette's syndrome (see Tics, p. 1030.1) or chronic tic disorders found that treatment with oral metoclopramide (up to 40 mg daily) significantly reduced tic score and severity compared with placebo.[1]

1. Nicolson R, *et al.* A randomized, double-blind, placebo-controlled trial of metoclopramide for the treatment of Tourette's disorder. *J Am Acad Child Adolesc Psychiatry* 2005; 44: 640–6.

Variceal haemorrhage. Metoclopramide 20 mg intravenously controlled bleeding from oesophageal varices within 15 minutes in 10 of 11 patients compared with 4 of 11 patients given placebo; all patients were treated by sclerotherapy.[1] Lower oesophageal sphincter pressure is increased by metoclopramide, thus reducing blood flow to varices and achieving haemostasis; another study[2] found use of metoclopramide with intravenous glyceryl trinitrate to be more effective than glyceryl trinitrate alone in reducing intravariceal pressure.

For a discussion of variceal haemorrhage and its management, see p. 2563.1.

Adverse Effects

Metoclopramide is a dopamine antagonist and may cause extrapyramidal symptoms (usually acute dystonic reactions); these are more common in children and young adults, and at daily doses above 500 micrograms/kg. Parkinsonism and tardive dyskinesia have occasionally occurred, usually during prolonged treatment in elderly patients.

Other adverse effects affecting the CNS include restlessness, drowsiness, dizziness, anxiety, confusion, and tremor; hallucinations have been reported rarely. Depression has occurred and can be severe, with suicidal ideation and suicide reported. Hypotension, hypertension, gastrointestinal disturbances, dyspnoea, visual disturbances, urinary frequency and incontinence, and headache may also occur and there are isolated reports of blood disorders, hypersensitivity reactions (rash, bronchospasm, angioedema), and neuroleptic malignant syndrome. Disorders of cardiac conduction have been reported with intravenous metoclopramide and transient flushing of the face and upper body has followed high intravenous doses.

Metoclopramide stimulates prolactin secretion and may cause galactorrhoea or related disorders. Transient increases in plasma-aldosterone concentrations have been reported.

Effects on the blood. Agranulocytosis was associated with use of metoclopramide on 2 separate occasions.[1] Both episodes resolved within 2 to 3 weeks of withdrawing metoclopramide. Methaemoglobinaemia[2-4] and sulfhaemoglobinaemia[5,6] have also been reported. Methaemoglobinaemia (p. 1559.3) may be treated with methylthioninium chloride. In one case,[3] the patient died despite such treatment; blood samples taken before death were found to be haemolysed, and assays showed deficiency in G6PD activity (methylthioninium chloride should not be used in G6PD-deficient patients, see Adverse Effects of Methylthioninium Chloride, p. 1560.2).

Effects on the cardiovascular system. There have been reports of hypotension,[1] hypertension,[2,3] and supraventricular tachycardia[4] associated with metoclopramide. Bradycardia followed by total heart block,[5] and sinus arrest,[6] have also been reported. It was suggested that metoclopramide may have contributed to a prolonged QT interval and torsade de pointes in a patient with heart failure and renal impairment.[7]

7. Siddique SM, *et al.* Metoclopramide as a possible cause of prolonged QT syndrome and torsade de pointes in a patient with heart failure and renal insufficiency. *Ann Intern Med* 2009; 150: 502–4.

Effects on the endocrine system. *ALDOSTERONISM.* Metoclopramide has been reported to increase plasma-aldosterone concentrations in healthy individuals[1] and in patients with liver cirrhosis and ascites associated with secondary hyperaldosteronism.[2] Increased plasma aldosterone after metoclopramide use has also been associated with the development of oedema in a patient with congestive heart failure.[3] The metoclopramide-induced aldosterone response was blunted by giving neostigmine beforehand.[1]

3. Zumoff B. Metoclopramide and edema. *Ann Intern Med* 1983; 98: 557.

HYPERPROLACTINAEMIA. Hyperprolactinaemia, galactorrhoea, and pituitary adenoma occurred in a 49-year-old woman with reflux oesophagitis who had received metoclopramide for 3 months.[1] Her plasma-prolactin concentrations fell to normal and her symptoms resolved over 4 months after withdrawal of metoclopramide. The pituitary tumour was considered to be incidental to, and not caused by, metoclopramide therapy. A 21-year-old female developed mastodynia, galactorrhoea, and hyperprolactinaemia after 2 days of treatment with metoclopramide;[2] she had previously taken domperidone intermittently without any problems. Her symptoms resolved rapidly on stopping therapy. Galactorrhoea has also been reported[3] in a neonate given metoclopramide.

Effects on mental state. There are isolated reports of dose-related delirium, depression, and uncontrollable crying in patients treated with metoclopramide in doses of 40 to 80 mg daily.[1-3] Symptoms resolved on reducing the dose or withdrawing metoclopramide, and tolerance could be achieved by gradually increasing the dose. In another report,[4] a patient developed acute akathisia (see Extrapyramidal Effects p. 1864.1) shortly after starting metoclopramide 10 mg four times daily; this was accompanied by restlessness, anxiety, and irritability. Despite stopping the drug after 2 days, and treatment with paroxetine and lorazepam, the patient started to have panic attacks, which increased in frequency and severity; he also developed agoraphobia. Two months after taking metoclopramide he was diagnosed with major depressive disorder, which included intermittent suicidal ideation. Following aggressive therapy and hospitalisation, his symptoms gradually resolved.

Encephalopathy has been associated with intravenous metoclopramide in a patient with Parkinson's disease.[5]

Insomnia, with or without daytime drowsiness, has also been reported in patients taking metoclopramide 40 mg daily.[6]

Hypersensitivity psychosis has also been reported, shortly after stopping metoclopramide.[7] Symptoms included hallucinations, delusional experiences, anxiety, restlessness, and sleep disturbances; improvement and gradual resolution were noted after treatment with risperidone.

Extrapyramidal effects. The Adverse Reactions Register of the UK CSM for the years 1967 to 1982 contained 479 reports of extrapyramidal reactions in which metoclopramide was the suspected drug: 455 were for dystonic-dyskinetic reactions, 20 for parkinsonism, and 4 for tardive dyskinesia.[1]

Acute **dystonic-dyskinetic** reactions occur most commonly in children and young adults[1-3] and about 70% of reactions are in females;[1,3] many are associated with doses above those recommended by the manufacturers.[1,3,4] Symptoms reported include oculogyric crisis,[4,5] opisthotonus,[6] torticollis,[5,7] trismus,[5,7] a tetanus-like reaction,[8] and blue coloration of the tongue;[6] akathisia after the use of metoclopramide alone,[9] or with droperidol[10] or haloperidol[9] has been reported (see also Effects on Mental State, p. 1863.3).

These effects usually occur within 72 hours of starting treatment[1] but have been reported within 30 minutes of receiving metoclopramide.[4] When metoclopramide is given intravenously, the rate may be important in determining the incidence of acute extrapyramidal reactions: a study indicated that akathisia was less frequent when the same dose was given as a 15-minute infusion rather than a 2-minute bolus injection.[11] Acute effects can occur in patients who have previously taken metoclopramide without complications[5,6,10] and may be precipitated by other drugs. Although generally self-limiting, deaths have occurred.[1,5] The reactions are readily reversed by an antihistamine such as diphenhydramine,[7] or an antimuscarinic such as benzatropine;[4,6] prophylactic use of diphenhydramine has been suggested for patients with a history of extrapyramidal reactions and in those less than 30 years of age.[7,8]

Metoclopramide-associated **parkinsonism** is thought to occur less commonly than the acute dystonias and is seen mainly in older patients. Symptoms usually appear several months after starting metoclopramide, but may occur within days or not for several years. Withdrawal of metoclopramide usually results in resolution of symptoms, although it may take several months.[1] A study has suggested that metoclopramide-induced parkinsonism (misdiagnosed as idiopathic Parkinson's disease) may be more common in the elderly than generally realised.[12]

Tardive dyskinesia may rarely be associated with use of metoclopramide. Development of this condition is directly related to the length of treatment with metoclopramide and the number of doses taken.[13] The reaction is usually confined to elderly patients after prolonged oral use,[14,15] but it has been reported with short-term high-dose parenteral use as an antiemetic in cancer chemotherapy,[16] and a case has been reported in an 8-year-old child treated with metoclopramide for gastro-oesophageal reflux disease in usual doses.[17] The average duration of treatment before the onset of symptoms was 14 months (range 4 to 44 months) in a report of 11 cases[15] and 26 months (range 8 to 60 months) in a report of 12 cases;[18] some patients did not have symptoms until after withdrawal of metoclopramide. Tardive dyskinesia is potentially irreversible and its management is difficult.[18] Some patients improve after withdrawal of metoclopramide but symptoms persisting during follow-up periods of up to 3 years have been reported.[14,15] The emphasis must be on prevention, hence the recommendation that metoclopramide should not be prescribed for the long-term treatment of minor symptoms, especially in elderly patients.[18] After analyses suggested that metoclopramide was the most common cause of drug-induced movement disorders and that about 20% of patients who used metoclopramide used it for longer than 3 months, the FDA recommended that chronic use of metoclopramide should be avoided in all patients unless the benefit of treatment is believed to outweigh the risk.[13] The EMA[19] has also restricted metoclopramide use to a maximum of five days and does not recommend its use for chronic conditions or as an adjunct in surgical or radiological procedures; its use in children is also restricted (see Administration in Children, p. 1862.3).

19. EMA. European Medicines Agency recommends changes to the use of metoclopramide: changes aim mainly to reduce the risk of neurological side effects (issued 26 July, 2013). Available at: http://www.ema.europa.eu/docs/en_GB/document_library/Referrals_document/Metoclopramide_31/WC500146610.pdf (accessed 02/10/13)

Hypersensitivity. A patient given intravenous metoclopramide and butylhyoscine for gastrointestinal disturbances developed pruritus, generalised urticaria, hypotension, and loss of consciousness. She was treated with intravenous fluid, antihistamines, and corticosteroids. Skin prick tests revealed a response to metoclopramide, suggesting an IgE-mediated allergic reaction.[1]

1. Kerstan A, *et al.* Anaphylaxis during treatment of nausea and vomiting: IgE-mediated metoclopramide allergy. *Ann Pharmacother* 2006; 40: 1889–90.

Neuroleptic malignant syndrome. Neuroleptic malignant syndrome (NMS, p. 1050.2) has occurred very rarely with metoclopramide. In a report of a case with a fatal outcome, it was noted that 17 additional cases had been published in the years 1978 to 1998, three of which resulted in death.[1] A case report in a 6-month-old female with Freeman-Sheldon syndrome[2] given metoclopramide suggested that pre-existing fever and myopathy may be predisposing factors. In another case,[3] a burns patient, there was some suggestion that the patient may have been susceptible to neuroleptic hyperthermic syndromes such as NMS and malignant hyperthermia. Metoclopramide should be stopped immediately if NMS occurs, and the patient treated urgently with bromocriptine.

Precautions

Metoclopramide should not be used when stimulation of muscular contractions might adversely affect gastrointestinal conditions, as in gastrointestinal haemorrhage, obstruction, perforation, or for a few days after surgery. There have been reports of hypertensive crises in patients with phaeochromocytoma given metoclopramide, thus its use is not recommended in such patients; caution is advised in patients with hypertension. Metoclopramide is also not recommended for use in patients with epilepsy as the frequency and severity of seizures may be increased.

Children, young adults, and the elderly should be treated with care as they are at increased risk of extrapyramidal reactions; the use of metoclopramide is restricted in children and young adults under 20 years (see Administration in Children, p. 1862.3). Prolonged therapy should generally be avoided (see Extrapyramidal Effects, above). Care should also be taken when metoclopramide is given to patients with renal or hepatic impairment, Parkinson's disease, or a history of depression, atopy (including asthma), or porphyria. Intravenous metoclopramide should be given with caution to patients at increased risk of cardiovascular reactions, including those with cardiac conduction abnormalities such as sick sinus syndrome.

Metoclopramide may cause drowsiness or impaired reactions; patients so affected should not drive or operate machinery.

Breast feeding. Metoclopramide is excreted into breast milk. The American Academy of Pediatrics[1] considers that the use of metoclopramide by mothers during breast feeding may be of concern, owing to its dopamine-receptor blocking activity. UK licensed product information states that problems in humans have not been reported.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *Ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 07/05/04)

Porphyria. Metoclopramide has been used successfully in the management of acute attacks of porphyria.[1] The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies metoclopramide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[2]

2. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 11/11/11)

Pregnancy. Metoclopramide is often used to treat nausea and vomiting in pregnancy. A large retrospective cohort study confirmed that exposure to metoclopramide in the first trimester was not associated with adverse effects on the fetus including congenital malformations, perinatal death, and low birth-weight.[1]

1. Matok I, *et al.* The safety of metoclopramide use in the first trimester of pregnancy. *N Engl J Med* 2009; 360: 2528–35.

Interactions

Increased toxicity may occur if metoclopramide is given with other centrally active drugs. Metoclopramide should be used with caution in patients taking other drugs that can also cause extrapyramidal reactions, such as the phenothiazines. It should also be used with care with other drugs acting at central dopamine receptors, such as pergolide. Combining metoclopramide with CNS depressant drugs can lead to increased sedative effects. Antimuscarinics and opioid analgesics antagonise the gastrointestinal effects of metoclopramide.

The absorption of other drugs may be affected by metoclopramide; it may either diminish absorption from the stomach (as with digoxin) or enhance absorption from the small intestine (for example, with alcohol, ciclosporin, levodopa, aspirin, or paracetamol). The absorption of food may be affected requiring adjustment of the insulin regimen in diabetic patients. Metoclopramide inhibits serum cholinesterase and may prolong neuromuscular blockade produced by suxamethonium (see p. 2040.1) and mivacurium (p. 2035.1). Metoclopramide may also increase prolactin blood concentrations and therefore interfere with drugs which have a hypoprolactinaemic effect such as bromocriptine (but see p. 899.1). The response to gonadorelin may be altered by metoclopramide, see p. 2282.2. Caution is required if metoclopramide must be given to patients receiving MAOIs and care is required when metoclopramide is given with drugs that affect cardiac conduction.

Antidepressants. For reference to extrapyramidal effects and other adverse effects suggestive of serotonin syndrome in patients taking metoclopramide with SSRIs or venlafaxine, see Gastrointestinal Drugs under Interactions for Fluoxetine (p. 424.3) and Venlafaxine (p. 457.1) respectively.

Carbamazepine. For a report of neurotoxicity associated with the use of metoclopramide with carbamazepine, see p. 517.3.

Hydroxyzine. Acute anxiety, rigidity, generalised tremor, opisthotonus, and hypertension developed in a 20-year-old man given metoclopramide 10 mg intravenously and hydroxyzine 100 mg intramuscularly.[1] The adverse effects occurred 30 minutes after giving hydroxyzine and it was suggested that hydroxyzine potentiated the onset of the reaction.

1. Fouilladieu JL, *et al.* Possible potentiation by hydroxyzine of metoclopramide's undesirable side effects. *Anesth Analg* 1985; 64: 1227–8.

Pharmacokinetics

Metoclopramide is rapidly and almost completely absorbed from the gastrointestinal tract after oral doses, although conditions such as vomiting or impaired gastric motility may reduce absorption. However, it undergoes hepatic first-pass metabolism, which varies considerably between subjects, and hence absolute bioavailability and plasma concentrations are subject to wide interindividual variation. On average, the bioavailability of oral metoclopramide is about 80%, but it varies between about 30 and 100%. Peak plasma concentrations of metoclopramide occur about 1 to 2 hours after an oral dose. Bioavailability is equally variable after rectal or intranasal doses, although it may be somewhat better if the drug is given intramuscularly.

Metoclopramide is weakly bound to plasma proteins (13 to 30%).

Metoclopramide is widely distributed in the body, and readily crosses the blood-brain barrier into the CNS. It also freely crosses the placenta, and has been reported to attain concentrations in fetal plasma about 60 to 70% of those in maternal plasma. Concentrations in breast milk may be higher than those in maternal plasma, particularly in the early puerperium, although concentrations decrease somewhat in the late puerperium.

Elimination of metoclopramide is biphasic, with a terminal elimination half-life of about 4 to 6 hours, although this may be prolonged in renal impairment, with consequent elevation of plasma concentrations. It is excreted in the urine, about 85% of a dose being eliminated in 72 hours, 20% as unchanged metoclopramide and the remainder as sulfate or glucuronide conjugates, or as metabolites. About 5% of a dose is excreted in faeces via the bile.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Disgradon†; Ponderyl; Gastrocalm; Lizarona; Metoc; Midatenk; Novomit; Praux; Primavera-N; Primperil; Reliveran; Rilaquin; Rupemet; Saften; Sintegran; *Austral.*: Maxolon; Pramin; *Austria*: Gastrosil; Metogastron; Paspertin; *Belg.*: Dibertil; Docmetoclo†; Primperan; *Braz.*: Aristopramida; Emetic†; Eucil; Fluccil; Metoclosan; Metoclosantisa; Metoplamin†; Neolasil; No-Vomit†; Plabel; Plagex; Plamida†; Plamidasil; Plamivon; Plasil; Pramil; *Canad.*: Apo-Metoclop; *Chile*: Hemibe; Itan; *Cz.*: Cerucal; Degan; MCP; *Denm.*: Emperal; Gastro-Timelets; Primperan; *Fin.*: Primperan; *Fr.*: Anausin; Primperan; *Ger.*: Cerucal; Gastronerton; MCP; Paspertin; *Gr.*: Gaspalon; Geneprami-D; Lumania; Luv; Pharmyork; Primperan; *Hong Kong*: Emeliv†; Maril; Martomide†; Maxolon†; Metolon†; Metomide†; Metram†; Pramin†; Primperan; Syntomide†; *Hung.*: Cerucal; *India*: Bacnorm; Donmet; Emenil; Emenorm; Labmet; Maxeron; Maxinorm; Metajex; Metamin; Metoclop; Metocontin; Perinorm; Reglan; Tomid; Vominorm; *Indon.*: Clopramel; Damaben; Emeran; Ethiferan; Gavistal; Lexapram; Meclam; Mepramide; Metolon†; Nilatika; Nofoklam; Normastin†; Obteran†; Opram; Piralen; Plasil; Praminal†; Primperan; Raclonid; Reguloop†; Sotatic; Tivomit; Tomit; Vertivom; Vilapon; Vomidex†; Vomipram; Vomitrol; Zumatrol†; *Irl.*: Antimet†; Gastrobid Continus†; Maxolon; Metocyl†; *Israel*: Pramin; *Ital.*: Delipramil; Digestivo S Pellegrino; Isaprandil; Plasil; Pramidin; Randum; *Jpn*: Primperan; *Malaysia*: Malon; Maril; Maxolon†; Mexomide; Primperan; Pulin; *Mex.*: Biopram; Carnotprim; Cirulan; Clorimet-Z; Conysmin; Dolmisin; Eudiges; Gigemet; Hopram; Meclomid; Midetol; Mipramid; Plasil; Polcotec; Pradex; Pramilem†; Primperan†; Propace; Raamfen; Synespramid; *Mon.*: Prokinyl; *Neth.*: Primperan; *Norw.*: Afipran; *NZ*: Maxolon; Metamide; *Philipp.*: Biclomet; Clometide; Clomitene; Clozil; Metsil; Novom†; Plasil; Reglomar; Vitamet; Vomaine; *Pol.*: Pramidin†; *Port.*: Primperan; *Rus.*: Apo-Metoclop (Апометоклоп)†; Cerucal (Церукал); Ceruglan (Церуглан); Cerulan (Церулан); Metamol (Метамол); Perinorm (Перинорм); *S.Afr.*: Acumet†; Adco-Contromet; Betaclopramide; Clopamon; Maxolon; Metalon†; Perinorm†; Pramalon†; Setin; *Singapore*: Apo-Metoclop; Emeliv; Maril; Metolon; Primperan; Pulin; Syntomide; *Spain*: Primperan; *Swed.*: Primperan; *Switz.*: Paspertin; Primperan; *Thai.*: Emetal; Gensil†; H-Peran; Hawkperan; KB Meta; Manosil; Maril; Met-Sil; Metoclor; Nausil; Nausin†; Plamide; Plamine; Plasil; R-J; Vomesea; *Turk.*: Emoject; Metoklamide; Metpamid; Primperan; *UAE*: Premosan; *UK*: Maxolon; Primperan; *Ukr.*: Cerucal (Церукал); Metucal (Метукал)†; *USA*: Metozolv; Octamide†; Reclomide; Reglan; *Venez.*: Clodoxin; Irtopan; Mepramida; Pramide; Primperan.

ATC Vet — QA04AD05.

UNII — 238575V9AV.

Pharmacopoeias. In *Fr.*

Profile

Metopimazine, a phenothiazine dopamine antagonist, is an antiemetic with general properties similar to those of chlorpromazine (p. 1045.2). It is used in the management of nausea and vomiting, including that associated with cancer chemotherapy (p. 1811.3). It is given in usual oral doses of 15 to 30 mg daily, in up to 4 divided doses; similar daily doses have been given rectally in 3 divided doses. It has also been given by injection in a dose of 10 to 20 mg daily, usually intramuscularly but occasionally by the intravenous route. Higher doses of 30 to 50 mg daily in divided doses by intramuscular injection or intravenous infusion have been given for chemotherapy-induced nausea and vomiting; the first dose is given before chemotherapy.

$C_{21}H_{25}ClFN_3O_3,C_6H_8O_7,2H_2O$=650.1

CAS — 112885-41-3 (mosapride); 112885-42-4 (mosapride citrate).

UNII — MF497J489P (mosapride citrate); 73033I28Y6 (mosapride citrate dihydrate).

Profile

Mosapride is a substituted benzamide used for its prokinetic properties. It is reported to be an agonist at 5-HT_4 receptors, increasing acetylcholine release and stimulating gastrointestinal motility (see also Cisapride, p. 1832.1), as well as having 5-HT_3 antagonist properties. It is given orally as the citrate dihydrate, but doses are expressed as the anhydrous citrate, and are 5 mg three times daily before or after meals.

$C_{24}H_{36}O_3$=372.5

CAS — 51022-71-0.

ATC — A04AD11.

ATC Vet — QA04AD11.

UNII — 2N4O9L084N.

Uses and Administration

Nabilone, a synthetic cannabinoid with antiemetic properties, is used for the control of nausea and vomiting associated with cancer chemotherapy in patients who have failed to respond adequately to conventional antiemetics (p. 1811.3).

The usual initial oral dose is 1 mg twice daily, increased to 2 mg twice daily if necessary. The first dose should be given the evening before starting chemotherapy, and the second dose 1 to 3 hours before the first dose of antineoplastic. Nabilone may be given throughout each cycle of chemotherapy and for 48 hours after the last dose of chemotherapy, if required. The dose of nabilone should not exceed 6 mg daily, given in 3 divided doses.

2. Davis MP. Oral nabilone capsules in the treatment of chemotherapy-induced nausea and vomiting and pain. *Expert Opin Invest Drugs* 2008; 17: 85–95.

Multiple sclerosis. There is a report of reduction in spasticity and nocturia, and improvement in mood and well-being, in a patient with multiple sclerosis (p. 996.3) who received nabilone 1 mg every second day.[1] A subsequent small crossover study[2] in patients with chronic upper motor neurone syndrome found that oral nabilone 1 mg daily reduced spasticity-related pain in this group. There are also anecdotal reports of improvement in symptoms in patients with multiple sclerosis who took cannabis, however, a review[3] considered evidence of efficacy to be lacking.

1. Martyn CN, *et al.* Nabilone in the treatment of multiple sclerosis. *Lancet* 1995; 345: 579.
2. Wissel J, *et al.* Low dose treatment with the synthetic cannabinoid nabilone significantly reduces spasticity-related pain: a double-blind placebo-controlled cross-over trial. *J Neurol* 2006; 253: 1337–41.
3. Killestein J, *et al.* Cannabinoids in multiple sclerosis: do they have a therapeutic role? *Drugs* 2004; 64: 1–11.

Adverse Effects

Nabilone may produce adverse effects similar to those of cannabis (see p. 2468.2). The most common adverse effects are drowsiness, vertigo, and dry mouth. Neurological effects have included ataxia, confusion, disorientation, dizziness, euphoria, dysphoria, hallucinations, psychosis, depression, headache, decreased coordination, and tremors. Adverse cardiovascular reactions including hypotension, orthostatic hypotension, and tachycardia have occurred. Gastrointestinal disturbances, decreased appetite, and abdominal pain have also been reported.

Precautions

Nabilone is extensively metabolised and largely excreted in bile, and therefore is not recommended in patients with severe hepatic impairment. It should be used with caution in patients with a history of psychiatric disorders or depression, or those with hypertension or heart disease.

Because of the possibility of CNS depression, patients should be warned not to drive or operate machinery.

The possibility of dependence similar to that of cannabis should be borne in mind.

Interactions

Nabilone has been shown to have an additive CNS depressant effect when given with alcohol, codeine, diazepam, or other CNS depressants.

Pharmacokinetics

Nabilone is well absorbed from the gastrointestinal tract and is rapidly and extensively metabolised; one or more of the metabolites may be active. The major excretory pathway is the biliary system; about 65% of a dose is excreted in the faeces and about 20% in the urine. The elimination half-life of nabilone is about 2 hours, but the half-life of its combined metabolites is about 35 hours after an oral dose.

$C_{12}H_{21}N_5O_2S_2$=331.5

CAS — 76963-41-2.

ATC — A02BA04.

ATC Vet — QA02BA04.

UNII — P41PML4GHR.

Pharmacopoeias. In *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Nizatidine). An almost white or slightly brownish, crystalline powder. Sparingly soluble in water; soluble in methyl alcohol. A 1% solution in water has a pH of 8.5 to 10.0.

USP 36: (Nizatidine). An off-white to buff crystalline solid. Sparingly soluble in water; freely soluble in chloroform; soluble in methyl alcohol. Store in airtight containers. Protect from light.

Uses and Administration

Nizatidine is a histamine H_2-antagonist with actions and uses similar to those of cimetidine (see p. 1827.2).

In the management of benign **gastric and duodenal ulceration** (p. 1813.2), and NSAID-associated ulceration, a daily oral dose of nizatidine 300 mg is given either as a single dose at bedtime or in 2 divided doses, for 4 to 8 weeks. Where appropriate a maintenance dose of 150 mg daily may be given at night.

In **gastro-oesophageal reflux disease** (p. 1807.2) an oral dose of 150 to 300 mg twice daily is recommended for up to 12 weeks.

For the short-term symptomatic relief of **dyspepsia** an oral dose of 75 mg, repeated if necessary, up to a maximum of 150 mg daily may be taken for up to 14 days.

Nizatidine has also been given intravenously by continuous or intermittent infusion.

Doses of nizatidine should be reduced in patients with renal impairment (see below). For doses in children, see below.

Administration in children. Nizatidine is given to children for oesophagitis and gastro-oesophageal reflux disease in the USA; an oral dose of 150 mg twice daily for up to 8 weeks is licensed in those 12 years of age or over.

Administration in renal impairment. The dosage of nizatidine should be reduced in patients with renal impairment according to creatinine clearance (CC). Licensed product information recommends the following oral doses in renal impairment:

- CC 20 to 50 mL/minute: doses should be reduced by 50%, *or* where the standard dose would be 150 mg daily, 150 mg may be given on alternate days
- CC less than 20 mL/minute: doses should be reduced by 75%, *or* where the standard dose would be 300 mg daily, 150 mg may be given on alternate days, and where the standard dose would be 150 mg daily, 150 mg may be given every third day

Adverse Effects

As for Cimetidine, p. 1828.3. Some patients taking nizatidine may experience excessive sweating and urticaria; anaemia may also occur.

Nizatidine is considered to have no anti-androgenic activity although there are isolated reports of gynaecomastia and impotence.

Precautions

As for Cimetidine, p. 1830.2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies nizatidine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Interactions

Unlike cimetidine (p. 1830.3) nizatidine does not inhibit cytochrome P450 isoenzymes, and therefore is considered to have little effect on drugs metabolised by this route. However, like other H_2-antagonists its effects on gastric pH may affect the absorption of drugs whose absorption is dependent on an acid gastric pH.

Alcohol. Any interaction between H_2-antagonists and alcohol is generally thought unlikely to be clinically significant (see p. 1735.2).

Antacids. For discussion of the effect of antacids on the bioavailability of H_2-antagonists, see Cimetidine, p. 1831.1.

Sucralfate. For information on the effect of sucralfate on the bioavailability of H_2-antagonists, see Cimetidine, p. 1831.1.

Pharmacokinetics

Nizatidine is readily absorbed from the gastrointestinal tract with peak plasma concentrations about 0.5 to 3 hours after an oral dose. The bioavailability of nizatidine exceeds 70% and may be slightly increased by the presence of food. It is widely distributed and is about 35% bound to plasma proteins.

The elimination half-life of nizatidine is 1 to 2 hours and is prolonged in renal impairment. A small amount is metabolised in the liver: nizatidine *N*-2-oxide, nizatidine *S*-oxide, and *N*-2-monodesmethylnizatidine have been identified, the latter having about 60% of the activity of nizatidine.

More than 90% of a dose of nizatidine is excreted in the urine, in part by active tubular secretion, within 12 hours, about 60% as unchanged drug. Less than 6% is excreted in the faeces. Nizatidine is distributed into breast milk.

Bioavailability. The bioequivalence of 3 oral liquid formulations of nizatidine was investigated relative to a commercially available nizatidine capsule. Of the 3 liquid formulations, one was a commercially available oral syrup (15 mg/mL), and 2 others were extemporaneously prepared, one as a solution in apple juice (1.2 mg/mL) and another as a suspension in an infant formula (*Enfamil; Ross, USA*; 15 mg/mL). Nizatidine in apple juice showed markedly less bioavailability, whereas the other 2 formulations were considered to be bioequivalent to the reference capsule.[1]

1. Abdel-Rahman SM, *et al.* The bioequivalence of nizatidine (Axid) in two extemporaneously and one commercially prepared oral liquid formulations compared with capsule. *J Clin Pharmacol* 2003; **43**: 148–53.

Distribution into breast milk. About 0.1% of an oral dose of nizatidine was secreted in breast milk in a study in lactating women.[1] The milk to serum ratio varied (from 1:1 to 4.9:1) with the time of samples.

CAS — 6054-98-4.

ATC — A07EC03.

ATC Vet — QA07EC03.

UNII — Y7JEW0XG7L.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Olsalazine Sodium). A yellow, fine, crystalline powder; it exhibits polymorphism. Sparingly soluble in water; soluble in dimethyl sulfoxide; very slightly soluble in methyl alcohol.

Uses and Administration

Olsalazine consists of two molecules of mesalazine (p. 1859.2) linked with an azo bond. It is activated in the colon where the active mesalazine is released. It is given orally as the sodium salt in the management of acute mild ulcerative colitis and for the maintenance of remission (see Inflammatory Bowel Disease, p. 1808.3). The usual initial dose of olsalazine sodium is 1 g daily in divided doses and this is gradually increased, if necessary, over one week, to a maximum dose of 3 g daily. The usual dose for the maintenance of remission is 500 mg twice daily. Doses should be taken after meals and a single dose should not exceed 1 g. For doses in children, see below.

Administration in children. Although not licensed in the UK for use in children under 12 years, the *BNFC* suggests an oral dose of olsalazine for children aged 2 years and over; the adult dose may be given for an acute attack of mild ulcerative colitis (see Uses and Administration, above), and for maintenance of remission, a dose of 250 to 500 mg may be given twice daily, after food.

Adverse Effects and Precautions

As for Mesalazine, p. 1860.1. The most common adverse effects associated with olsalazine sodium are diarrhoea, arthralgia, and skin rashes. Diarrhoea may be watery in some patients; it may resolve with dosage reduction but can be severe enough to require withdrawal of treatment. Diarrhoea is less likely if the drug is taken after meals. There have been a few reports of blood dyscrasias. If a blood dyscrasia is suspected treatment should be stopped immediately and a blood count performed. Patients or their carers should be told how to recognise signs of haematotoxicity and should be advised to seek immediate medical attention if symptoms such as fever, sore throat, mouth ulcers, bruising, or bleeding develop.

Incidence of adverse effects. In an open study[1] of oral olsalazine 1 g daily involving 160 patients with active ulcerative colitis and a history of sulfasalazine intolerance, 103 (64.4%) patients had no adverse effects; 29 patients reported only minor adverse effects: gastrointestinal disturbances in 22 patients, transient skin rash in 3, and headache, increased salivation, cough, and irritability each in one patient. The most common adverse effect was frequent loose stools which affected 25 patients, 20 of whom had to stop treatment. This adverse effect occurred early in treatment, within 10 hours of the first dose in 13 patients. Severe diarrhoea was more frequent in patients with widespread disease, but the incidence of diarrhoea did not correlate with disease severity.

A subsequent study[2] in healthy subjects has shown that olsalazine has a significant inhibitory effect on water and electrolyte absorption in the small intestine, which may account, at least in part, for the induction of diarrhoea. Patients with extensive colitis have reduced colonic absorptive function and may be less able to assimilate the increased colonic inflow volumes.

1. Sandberg-Gertzén H, *et al.* Azodisal sodium in the treatment of ulcerative colitis: a study of tolerance and relapse-prevention properties. *Gastroenterology* 1986; 90: 1024–30.
2. Raimundo AH, *et al.* Effects of olsalazine and sulphasalazine on jejunal and ileal water and electrolyte absorption in normal human subjects. *Gut* 1991; 32: 270–4.

Breast feeding. A study[1] involving a 39-year-old woman with Crohn's disease found that olsalazine did not appear to present a clinically significant risk to the breast-fed infant. Olsalazine was undetectable in the breast milk for 48 hours after a single oral 500-mg dose, and although small amounts of the metabolite acetylated 5-aminosalicylic acid were detected in breast milk the infant showed no adverse effects during the 3 weeks afterwards in which the mother continued taking olsalazine.

1. Miller LG, *et al.* Disposition of olsalazine and metabolites in breast milk. *J Clin Pharmacol* 1993; 33: 703–6.

Effects on the blood. As of July 1995, the UK CSM had received 4 reports of blood dyscrasias associated with olsalazine, none of them fatal.[1] It was recommended that a blood count be performed and the drug stopped immediately if there was suspicion of a dyscrasia. See also under Mesalazine, p. 1860.2.

1. CSM/MCA. Blood dyscrasias and mesalazine. *Current Problems* 1995; 21: 5–6. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2015619&RevisionSelectionMethod=LatestReleased (accessed 15/06/06)

Effects on the kidneys. A report of nephrotoxicity, characterised by interstitial nephritis, was associated with the use of olsalazine.[1] Symptoms resolved on stopping of the drug. See also under Mesalazine, p. 1860.3.

1. Wilcox GM, *et al.* Nephrotoxicity associated with olsalazine. *Am J Med* 1996; 100: 238–40.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies olsalazine as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Interactions

Antineoplastics. For mention of 5-aminosalicylates such as olsalazine inhibiting the metabolism of thiopurine antineoplastics, and increasing their toxicity, see Gastrointestinal Drugs, p. 822.1.

Pharmacokinetics

Very little of an oral dose of olsalazine is absorbed via the upper gastrointestinal tract, and almost the entire dose reaches its site of action in the colon intact. It is broken down by the colonic bacterial flora into 2 molecules of 5-aminosalicylic acid (mesalazine). Some mesalazine is absorbed and acetylated (see p. 1861.2) but systemic concentrations of mesalazine and its metabolite are lower than after comparable oral doses of mesalazine, perhaps because there is less release of mesalazine in the small intestine, where absorption is better. Mesalazine concentrations in the colon after a dose of olsalazine are stated to be about 1000 times greater than systemic concentrations.

The small amounts (1 to 2% of the dose or less) of intact olsalazine that are absorbed are excreted mainly in urine; the elimination half-life after an intravenous dose has been calculated at about 1 hour. Some olsalazine is metabolised by sulfate conjugation in the liver: the elimination half-life of the metabolite is reported to be about 7 days.

UNII — *426QFE7XLK.*

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Omeprazole Magnesium). A white or almost white, hygroscopic powder. Very slightly soluble in water; sparingly soluble in methyl alcohol; practically insoluble in heptane. Store in airtight containers. Protect from light.

USP 36: (Omeprazole Magnesium). A white to off-white powder. Very soluble in water and in dichloromethane; slightly soluble in alcohol; sparingly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Omeprazole Sodium *(BANM, USAN, rINNM)*

Natrii Omeprazolum; Omepratsolinatrium; Omeprazol-Natrium; Omeprazol sódico; Omeprazol sódná sůl monohydrát; Oméprazole sodique; Omeprazolnatrium; Omeprazol-nátrium; Omeprazolo natrio druska; Omeprazolum natricum; Omeprazolum Natricum Monohydricum; Натрий Омепразол.

$C_{17}H_{18}N_3NaO_3S$=367.4

CAS — 95510-70-6.

ATC — *A02BC01.*

ATC Vet — *QA02BC01.*

UNII — *KV03YZ6QLW.*

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Omeprazole Sodium). A white or almost white, hygroscopic powder. Freely soluble in water and in alcohol; very slightly soluble in dichloromethane; soluble in propylene glycol. The pH of a 2% solution in water is 10.3 to 11.3. Store in airtight containers. Protect from light.

Uses and Administration

Omeprazole is a proton pump inhibitor. It suppresses secretion of gastric acid by inhibiting the enzyme system of hydrogen/potassium adenosine triphosphatase (H^+/K^+ ATPase), the 'proton pump' of the gastric parietal cell. It is used in conditions where inhibition of gastric acid secretion may be beneficial, including aspiration syndromes (p. 1804.2), dyspepsia (p. 1868.1), gastro-oesophageal reflux disease (p. 1807.2), peptic ulcer disease (p. 1813.2), and the Zollinger-Ellison syndrome (p. 1814.3).

Esomeprazole (p. 1841.1), an isomer of omeprazole, is also used.

Omeprazole may be given orally as the base or magnesium salt, or intravenously as the sodium salt. Doses are expressed in terms of the base. Omeprazole magnesium 10.32 mg and omeprazole sodium 10.64 mg are each equivalent to about 10 mg of omeprazole.

For the relief of acid-related **dyspepsia** omeprazole is given in usual doses of 10 or 20 mg daily orally for 2 to 4 weeks.

The usual dose for the treatment of **gastro-oesophageal reflux disease** is 20 mg orally once daily for 4 weeks, followed by a further 4 to 8 weeks if not fully healed. In refractory oesophagitis, a dose of 40 mg daily may be used. Maintenance therapy after healing of oesophagitis is 20 mg once daily, and for acid reflux is 10 mg daily. For dosage in children see below.

In the management of **peptic ulcer disease** a single daily dose of 20 mg orally, or 40 mg in severe cases, is given. Treatment is usually continued for 4 weeks for duodenal ulcer and 8 weeks for gastric ulcer. Where appropriate, a dose of 10 to 20 mg once daily may be given for maintenance.

For the eradication of *Helicobacter pylori* in peptic ulceration omeprazole may be combined with antibacterials in dual or triple therapy. Effective **triple therapy** regimens include omeprazole 20 mg twice daily or 40 mg once daily combined with: amoxicillin 500 mg and metronidazole 400 mg, both three times daily; clarithromycin 250 mg and metronidazole 400 mg (or tinidazole 500 mg) both twice daily; or with amoxicillin 1 g and clarithromycin 500 mg, both twice daily. These regimens are given for 7 or 10 days. **Dual therapy** regimens such as omeprazole 40 mg daily with clarithromycin 500 mg three times daily are licensed but are much less effective and must be given for 2 weeks. Omeprazole monotherapy may be continued after dual or triple therapy in patients with ulceration at the start of therapy; antisecretory therapy can be continued after triple therapy in those with large ulcers or complications.

Doses of 20 mg daily orally are used in the treatment of **NSAID-associated ulceration**; a dose of 20 mg daily may also be used for prophylaxis in patients with a history of gastroduodenal lesions who require continued NSAID treatment.

The initial recommended dosage for patients with the **Zollinger-Ellison syndrome** is 60 mg orally once daily, adjusted as required. The majority of patients are effectively controlled by doses in the range 20 to 120 mg daily, but doses up to 120 mg three times daily have been used. Daily doses above 80 mg should be given as divided doses (usually 2).

Omeprazole is also used for the prophylaxis of **acid aspiration** during general anaesthesia, in a dose of 40 mg the evening before surgery and a further 40 mg two to six hours before the procedure.

The dose of omeprazole may need to be reduced in patients with hepatic impairment (see p. 1868.1).

PARENTERAL DOSAGE.

In patients who are unsuited to receive oral therapy omeprazole sodium may be given on a short-term basis by intravenous infusion, in a usual dose equivalent to 40 mg of the base over a period of 20 to 30 minutes in 100 mL of sodium chloride 0.9% or glucose 5%. It may also be given by slow intravenous injection. Higher intravenous doses have been given to patients with Zollinger-Ellison syndrome, with a usual initial dose of 60 mg daily.

Although unlicensed in the UK for major peptic bleeding after endoscopy, the *BNF* suggests that omeprazole 80 mg can be infused intravenously over 40 to 60 minutes, followed by a continuous infusion of 8 mg/hour for 72 hours; treatment can then be continued orally.

Administration. Omeprazole is given orally as tablets or capsules containing enteric-coated pellets or granules, which should be swallowed whole and not crushed or chewed. In children or patients with swallowing difficulties, UK licensed product information (*Losec; AstraZeneca*) states that the tablet be dispersed in water and then mixed with fruit juice (with a pH less than 5) or yogurt before swallowing without chewing. Similarly the contents of the capsules can be mixed with water, fruit juice (with a pH less than 5) or yogurt and swallowed without chewing. An oral suspension is available in some countries.

Administration in children. Licensed UK *oral* doses of omeprazole for the treatment of gastro-oesophageal reflux disease or reflux oesophagitis in children 1 year of age and over are determined by body-weight as follows:

- 10 to 20 kg: 10 mg once daily
- over 20 kg: 20 mg once daily

These doses may be doubled if necessary. Treatment may be given for 2 to 4 weeks for gastro-oesophageal reflux disease and for 4 to 8 weeks for reflux oesophagitis. Similar doses

are licensed in the USA, where an oral dose of 5 mg daily is included for children weighing from 5 kg up to 10 kg.

For gastro-oesophageal reflux disease, acid-related dyspepsia, treatment of duodenal and benign gastric ulcers including NSAID-associated ulceration, prophylaxis of acid aspiration, Zollinger-Ellison syndrome, and to reduce the degradation of pancreatic enzyme supplements in children with cystic fibrosis, the *BNFC* recommends an oral dose of 700 micrograms/kg once daily in neonates and children 1 month to 2 years of age. If needed, doses may be increased in neonates after 7 to 14 days, to 1.4 mg/kg once daily; some neonates may require up to 2.8 mg/kg once daily. In children up to 2 years of age, doses may be increased up to 3 mg/kg (to a maximum of 20 mg) once daily.

For *parenteral* dosage in children the *BNFC* recommends an intravenous dose of 500 micrograms/kg (to a maximum of 20 mg) once daily in children aged 1 month to 12 years; this may be increased to 2 mg/kg (to a maximum of 40 mg) once daily if needed.

For the eradication of *Helicobacter pylori* licensed oral doses in the UK for children from 4 years of age are omeprazole 10 mg in those weighing 15 to 30 kg or omeprazole 20 mg in those weighing over 30 kg, given twice daily with amoxicillin and clarithromycin for 1 week. In children from 1 to 12 years of age, the *BNFC* recommends an oral dose of omeprazole 1 to 2 mg/kg (to a maximum dose of 40 mg) once daily. This is given with antibacterial therapy under specialist supervision.

For administration of the tablets or capsules to children, see Administration, p. 1867.3.

A systematic review found that evidence was insufficient to support the efficacy and safety of proton pump inhibitors for the treatment of gastro-oesophageal disease in children and adolescents, although short-term use was well tolerated; proton pump inhibitors were found to be ineffective for infants.[1]

1. van der Pol RJ, *et al.* Efficacy of proton-pump inhibitors in children with gastroesophageal reflux disease: a systematic review. *Pediatrics* 2011; 127: 925–35.

Administration in hepatic impairment. Bioavailability and half-life of omeprazole can increase in patients with hepatic impairment. UK licensed product information suggests that a daily oral or intravenous dose of 10 to 20 mg may be sufficient for these patients.

Dyspepsia. Although earlier UK guidelines on the use of proton pump inhibitors in dyspepsia (p. 1806.3) suggested that they should not be used routinely in non-ulcer dyspepsia,[1] subsequent guidelines on its general management in both the UK[2] and the USA[3] consider that a 1-month empirical course in patients aged under 55 without symptoms suggestive of more serious disease is a valid first-line treatment.

Inflammatory bowel disease. There are a few reports[1-3] of responses to omeprazole in patients with inflammatory bowel disease (p. 1808.3). Combination of omeprazole with mesalazine has also been tried.[2]

1. Reinstow U, Schlegelberger T. Omeprazole in ulcerative colitis. *Lancet* 1994; 343: 477.

Scleroderma. Gastro-oesophageal reflux is one of the gastrointestinal manifestations of systemic sclerosis, and proton pump inhibitors such as omeprazole play a major role in the management of such gastrointestinal disease.[1] For a discussion of the broader management of the condition see p. 1938.3.

1. Williamson DJ. Update on scleroderma. *Med J Aust* 1995; 162: 599–601.

Adverse Effects

Proton pump inhibitors are generally well tolerated, and adverse effects are relatively infrequent. The adverse effects reported most often with omeprazole and other proton pump inhibitors have been headache, gastrointestinal disturbances, and rash; they have sometimes been severe enough to require stopping treatment.

Other effects include pruritus, dizziness, fatigue, cough, back or abdominal pain, arthralgia and myalgia, urticaria, and dry mouth. Isolated cases of photosensitivity, bullous eruption, erythema multiforme, and Stevens-Johnson syndrome have occurred; toxic epidermal necrolysis has sometimes been fatal. Systemic hypersensitivity reactions, including fever, bronchospasm, angioedema, and anaphylaxis have been reported. Effects on the CNS include occasional insomnia, somnolence, aggression, and vertigo; reversible confusional states, agitation, depression, and hallucinations have occurred in severely ill patients. Raised liver enzymes, and isolated cases of hepatitis, jaundice, and hepatic encephalopathy have been reported; fatalities have occurred from hepatic failure or necrosis.

Other adverse effects reported rarely include gastrointestinal (including oesophageal) candidiasis, muscular weakness, paraesthesia, blurred vision, alopecia, stomatitis, increased sweating, taste disturbances, peripheral oedema, malaise, hyponatraemia, hypomagnesaemia, blood disorders (including agranulocytosis, leucopenia, and thrombocytopenia), gynaecomastia, impotence, and interstitial nephritis. Cardiovascular effects may occur, including angina, tachycardia or bradycardia. Pancreatitis (sometimes fatal) has been reported, as have tinnitus, urinary disorders, and eye disorders.

Proton pump inhibitors may increase the risk of gastrointestinal infections because of their acid suppressive effects. The absorption of some vitamins and minerals may be reduced.

Early toxicological studies identified carcinoid-like tumours of the gastric mucosa in *rats* given very high doses of omeprazole over long periods (see under Gastrointestinal Tumours, p. 1869.3).

Incidence of adverse effects. Prescription-event monitoring for 16 205 patients prescribed omeprazole, 17 329 prescribed lansoprazole, and 11 541 prescribed pantoprazole indicated that adverse events were reported infrequently, with the most common being gastrointestinal disturbances and headache. The incidences of diarrhoea, the most commonly reported event, per 1000 days of exposure, were 0.18 for omeprazole, 0.39 for lansoprazole, and 0.23 for pantoprazole. Despite the inherent biases of such a cohort study, there did seem to be some evidence that lansoprazole might be associated with a somewhat greater risk of diarrhoea, particularly in the elderly.[1]

Effects on the blood. There have been rare cases of leucopenia, agranulocytosis, thrombocytopenia, and pancytopenia, with omeprazole and other proton pump inhibitors such as lansoprazole and pantoprazole.[1-4] Auto-immune haemolytic anaemia has also been reported with omeprazole.[5]

Effects on the cardiovascular system. Results and preliminary analyses from 2 studies raised concerns about a possible increased risk of myocardial infarction, cardiac failure, and cardiac-related sudden death in patients taking *omeprazole* or *esomeprazole* compared with patients who had surgery for gastro-oesophageal reflux disease.[1,2] However, an FDA safety review found that patients who had surgery tended to be younger and less likely to have a history of cardiac problems or cardiac risk factors than those given such drugs.[2] The FDA concluded that long-term use of these drugs is not likely to be associated with an increased risk of cardiac problems.[3] However, while Health Canada[4] considered that there was no evidence to support such an increased risk with long-term use of esomeprazole they were unable to make such a definitive conclusion for omeprazole.

There is a possible increased risk of cardiovascular events when proton pump inhibitors are used with clopidogrel, see Proton Pump Inhibitors, under Interactions of Clopidogrel, p. 1344.2. However, patients given proton pump inhibitors after myocardial infarction were found to have an increased risk for adverse cardiovascular outcomes in a retrospective cohort study,[5] an effect which was independent of clopidogrel use.

Effects on electrolytes. Electrolyte disturbances have been reported with proton pump inhibitors, including hyponatraemia, with *omeprazole*,[1] *esomeprazole*,[2] *lansoprazole*,[3] and *pantoprazole*.[4] Refractory hypomagnesaemia with hypocalcaemia and hypokalaemia has been reported in 2 patients given omeprazole. Both patients were also taking other medicines that can affect electrolyte balance; however all abnormalities resolved when omeprazole was stopped.[5] In another case, severe hypomagnesaemia with hypocalcaemia and hypokalaemia occurred after prolonged treatment with omeprazole; electrolytes recovered when treatment with ranitidine was substituted, but fell again when pantoprazole and then lansoprazole therapy were tried.[6] The FDA reviewed 61 reports of hypomagnesaemia associated with proton pump inhibitors when used for at least 3 months and generally for more than 1 year. Serious adverse events included tetany, arrhythmias, and seizures. In about a quarter of cases, magnesium supplementation did not improve concentrations and the proton pump inhibitor had to be stopped. The mechanism responsible for proton pump inhibitors causing hypomagnesaemia is unknown; however, long-term use of proton pump inhibitors may cause changes in intestinal absorption of magnesium. Measurement of magnesium concentrations should be considered in patients starting long-term proton pump inhibitor treatment, those taking digoxin, or those taking other medicines which may cause hypomagnesaemia.[7]

Effects on the endocrine system. Up to December 1991, WHO had received 30 reports of impotence or gynaecomastia which might have been due to omeprazole;[1] of these reports 15 were of impotence, 13 of gynaecomastia in men, and 2 of breast enlargement in women. The Spanish Pharmacovigilance System reported 24 cases of gynaecomastia associated with the use of proton pump inhibitors, including lansoprazole and rabeprazole, between January 1982 and July 2006. In most of the cases, gynaecomastia improved after stopping the drug.[2] For reference to a case-control study showing no statistical link between gynaecomastia and omeprazole, see under Cimetidine, p. 1829.2.

Effects on the eyes. Visual disturbances associated with the use of omeprazole have included 6 cases of irreversible blindness or visual impairment in severely ill patients given the drug intravenously, and 13 cases of visual disturbances associated with oral use.[1] As a result of concern about these effects the availability of intravenous omeprazole was restricted in Germany; however, the consensus appears to be that a causal link has not been established. Suggestions that visual (and also auditory[2]) impairment could follow drug-induced vasculitis[2-4] appear to be contentious.[1,5-7] A cohort study involving 140 128 patients given antisecretory therapy, 33 988 of whom received omeprazole, found no evidence that any of the drugs used was associated with a major increase in risk of vascular or inflammatory disorders of the eye;[8] however, the statistical power of this study was not high.[9]

Effects on the gastrointestinal tract. Treatment with a proton pump inhibitor has been associated with rebound acid hypersecretion on withdrawal. In healthy subjects without gastric acid-related disease or symptoms, withdrawal of oral esomeprazole after 8 weeks treatment induced acid-related symptoms such as heartburn, acid regurgitation, and dyspepsia.[1]

1. Reimer C, *et al.* Proton-pump inhibitor therapy induces acid-related symptoms in healthy volunteers after withdrawal of therapy. *Gastroenterology* 2009; 137: 80–7.

Effects on the kidneys. A systematic review of proton pump inhibitor-associated interstitial nephritis included 47 cases with omeprazole, 6 with pantoprazole, 3 with esomeprazole, 2 with lansoprazole, and 2 with rabeprazole. Although there was insufficient evidence to conclude that proton pump inhibitors caused this reaction, there was a low-prevalence association between their use and the development of interstitial nephritis.[1]

A 2011 report by the Australian Therapeutic Goods Administration[2] stated that acute interstitial nephritis should be considered a class effect of proton pump inhibitors. There have been reports associated with all the proton pump inhibitors, although the incidence is unknown and may vary between individual drugs. Patients had usually presented with non-specific symptoms such as fever, anorexia, weight loss, fatigue, nausea, and vomiting; pyuria, proteinuria, and/or haematuria may also be noted. In some reports[3,4] of interstitial nephritis with omeprazole the condition was associated with rash and eosinophilia, and an allergic mechanism has been postulated.[4]

Effects on the liver. Raised liver enzymes have occurred with omeprazole and other proton pump inhibitors, and there have been isolated cases of hepatotoxicity. For a study comparing the incidence of acute liver injury in patients receiving omeprazole or histamine H_2-antagonists, see Cimetidine, p. 1829.3.

Effects on the musculoskeletal system. Progressive muscular weakness suggestive of *myopathy* developed in a 78-year-old patient given oral omeprazole.[1] After 4 weeks of treatment the patient required assistance in walking and rising from squatting. Weakness resolved on withdrawal of the drug, but returned on rechallenge. Acute myopathy has also been reported after a single infusion of omeprazole.[2] Analysis of the WHO adverse drug reaction database in March 2005 revealed 868 reports associating proton pump inhibitors with *myalgia*, of which 292 cases had symptoms indicative of muscle disorders including *polymyositis* and *rhabdomyolysis*.[3] Reports implicated omeprazole, pantoprazole, lansoprazole, esomeprazole, and rabeprazole, and it was suggested that myopathy was probably a class effect. The mechanism might involve induction of auto-immune antibodies.

A report of 5 cases of *arthralgia*, sometimes associated with swelling of the affected joints, in patients receiving omeprazole,[4] also noted that some reported cases of omeprazole-associated headache were accompanied by arthralgia or myalgia. In another case[5] arthralgia in a patient with a hereditary myopathy receiving omeprazole appeared to represent one aspect of a drug-induced *lupus* syndrome, being accompanied by malaise, fever, Raynaud's phenomenon, raised antinuclear antibody titres, and anticardiolipin and antihistone antibodies. Symptoms resolved on withdrawal of the drug.

A case of *eosinophilia* and myalgia related to lansoprazole treatment has been reported.[6]

There has also been a report of 2 cases of acute *gout* associated with omeprazole;[7] in one patient symptoms, which resolved on withdrawal, recurred on rechallenge. However, case control studies have failed to show an increased risk of polyarthralgia[8] or gout[9] associated with omeprazole use.

An FDA review[10] found an increased risk of *fractures* of the hip, wrist, or spine in 6 out of 7 epidemiological studies, in which patients took proton pump inhibitors for 1 to 12 years; the one study that did not find an association limited the study population to those without major risk factors for fracture. Patients in most studies were 50 years of age or older, and the increased risk was mainly in this age group, with treatment for one year or more. Two studies reported an increase in fractures with higher doses, and 2 reported an increase with longer duration of use. These data suggest patients taking proton pump inhibitors may be at an increased risk of fractures. However, factors that might influence this conclusion such as history of osteoporosis, smoking status, alcohol use, and BMI cannot be accounted for in epidemiological studies and 3 studies found no consistent association between chronic proton pump inhibitor use and bone mineral density; it is therefore unclear if proton pump inhibitor use causes an increased risk of fractures. A subsequent meta-analysis[11] of 11 observational studies (including 6 of the studies in the above FDA review) found that proton pump inhibitors modestly increased the risk of hip, spine, and fractures at any site. The MHRA[12] has also reported that meta-analyses of epidemiological studies suggest the risk of fracture is increased by 10 to 40% above baseline, although the studies varied in the extent to which they adjusted for confounders. It has been suggested that calcium malabsorption secondary to acid suppression may explain the association.[13]

Effects on the nervous system. Ataxia has been reported in a patient given omeprazole;[1] symptoms resolved on stopping the drug. A patient given rabeprazole developed marked anxiety with panic attacks, episodic night terrors, confusion, and attention deficit.[2] Her symptoms resolved 2 days after stopping therapy. A month later, she was given esomeprazole, with no adverse neuropsychiatric symptoms. The authors hypothesised that rabeprazole use had resulted in significantly greater plasma gastrin concentrations than esomeprazole, which may have affected gastrin receptors in the brain.

Effects on the respiratory system. An intractable, dry, non-productive cough started abruptly in a 42-year-old non-smoker given omeprazole for gastro-oesophageal reflux disease (GORD). The cough was initially thought to be related to the GORD and treatment was continued for 4 months, without any cessation in the cough. Omeprazole was stopped, and the cough ceased abruptly, with no recurrence during a 2-year follow-up.[1]

For discussion of a possible increased risk of respiratory infection and pneumonia in patients taking proton pump inhibitors see Infection, p. 1870.1.

Effects on the skin. An extensive blistering erythematous rash in an elderly woman given omeprazole[1] was characteristic of acute disseminated epidermal necrosis. The UK CSM had received 223 reports of cutaneous reactions to omeprazole up to August 1992, including 6 of erythema multiforme, but none of this severity. Other severe reactions that have subsequently been reported include a toxic bullous skin reaction,[2] exfoliative dermatitis,[3,4] erythema multiforme,[4] toxic erythema,[4] and dermatomyositis.[5] One patient developed exfoliative dermatitis with both omeprazole and lansoprazole.[4] The authors of this report noted that by January 1998 a total of 1296 skin reactions to omeprazole, 500 to lansoprazole, and 44 to pantoprazole, had been reported to the CSM. Most were non-specific rashes, pruritus, urticaria, erythematous rashes, and photosensitive eruptions. A lichenoid reaction that occurred in a patient taking omeprazole cleared after ceasing the drug, but recurred during treatment with both lansoprazole and pantoprazole.[6] Proton pump inhibitors, including esomeprazole, have been reported to worsen vitiligo.[7]

For a report of urticaria and angioedema possibly associated with the formulation of omeprazole see Hypersensitivity, p. 1870.1. For the association of rash with interstitial nephritis, see Effects on the Kidneys, above.

Fever. Fever, associated with severe myalgia and headache, was seen in a 64-year-old man on 2 occasions, several hours after taking a dose of esomeprazole.[1] Although it was suggested[2] that the patient's hyperpyrexia was due to a hypersensitivity reaction, the authors argued[3] that esomeprazole may have interfered with the hypothalamic regulatory centres of body temperature.[1,3]

Gastrointestinal tumours. Early toxicological studies in *rats* given high doses of omeprazole over 2 years identified carcinoid tumours of the gastric mucosa associated with complete block of gastric acid secretion leading to *hypergastrinaemia and hyperplasia of enterochromaffin-like cells*.[1] This has been the main issue concerning the safety of omeprazole and other proton pump inhibitors and initially led to restrictions in use and duration of treatment. A drug manufacturer, *Glaxo*, developed a new test to detect genotoxicity of antisecretory drugs which indicated that a genotoxic effect of omeprazole could not be discounted.[2] This study was heavily criticised; more established genotoxicity tests have been reported to be negative for omeprazole,[3-5] and other groups have not been able to replicate the findings with the new test.[6] The lowest doses at which *Glaxo* found[2] a genotoxic effect of omeprazole were 10 to 20 mg/kg and the clinical significance of their results was questioned.[3] Long-term studies of omeprazole in patients with Zollinger-Ellison syndrome have found no increase in fasting serum-gastrin concentrations and no evidence of gastric carcinoid tumours.[7,8] For mention of the risk of proton pump inhibitors delaying the diagnosis of gastric carcinoma, see under Precautions, p. 1870.2. Hypergastrinaemia can occur with both short- and long-term omeprazole therapy,[9] and may be higher in patients with *Helicobacter pylori* infection.[10,11] Patients who had *H. pylori* eradicated before long-term omeprazole treatment had lower gastrin concentrations than those who did not, since *H. pylori* eradication reduced the pretreatment gastrin concentrations.[12]

H. pylori is also a cause of *atrophic gastritis*, another risk factor for stomach cancer, and one study found that omeprazole increased the risk of atrophic gastritis in *H. pylori*-positive patients with gastro-oesophageal reflux disease.[13] However, the results of this study require confirmation since it was nonrandomised and retrospective. Nevertheless, some have suggested that it may be appropriate to eradicate *H. pylori* before long-term treatment with a proton pump inhibitor.[12,13] Conversely, there is some evidence that *H. pylori* may be protective in gastro-oesophageal reflux disease.[14]

There has been a report of *gastric polyps* developing in 3 of 8 patients after receiving omeprazole 20 or 40 mg daily for one year.[15] In a subsequent report it was noted that these omeprazole-induced fundic gland polyps had remained asymptomatic and non-malignant for up to five years after their onset.[16]

The possible association between acid suppressing drugs and risk of gastric cancer has been studied (see also Cimetidine, under Carcinogenicity, p. 1828.3). A small increase in the risk of gastric cancer has been reported with the use of proton pump inhibitors, although the authors of this case control study suggested that confounding by indication was the most likely explanation.[17]

Further long-term studies of omeprazole may be needed before a realistic risk assessment can be made.

Hypersensitivity. Cases of anaphylactic reactions after treatment with omeprazole, lansoprazole, and pantoprazole, have been reported in the literature and to WHO.[1] Cross-sensitivity to pantoprazole was reported[2] on skin-testing in 4 of 9 patients sensitive to omeprazole; oral challenge tests with pantoprazole in 3 patients, 2 of whom were negative on skin testing, produced pruritus and urticaria in all 3. However, none of the patients had a reaction to skin tests with lansoprazole, and 8 of the 9 tolerated oral challenge with lansoprazole without problems; the other developed widespread urticaria one hour after a therapeutic dose was reached.

Urticaria, facial angioedema, and bronchospasm in a patient given omeprazole capsules did not recur when the patient was given omeprazole granules and the reaction might have been precipitated by the ingredients of the capsule shell.[3]

Infection. Gastric-acid suppressing drugs such as proton pump inhibitors and H_2-antagonists have been linked to an increased risk of infection. A systematic review[1] found an increased risk of enteric infections such as *Salmonella, Campylobacter, Shigella,* or *Clostridium difficile* in patients taking acid suppressing drugs, although there was considerable heterogeneity between studies. Increased rates of sepsis[2] and necrotising enterocolitis[3] have also been reported in infants given H_2-antagonists. It has been suggested that the increased rate of infection could be due to the rise in gastric pH after acid suppressive treatment, resulting in increased microbial colonisation of the upper gastrointestinal tract.[1-3]

Results from studies into the risk of developing community-acquired pneumonia with the use of acid suppressants have been inconsistent. Increased rates of pneumonia have been reported with current use of acid suppressants in case-control and cohort studies,[4-7] whereas an industry-sponsored analysis of pooled adverse effect data on esomeprazole did not support an association between its use and respiratory-tract infections, including pneumonia.[8] A case control study found no overall increase in the risk of community-acquired pneumonia with current use of proton pump inhibitors, although unexpectedly, an increased risk was noted when proton pump inhibitors had been started in the previous month.[9] A systematic review also failed to find an association between use of proton pump inhibitors (esomeprazole, rabeprazole, pantoprazole and omeprazole) and respiratory infections, although it noted a trend towards an association.[10]

Lupus syndrome. For a report of drug-induced lupus syndrome associated with omeprazole therapy, see Effects on the Musculoskeletal System, p. 1869.1.

Malabsorption. Omeprazole has been reported to result in a substantial reduction in *cyanocobalamin* (vitamin B_{12}) absorption,[1] probably related to the increase in gastric pH, and indicating a potential risk of vitamin deficiency with long-term therapy.[2] UK licensed product information recommends that severely ill children, who may have borderline body stores of cyanocobalamin, should have serum vitamin B_{12} concentrations monitored if they require long-term therapy. Omeprazole has also been reported to impair the bioavailability of dietary *vitamin C*.[3] *Fat* malabsorption, secondary to increased deconjugation of bile acids caused by bacterial overgrowth in the jejunum, has also been reported with omeprazole treatment.[4] For the suggestion that proton pump inhibitors can cause *calcium* malabsorption, see Effects on the Musculoskeletal System, p. 1869.1.

Overdosage. A report of 2 cases of overdosage with omeprazole.[1] The major clinical features were drowsiness, headache (possibly due to a metabolite), and tachycardia. Both patients recovered uneventfully without specific treatment.

1. Ferner RE, Allison TR. Omeprazole overdose. *Hum Exp Toxicol* 1993; 12: 541–2.

Precautions

Before giving omeprazole or other proton pump inhibitors to patients with gastric ulcers the possibility of malignancy should be excluded since these drugs may mask symptoms and delay diagnosis. Omeprazole and other proton pump inhibitors should be used with caution in hepatic impairment and dose adjustment may be required.

Breast feeding. Omeprazole is excreted in human milk. After a single oral dose, peak concentrations of omeprazole in breast milk were reported to be less than 7% of the peak serum concentration.[1]

1. Marshall JK, *et al.* Omeprazole for refractory gastroesophageal reflux disease during pregnancy and lactation. *Can J Gastroenterol* 1998; 12: 225–7.

Gastric carcinoma. Proton pump inhibitors relieve dyspeptic symptoms associated with gastric carcinoma and can therefore delay its diagnosis. In addition, there is some evidence that they may also endoscopically 'heal' early gastric carcinoma so that the diagnosis is missed.[1] Consequently, some commentators recommend that proton pump inhibitors should not be prescribed for symptom control before endoscopy in patients at risk for gastric carcinoma.[2]

1. Wayman J, *et al.* The response of early gastric cancer to proton-pump inhibitors. *N Engl J Med* 1998; 338: 1924–5.
2. Griffin SM, Raimes SA. Proton pump inhibitors may mask early gastric cancer: dyspeptic patients over 45 should undergo endoscopy before these drugs are started. *BMJ* 1998; 317: 1606–7.

Helicobacter infection. Treatment with proton pump inhibitors may cause false-negative results in the urea breath test for *Helicobacter pylori* infection. In one study in patients with *H. pylori* infection, lansoprazole 30 mg daily for 4 weeks caused 33% of patients to have negative urea breath tests.[1] The breath test became positive again in all patients within 2 weeks of stopping lansoprazole therapy. In a similar study, 52% of patients had negative urea breath tests for *H. pylori* while receiving omeprazole 20 mg daily, and the breath test became positive again in all patients within 2 to 6 days of stopping treatment.[2] The manufacturers of the urea breath test for *H. pylori* recommend that it should not be performed for at least 2 weeks after stopping treatment with an antisecretory drug.

For a discussion of the link between proton pump inhibitors, *H. pylori*, and gastritis, see under Gastrointestinal Tumours p. 1869.3.

Hepatic impairment. In patients with cirrhosis an increase in omeprazole bioavailability, and elimination half-life has been reported.[1] For dosage adjustment in hepatic impairment see Administration in Hepatic Impairment, p. 1868.1.

1. Andersson T, *et al.* Pharmacokinetics of [^{14}C]omeprazole in patients with liver cirrhosis. *Clin Pharmacokinet* 1993; 24: 71–8.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies omeprazole as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Pregnancy. Proton pump inhibitors are not generally licensed for use during pregnancy (although the UK has licensed omeprazole for such use), but a meta-analysis[1] of 5 studies of exposure to proton pump inhibitors during the first trimester, involving 593 exposed infants, found the relative risk of major abnormalities associated with such exposure to be only 1.18, with a 95% confidence interval ranging from 0.72 to 1.94. Meta-analysis of exposures to omeprazole (from 4 studies only) gave a relative risk of 1.05 (95% confidence interval 0.59 to 1.85). It was concluded that exposure to proton pump inhibitors, and omeprazole in particular, did not pose an important teratogenic risk. A retrospective epidemiological study of data from the Swedish Medical Birth Registry, which identified 955 exposed infants, also found no evidence of significant risk after exposure to omeprazole during pregnancy,[2] a finding confirmed by a subsequent meta-analysis.[3] Additionally, a cohort study[4] into the use of proton pump inhibitors in the first trimester did not find an increased risk of major birth defects.

Interactions

Omeprazole and other proton pump inhibitors are metabolised by the cytochrome P450 system, mainly by isoenzyme CYP2C19, and to a smaller extent by CYP3A4. Inhibitors or inducers of these isoenzymes may affect exposure to omeprazole and other proton pump inhibitors. In turn, proton pump inhibitors may alter the metabolism of some drugs metabolised by these enzymes. Omeprazole also inhibits CYP2C19 and may prolong the elimination of cilostazol, diazepam, phenytoin, and warfarin (but see below). Omeprazole and other proton pump inhibitors can affect the absorption of drugs such as dasatinib, erlotinib, posaconazole, ketoconazole, and itraconazole, whose absorption is dependent on an acid gastric pH. With voriconazole, the plasma concentration of both drugs may be increased (for further information, see p. 1871.1). Other proton pump inhibitors may be similarly affected by voriconazole. Omeprazole and other proton pump inhibitors should not be used with atazanavir or nelfinavir, as it substantially reduces exposure to the HIV-protease inhibitor.

The decrease in gastric activity with proton pump inhibitors may give false positive results in diagnostic investigations for neuroendocrine tumours and treatment should be stopped before such investigations.

Omeprazole is mainly metabolised by the cytochrome P450 isoenzyme CYP2C19 (see Metabolism, p. 1871.2) and therefore may interact with diazepam (see under Gastrointestinal Drugs, p. 1069.3). Some metabolism of phenytoin (see p. 544.3), tolbutamide, and the *R*-enantiomer of warfarin (see p. 1534.1) also takes place by CYP2C19, but the effects seen have been minor.[1] Although some induction of CYP1A2, which metabolises caffeine and

theophylline (p. 1236.1), has been reported this does not appear to be clinically significant.[2] While some consider the effect of omeprazole on CYP3A4 activity to be insignificant,[3] others have noted increasing evidence that competitive inhibition of intestinal CYP3A4 by omeprazole may affect the first-pass metabolism of several drugs.[4] A review concluded that, while omeprazole and possibly esomeprazole have a considerable potential for drug interactions, lansoprazole, pantoprazole and rabeprazole are associated with a lower incidence of drug interactions.[4]

For a study *in vitro* suggesting that omeprazole affected CYP3A4 metabolism of tacrolimus, see under Interactions of Tacrolimus, p. 1972.3. For more on the effect of proton pump inhibitors on tacrolimus, see Gastrointestinal Drugs, p. 1973.3. Proton pump inhibitors, including omeprazole, may also affect exposure to mycophenolate, see p. 1965.1.

For reference to the possibility of enhanced digoxin absorption with omeprazole, see p. 1357.3. For a study suggesting that omeprazole reduces the absorption of cyanocobalamin and vitamin C, see Malabsorption, p. 1870.2, and for its effect on calcium absorption see p. 1825.1. For reference to possible interactions between methotrexate and omeprazole, see p. 828.1.

4. Blume H, *et al.* Pharmacokinetic drug interaction profiles of proton pump inhibitors. *Drug Safety* 2006; 29: 769–84.

Clarithromycin. Studies in healthy subjects have indicated that use of omeprazole with clarithromycin results in an approximate 30% increase in peak plasma concentrations of omeprazole, and an increase in its mean half-life from 1.2 to 1.6 hours.[1] At the same time, plasma concentrations of clarithromycin were also modestly increased, as were local concentrations in gastric tissue and mucus.[1] Clarithromycin inhibits[2] the metabolism of omeprazole mediated by the cytochrome P450 isoenzyme CYP3A4. The interaction may contribute to the benefits of combined therapy for *Helicobacter pylori* infection.

2. Furuta T, *et al.* Effects of clarithromycin on the metabolism of omeprazole in relation to CYP2C19 genotype status in humans. *Clin Pharmacol Ther* 1999; 66: 265–74.

Clopidogrel. For recommendations that the use of proton pump inhibitors such as omeprazole with clopidogrel should be discouraged, see p. 1344.2.

Fluvoxamine. Omeprazole and other proton pump inhibitors are metabolised mainly by cytochrome P450 isoenzyme CYP2C19, which shows genetically determined polymorphism, yielding extensive metabolisers and poor metabolisers. Fluvoxamine increased exposure to omeprazole, lansoprazole, and rabeprazole in patients who were extensive metabolisers, but had no effect on pharmacokinetic parameters in poor metabolisers.[1-3] Dose reductions may need to be considered in patients treated with fluvoxamine and proton pump inhibitors.

3. Uno T, *et al.* Different effects of fluvoxamine on rabeprazole pharmacokinetics in relation to CYP2C19 genotype status. *Br J Clin Pharmacol* 2006; 61: 309–14.

Voriconazole. When omeprazole is given with voriconazole, exposure to both drugs is increased. UK licensed product information for omeprazole states that a dose adjustment of omeprazole is not routinely indicated, unless patients have severe hepatic impairment and long-term therapy is indicated. However, UK licensed product information for voriconazole states that, while no dosage adjustment is considered necessary for voriconazole, when patients already receiving omeprazole are started on voriconazole, the dose of omeprazole should be halved. Other proton pump inhibitors may be similarly affected by voriconazole.

Pharmacokinetics

Omeprazole is rapidly but variably absorbed after oral doses. Absorption is not significantly affected by food. Omeprazole is acid-labile and the pharmacokinetics of the various formulations developed to improve oral bioavailability may vary. The absorption of omeprazole also appears to be dose-dependent; increasing the dosage above 40 mg has been reported to increase the plasma concentrations in a non-linear fashion because of saturable first-pass hepatic metabolism. In addition, bioavailability is higher after long-term use.

Bioavailability of omeprazole may be increased in elderly patients, in some ethnic groups such as Chinese, and in patients with hepatic impairment, but is not markedly affected in patients with renal impairment.

On absorption, omeprazole is almost completely metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP2C19 to form hydroxy-omeprazole, and to a small extent by CYP3A4 to form omeprazole sulfone. The metabolites are inactive, and are excreted mostly in the urine and to a lesser extent in bile. The elimination half-life from plasma is reported to be about 0.5 to 3 hours. Omeprazole is about 95% bound to plasma proteins.

Metabolism. The major enzyme involved in omeprazole metabolism is cytochrome P450 isoenzyme CYP2C19. This enzyme is polymorphically expressed, and individuals who are deficient in the enzyme are poor metabolisers of omeprazole. This occurs in about 3% of Caucasians and 15% of Chinese, Japanese, and Koreans. These individuals have markedly higher plasma concentrations of omeprazole, and they may require dosage adjustment. Some omeprazole is metabolised by CYP3A4, and some by CYP2D6 to form desmethylomeprazole.

UNII — NMH84OZK2B.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US.*

Ph. Eur. 8: (Ondansetron Hydrochloride Dihydrate). A white or almost white powder. Sparingly soluble in water and in alcohol; slightly soluble in dichloromethane; soluble in methyl alcohol. Protect from light.

USP 36: (Ondansetron Hydrochloride). A white to off-white powder. Sparingly soluble in water and in alcohol; very slightly soluble in acetone, in chloroform, and in ethyl acetate; slightly soluble in dichloromethane and in isopropyl alcohol; soluble in methyl alcohol. Store in airtight containers at a temperature of 25 degrees, excursions permitted between 15 degrees and 30 degrees. Protect from light.

Incompatibility. Ondansetron hydrochloride and dexamethasone sodium phosphate were not compatible when high concentrations were combined in polypropylene syringes.[1] Lower concentrations (up to 640 micrograms/mL of ondansetron and 400 micrograms/mL of dexamethasone phosphate) were stable in 50 mL containers of infusion fluid for 30 days under refrigeration. Compatibility has been reported for 24 hours in plastic syringes at 4 degrees or 23 degrees with a variety of other drugs,[2] and with several antineoplastics (cytarabine, dacarbazine, doxorubicin, etoposide, or methotrexate) in PVC infusion bags for 48 hours at room temperature.[3]

3. Stewart JT, *et al.* Stability of ondansetron hydrochloride and five antineoplastic medications. *Am J Health-Syst Pharm* 1996; 53: 1297–1300.

Uses and Administration

Ondansetron is a 5-HT_3 antagonist (5-HT_3-receptor antagonist) with antiemetic activity. It is used in the management of **nausea and vomiting** induced by cytotoxic chemotherapy and radiotherapy. It is also used for the prevention and treatment of postoperative nausea and vomiting. For the management of nausea and vomiting, and the important role of 5-HT_3 antagonists, see p. 1811.3.

Ondansetron is given by intramuscular or slow intravenous injection or infusion as the hydrochloride, orally as the hydrochloride or base, or rectally as the base. Doses are expressed in terms of the base. Ondansetron hydrochloride 4.99 mg is equivalent to about 4 mg of ondansetron base.

Numerous dosing schedules of ondansetron have been used; some typical examples are cited below.

For *highly emetogenic* **chemotherapy** the following dose schedules appear to be equally effective in *preventing* acute emesis:

- a single dose of 8 mg by slow intravenous or intramuscular injection immediately before treatment

or

- 8 mg by slow intravenous or intramuscular injection immediately before treatment, either followed by a continuous intravenous infusion of 1 mg/hour for up to 24 hours, or by a further two doses of 8 mg two to four hours apart

or

- a single dose of 16 mg given by intravenous infusion over at least 15 minutes immediately before treatment, which can be followed by a further 2 doses of 8 mg by slow intravenous or intramuscular injection four hours apart

or

- 150 micrograms/kg (maximum 16 mg) by intravenous infusion over 15 minutes, beginning 30 minutes before chemotherapy, followed by a further 2 doses four hours apart

or

- a 16-mg suppository rectally, given 1 to 2 hours before treatment

or

- a single oral dose of 24 mg taken 30 minutes before the start of single-day chemotherapy

The efficacy of ondansetron in highly emetogenic chemotherapy may be enhanced by giving intravenous dexamethasone sodium phosphate 20 mg before chemotherapy.

Similar regimens to those given above are used for preventing acute emesis with *less emetogenic chemotherapy* and/or **radiotherapy** and also include:

- 8 mg given orally or by slow intravenous injection up to 2 hours before treatment, followed by an oral dose of 8 mg given 8 to 12 hours later

To protect against delayed emesis these regimens are followed by oral ondansetron 8 mg twice daily, or 16 mg rectally once daily, for up to 5 days after the end of a course of chemotherapy.

To *prevent* **postoperative nausea and vomiting** the following doses may be given:

- 16 mg orally an hour before anaesthesia

or

- 8 mg orally an hour before anaesthesia followed by 2 further doses of 8 mg at 8-hour intervals

or

- a single dose of 4 mg by slow intravenous or intramuscular injection at induction of anaesthesia

For the *treatment* of postoperative nausea and vomiting a single dose of 4 mg by intramuscular or slow intravenous injection is recommended.

For dosing in children, elderly patients, or those with hepatic impairment, see below.

Administration. Ondansetron has been successfully used by continuous *subcutaneous* infusion to control intractable nausea and vomiting.[1] Despite concern about the low pH of ondansetron injection there was no problem with the skin at the infusion site. An *oral* protocol for chemotherapy-induced emesis in children has been described;[2] efficacy was similar to intravenous use.

Administration in children. Ondansetron is used in children for the management of nausea and vomiting induced by cytotoxic chemotherapy and radiotherapy. It is also used for the prevention and treatment of postoperative nausea and vomiting. Ondansetron is given by slow intravenous injection or infusion as the hydrochloride, or orally as the hydrochloride or base. Doses are expressed in terms of the base.

In the USA a licensed regimen for **chemotherapy**-induced nausea and vomiting in children over 6 months of age is ondansetron 150 micrograms/kg by intravenous infusion 30 minutes before moderately to highly emetogenic chemotherapy, repeated 4 and 8 hours after the first dose. Alternatively, for children aged 4 to 11 years, an oral dose of 4 mg may be given 30 minutes before the start of moderately emetogenic chemotherapy, with subsequent 4-mg doses given 4 and 8 hours thereafter. An oral dose of 4 mg three times daily may be given for 1 to 2 days after the end of chemotherapy.

In the UK, ondansetron is licensed for use in children aged from 6 months and doses are calculated using body-weight or body-surface; weight-based dosing results in higher daily doses compared with those based on body-surface. In a typical regimen based on body-surface, an intravenous dose of ondansetron 5 mg/m^2 (maximum 8 mg) is infused (over at least 15 minutes) immediately before chemotherapy and followed after 12 hours by oral dosing for up to 5 days:

- children aged from 6 months and less than 0.6 m^2 body-surface: 2 mg every 12 hours
- from 6 months and 0.6 m^2 and over: 4 mg every 12 hours

When using body-weight, an intravenous dose of ondansetron 150 micrograms/kg (maximum 8 mg) is given immediately before chemotherapy and repeated every 4 hours for up to 3 doses. This is followed after 12 hours by oral dosing for up to 5 days:

- body-weight 10 kg and less: 2 mg every 12 hours
- over 10 kg: 4 mg every 12 hours

The daily dose of ondansetron by any route should not exceed 32 mg.

While ondansetron is not licensed in the UK for **radiotherapy**-induced nausea and vomiting in children the *BNFC* recommends the same doses as those used for chemotherapy-induced nausea and vomiting (above).

A protocol for oral ondansetron dosage, with similar efficacy to intravenous use, has also been described, see Administration, above.

For the prevention and treatment of **postoperative nausea and vomiting** in children aged from 1 month 100 micrograms/kg may be given by slow intravenous injection, up to a maximum dose of 4 mg.

Administration in the elderly. Most licensed product information for ondansetron states that dose adjustments for patients over 65 years of age are not necessary. However the product information for one preparation (*Zofran; GSK UK*) recommends that patients over 75 years of age are given an initial dose of 8 mg by intravenous infusion over 15 minutes for the management of nausea and vomiting induced by cytotoxic chemotherapy and radiotherapy; this may be followed by a further 2 infusions of 8 mg given at least four hours apart.

Administration in hepatic impairment. Licensed product information recommends that the dose of ondansetron should not exceed 8 mg daily in patients with moderate or severe hepatic impairment. When this dose was given intravenously to patients with hepatic impairment, those with severe impairment showed an increase in the area under the plasma concentration/time curve and in the terminal plasma half-life, and a decrease in plasma clearance.[1] The authors of this study, some of whom worked for the manufacturers (*Glaxo*), considered that ondansetron should be restricted to once daily dosage in severe hepatic impairment.

Bulimia nervosa. A combination of counselling, supportive psychotherapy, and antidepressants is the usual treatment of bulimia nervosa. Preliminary reports have indicated

that ondansetron may be of benefit in the treatment of this disorder.[1,2]

1. Faris PL, *et al.* Effect of decreasing afferent vagal activity with ondansetron on symptoms of bulimia nervosa: a randomised, double-blind trial. *Lancet* 2000; 355: 792–7.

Fatigue. Preliminary results indicated that treatment with 5-HT_3 antagonists such as ondansetron and tropisetron may be of benefit in patients with chronic fatigue.[1] Oral ondansetron 4 mg twice daily was reported[2] to resolve fatigue in a woman with chronic hepatitis C. In a randomised study in 36 patients with chronic hepatitis C, this dose of ondansetron given for 1 month significantly improved fatigue scores at day 15 and day 60 (beyond the treatment period) when compared with placebo.[3] The authors noted that patient awareness that constipation was a possible effect of active treatment may have potentially unblinded the study. Further confirmation by larger studies is needed.

Gastroenteritis. Antiemetics such as ondansetron have been tried to reduce vomiting during acute gastroenteritis in children. Reviews[1-3] have found that ondansetron (given orally or intravenously) reduces the risk of persistent vomiting, the need for intravenous fluids, and hospital admissions; an increased incidence of diarrhoea was seen, but further research was considered necessary to determine its clinical significance.[2] Metoclopramide was also effective in reducing the number of vomiting episodes and hospital admissions, although it was less often used because of its potentially serious adverse effects.[3]

Pain. Preliminary results from a small crossover study[1] indicated that oral ondansetron was more effective than paracetamol in relieving the pain of fibromyalgia, a chronic disorder that responds poorly to conventional analgesics. A single bolus of ondansetron given to patients with chronic neuropathic pain significantly reduced pain scores 2 hours after injection in a placebo-controlled study;[2] this effect may be due to an action on 5-HT_3 receptors in the spinal cord.

Other 5-HT_3 antagonists such as granisetron[3-5] and tropisetron[6-8] have also been investigated in various painful syndromes.

Pruritus. There are several case reports[1,2] of cholestatic pruritus (p. 1687.3) responding to intravenous or oral ondansetron, including one in pregnancy.[3] However, results from controlled studies[4-6] have been mixed. It is similarly unclear if ondansetron is of benefit in pruritus due to renal failure,[7-9] and results have been conflicting from controlled studies evaluating its use in opioid-induced pruritus.[10-15] There are reports of ondansetron ameliorating the pruritus associated with some skin disorders.[16] Other 5-HT_3 antagonists such as tropisetron[9] and dolasetron[14] have also been investigated.

Psychiatric disorders. Ondansetron has been tried experimentally in several psychiatric disorders including schizophrenia,[1-3] and psychosis in patients with parkinsonism,[4] and may be of value in moderating tardive dyskinesia.[5] A reduction in tic severity in Tourette's syndrome (see Tics, p. 1030.1) has been reported,[6] and preliminary results have suggested benefit in obsessive-compulsive disorder,[7] and bulimia nervosa (see p. 1872.3). It is also reported to be under investigation in the management of panic attacks (p. 1029.1). For the more conventional management of schizophrenia, parkinsonism, and obsessive-compulsive disorder see p. 1031.3, p. 889.1, and p. 1028.2, respectively.

Substance dependence. Ondansetron is being studied in the management of alcohol dependence (p. 1734.1). However, in one study[1] a significant reduction in alcohol consumption was found only in lighter drinkers after subgroup analysis. Another study[2] found a reduction in alcohol consumption by patients with early-onset alcoholism (onset before age 25) who took ondansetron compared with placebo. No such effect was seen, however, in patients with late-onset alcoholism. Further study found that ondansetron also effectively ameliorated mood disturbances including symptoms of depression, anxiety, and hostility, in early-onset alcoholics.[3] Self-reported alcohol consumption also reduced in adolescents (between ages 14 and 20) with alcohol dependence who were given ondansetron in an open study.[4]

Adverse Effects and Precautions

Ondansetron and other 5-HT_3 antagonists may cause headache, a sensation of flushing or warmth, hiccups, and constipation. A transient rise in liver enzymes has occasionally occurred. There have been rare reports of immediate hypersensitivity reactions, including anaphylaxis. Chest pain, arrhythmias, hypotension, tachycardia, and bradycardia have been reported rarely. Dizziness and transient visual disturbances such as blurred vision (or very rarely, transient blindness) have been reported during rapid intravenous injection. Transient ECG changes including QT interval prolongation have occurred very rarely, mainly with intravenous ondansetron. Seizures and movement disorders, including extrapyramidal reactions such as dystonia, dyskinesia, and oculogyric crisis have been reported. Rashes and urticaria have also occurred. Injection site reactions may develop, and local burning sensations are common after insertion of suppositories.

5-HT_3 antagonists should generally not be used in patients who have had a hypersensitivity reaction to a member of this drug class. They should be used with care in patients with signs of subacute intestinal obstruction or ileus. Ondansetron should be given in reduced doses to patients with moderate to severe hepatic impairment.

Effects on carbohydrate metabolism. Hypoglycaemia associated with dystonia and seizures developed in a four-year-old child after ondansetron treatment for vomiting.[1] Blood glucose concentrations returned to normal with intravenous glucose. Indirect inhibition of stress-induced corticotropin and cortisol secretion via the effects of ondansetron on serotonergic pathways was suggested as a possible cause for the hypoglycaemia. For more reports of extrapyramidal effects and seizures, see Effects on the Nervous System, p. 1874.1.

Effects on the cardiovascular system. In 1992 chest pain and/or cardiac arrhythmias that might have been associated with ondansetron were reported[1] in 4 patients, 2 of whom died. In 3 subsequent patients who developed severe chest or anginal pain, treatment with ondansetron was stopped.

The manufacturers (*Glaxo*) had at that time no evidence of a causal relationship between ondansetron and episodes of chest pain and cardiac abnormalities.[2] Giving ondansetron or granisetron intravenously produced no clinically important cardiovascular changes in a study in 12 healthy subjects.[3] Since then, however, hypotension, coronary vasospasm, and atrial fibrillation have been reported with ondansetron,[4] and myocardial ischaemia has been reported with both ondansetron[5] and dolasetron;[6] in the latter case this led to an acute myocardial infarction. Supraventricular tachycardia reported with dolasetron was attributed to an interaction with sevoflurane.[7] Dolasetron-induced torsade de pointes has also occurred,[8] and overdose of dolasetron has produced prolongation of the QT_c interval and hypotension.[9] Another study in healthy subjects found that dolasetron mainly altered ECG parameters indicative of ventricular depolarisation, whereas ondansetron affected mainly ventricular repolarisation.[10] However, ECG changes were transient and asymptomatic. Studies of high-dose intravenous granisetron[11-13] found no significant adverse effects on pulse, blood pressure, or ECG measurements. A review[14] of the electrocardiographic and cardiovascular effects of the 5-HT_3 antagonists concluded that although this class of drugs may cause small, transient ECG changes, the clinical benefits of the drugs outweighed the small theoretical risk of any clinically significant cardiovascular events. Nonetheless, the use of dolasetron in children has been contra-indicated in some countries (see Administration in Children, p. 1837.3).

Effects on the eyes. Blurring followed by transient loss of vision has been reported after rapid intravenous injection of ondansetron.[1] Oculogyric crisis may occur as part of

extrapyramidal reactions seen with ondansetron, see Effects on the Nervous System, below.

1. Cherian A, Maguire M. Transient blindness following intravenous ondansetron. *Anesthesia* 2005; 60: 938–9.

Effects on the liver. Although disturbances in liver enzyme values have been reported in patients given ondansetron,[1] more severe symptoms of liver disorder appear to be very rare; however, there is a report of severe jaundice associated with ondansetron as an antiemetic for chemotherapy.[2] Symptoms did not recur when the patient received granisetron.

2. Verrill M, Judson I. Jaundice with ondansetron. *Lancet* 1994; 344: 190–1.

Effects on the nervous system. Tonic-clonic movements and frothing at the mouth occurred in a patient 90 minutes after an infusion of ondansetron;[1] the patient responded to diazepam intravenously. The manufacturers had seen 10 patients who developed *seizures* during initial clinical studies, but considered that, unlike this case, all these patients had predisposing factors. Hypotension and generalised tonic-clonic seizures were reported in a patient with metastatic breast cancer given ondansetron as an intravenous bolus.[2] Although seizures might have been due to brain metastases, the authors concluded that ondansetron had been the likely cause, since the patient had no further problems when antiemetic therapy was changed to metoclopramide. A seizure associated with palonosetron therapy has also been reported.[3] *Extrapyramidal reactions* in patients given ondansetron as part of a chemotherapy regimen[4,5] and for postoperative nausea and vomiting[6–8] have also been reported. In one case,[8] transient multifocal encephalopathy developed. Clinical manifestations such as clonus, oculogyric crisis, and oromandibular and limb dystonia resembled those of structural brain injury, and response to diphenhydramine was poor; despite this, the patient made a full neurological recovery over the course of 12 hours. For reference to seizures and dystonia associated with hypoglycaemia in an ondansetron-treated child see Effects on Carbohydrate Metabolism, p. 1873.3. Ondansetron and related drugs can induce *headache*; it has sometimes been confused with post-dural puncture headache.[9]

Hypersensitivity. Anaphylactoid reactions have been reported in patients given ondansetron injections. The FDA stated in October 1993 that it had received 24 reports of such reactions,[1] mostly occurring after the first ondansetron dose of the second or third chemotherapy cycle, and characterised by urticaria, angioedema, hypotension, bronchospasm, and dyspnoea. Similar effects have been reported in a patient with no prior exposure to ondansetron.[2] A protocol for skin testing has been documented.[3]

Cross-sensitivity between 5-HT_3 antagonists has been reported;[4] 2 patients who had had a mild hypersensitivity reaction to one 5-HT_3 antagonist developed a more severe reaction after exposure to another. In the first case severe acute asthma, cyanosis, and loss of consciousness developed after ondansetron in a patient who had previously had an asthmatic reaction after tropisetron. The second patient had developed pruritus after a tropisetron injection and urticaria after ondansetron, and subsequently developed anaphylactic shock 5 minutes after a further dose of tropisetron. It was recommended that another 5-HT_3 antagonist should not be given as a replacement to patients who developed a hypersensitivity reaction to a drug of this class. However, there are reports of the successful use of granisetron in patients sensitive to ondansetron[5] and vice versa.[6]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies ondansetron as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Interactions

Ondansetron does not appear to induce or inhibit the cytochrome P450 isoenzyme system, but it is itself metabolised by multiple hepatic isoenzymes, including CYP3A4, CYP2D6, and CYP1A2. US licensed product information states that inducers or inhibitors of these isoenzymes may change the clearance and half-life of ondansetron, but that on the basis of available data, no dose adjustments are recommended. UK licensed product information states that enzyme inhibition of one isoenzyme is usually compensated for by other enzymes and should result in little or no significant change in overall ondansetron clearance or dose requirement. Potent inducers of CYP3A4, such as phenytoin, carbamazepine, and rifampicin, have been reported to increase ondansetron clearance and reduce ondansetron plasma concentrations.

Because of the reports of transient ECG changes in some patients taking 5-HT_3 antagonists (see p. 1873.3), there is a theoretical need for caution if given with drugs that prolong QT-interval or cardiotoxic drugs such as anthracyclines; however, clinical evidence of a significant interaction seems to be mostly lacking.

Analgesics. For evidence of reduced analgesic efficacy of *tramadol* in patients also given 5-HT_3-receptor antagonists, such as ondansetron, see p. 140.3.

Antibacterials. *Rifampicin* pretreatment reduced the area under the plasma concentration-time curve of oral ondansetron by 65% and of intravenous ondansetron by 48% in healthy subjects.[1] Use of rifampicin, or other potent inducers of cytochrome P450 isoenzyme CYP3A4, with ondansetron may reduce antiemetic efficacy.

1. Villikka K, *et al.* The effect of rifampin on the pharmacokinetics of oral and intravenous ondansetron. *Clin Pharmacol Ther* 1999; 65: 377–81.

Antineoplastics. For mention of retrospective studies suggesting a change of pharmacokinetic parameters of high-dose cyclophosphamide and cisplatin when given with an ondansetron-containing antiemetic regimen, see Gastrointestinal Drugs, p. 773.3.

Pharmacokinetics

Peak plasma concentrations of ondansetron occur about 1.5 hours after an oral dose of 8 mg, and about 6 hours after a rectal dose. The absolute bioavailability is about 60%, mainly because of hepatic first-pass metabolism. In elderly subjects, bioavailability may be somewhat higher (65%) and clearance lower, presumably due to reduced hepatic first-pass metabolism.

Ondansetron is extensively distributed in the body; about 70 to 75% of the drug in plasma is protein bound. It is metabolised in the liver through multiple enzymatic pathways; ondansetron is a substrate for cytochrome P450 isoenzymes, primarily CYP3A4, but also CYP1A2 and CYP2D6. Less than 5% of a dose is excreted unchanged in the urine.

The terminal elimination half-life is about 3 hours after oral or parenteral doses, and about 6 hours after rectal use. The terminal elimination half-life is prolonged to about 5 hours in the elderly and in those with renal impairment. These differences are not considered sufficient to warrant dosage adjustment. However, in patients with severe hepatic impairment, bioavailability may approach 100% and clearance is markedly reduced, with elimination half-lives of 15 to 32 hours; dosage restriction is advisable (see Administration in Hepatic Impairment, p. 1872.3). In general, children have a higher clearance than adults, although age-related reductions in clearance have also been reported, with younger children having lower clearances. Use of weight-based doses compensates for these changes and normalises exposure in paediatric patients.

$C_{19}H_{24}N_2O$,HCl=332.9

CAS — 135729-56-5 (palonosetron); 135729-55-4 (palonosetron hydrochloride); 135729-62-3 (palonosetron hydrochloride).

ATC — A04AA05.

ATC Vet — QA04AA05.

UNII — 233100D4I19.

Stability. The stability of palonosetron hydrochloride at concentrations of 5 and 30 micrograms/mL was assessed in PVC bags of the following 4 infusion solutions: glucose 5%, sodium chloride 0.9%, glucose 5% in sodium chloride 0.45%, and glucose 5% in lactated Ringer's solution. All solutions were considered to be physically and chemically stable for at least 48 hours at room temperature exposed to light, and for 14 days under refrigeration.[1]

Palonosetron 50 micrograms/mL (as palonosetron hydrochloride) was found to be physically and chemically stable during simulated Y-site administration with the following drugs:[2,3]

- atropine sulfate 400 micrograms/mL
- famotidine 2 mg/mL
- fentanyl citrate 50 micrograms/mL
- heparin sodium 100 units/mL
- hydromorphone hydrochloride 500 micrograms/mL
- lidocaine hydrochloride 10 mg/mL
- morphine sulfate 15 mg/mL
- pethidine hydrochloride 10 mg/mL
- potassium chloride 100 mmol/litre
- sufentanil 12.5 micrograms/mL (as sufentanil citrate)

Uses and Administration

Palonosetron is a 5-HT_3 antagonist used in the prevention of nausea and vomiting induced by cytotoxic chemotherapy and for the prevention of postoperative nausea and vomiting. Palonosetron is given as the hydrochloride but doses are expressed in terms of the base; 280.8 micrograms of palonosetron hydrochloride is equivalent to about 250 micrograms of palonosetron.

For the prevention of acute and delayed **nausea and vomiting** associated with initial and repeat courses of moderately or highly emetogenic cancer **chemotherapy**, a dose of 250 micrograms is given intravenously over 30 seconds about 30 minutes before chemotherapy. Palonosetron can also be given orally to prevent acute nausea and vomiting associated with initial and repeat courses of moderately emetogenic chemotherapy. A dose of 500 micrograms is given about 1 hour before the start of chemotherapy.

For the prevention of **postoperative** nausea and vomiting, for up to 24 hours after surgery, a single dose of 75 micrograms is given intravenously over 10 seconds immediately before the induction of anaesthesia. Efficacy beyond 24 hours has not been shown.

Adverse Effects and Precautions

As for Ondansetron, p. 1873.2, although no dosage reduction is considered necessary in hepatic impairment. Diarrhoea, fatigue, and abdominal pain may also occur. Patients with a history of constipation or signs of subacute intestinal obstruction should be monitored if given palonosetron.

Effects on the cardiovascular system. For a discussion of the effects of 5-HT_3 antagonists on the cardiovascular system, see under Ondansetron, p. 1873.3.

Effects on the nervous system. For mention of a seizure associated with palonosetron see under Ondansetron, p. 1874.1.

Interactions

As for Ondansetron, p. 1874.2.

Pharmacokinetics

Palonosetron is well absorbed after oral dosing, with an absolute bioavailability of about 97%. Peak plasma concentrations occur about 5 hours after an oral dose. Palonosetron has a volume of distribution of around 7 to 8 litres/kg; plasma protein binding is about 62%. About 50% of a dose is metabolised in the liver by cytochrome P450 isoenzymes (notably CYP2D6, but also CYP3A4 and CYP1A2). About 80% of a dose is recovered in the urine within 144 hours, as palonosetron and its metabolites. The mean terminal elimination half-life is reported to be about 40 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Austria***: Aloxi; ***Belg.***: Aloxi; ***Braz.***: Onicit; ***Chile***: Onicit; ***China***: Jiouting (吉欧停); Zhiruo (止若); ***Cz.***: Aloxi; ***Denm.***: Aloxi; ***Ger.***: Aloxi; ***Gr.***: Aloxi; ***Hung.***: Aloxi; ***India***: Palnox; Palonew; Palzen; ***Indon.***: Paloxi; ***Irl.***: Aloxi; ***Israel***: Paloxi; ***Ital.***: Aloxi; ***Jpn***: Aloxi; ***Mex.***: Onicit; ***Neth.***: Aloxi; ***Norw.***: Aloxi; ***Pol.***: Aloxi; ***Port.***: Aloxi; ***S.Afr.***: Onicit; ***Singapore***: Aloxi; ***Spain***: Aloxi; ***Swed.***: Aloxi; ***Switz.***: Aloxi; ***Thai.***: Aloxi; ***Turk.***: Aloxi; ***UK***: Aloxi; ***USA***: Aloxi; ***Venez.***: Onicit.

Pantoprazole *(BAN, USAN, rINN)*

BY-1023; Pantopratsoli; Pantoprazol; Pantoprazolum; SKF-96022; Пантопразол.

5-Difluoromethoxybenzimidazol-2-yl 3,4-dimethoxy-2-pyridylmethyl sulphoxide.

$C_{16}H_{15}F_2N_3O_4S$=383.4

CAS — 102625-70-7.

ATC — A02BC02.

ATC Vet — QA02BC02.

UNII — D8TST4O562.

Pantoprazole Sodium *(BANM, USAN, rINNM)*

Natrii Pantoprazolum; Pantoprazol sódico; Pantoprazole Sodique; Pantoprazolum natricum; Натрий Пантопразол.

Pantoprazole sodium sesquihydrate.

$C_{16}H_{14}F_2N_3NaO_4S$,1½H_2O=432.4

CAS — 138786-67-1 (anhydrous pantoprazole sodium); 164579-32-2 (pantoprazole sodium sesquihydrate).

ATC — A02BC02.

ATC Vet — QA02BC02.

UNII — 6871619Q5X.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Ph. Eur. 8: (Pantoprazole Sodium Sesquihydrate). A white or almost white powder. Freely soluble in water and in alcohol; practically insoluble in hexane. Protect from light.

USP 36: (Pantoprazole Sodium). A white to off-white powder. Freely soluble in water, in dehydrated alcohol, and in methyl alcohol; practically insoluble in dichloromethane and in hexane. Protect from light.

Stability. A suspension of pantoprazole 2 mg/mL in sterile water and sodium bicarbonate was deemed to be physically and chemically stable[1] in amber polyethylene terephthalate bottles for 62 days at 2 degrees to 8 degrees.

1. Dentinger PJ, *et al.* Stability of pantoprazole in an extemporaneously compounded oral liquid. *Am J Health-Syst Pharm* 2002; 59: 953–6.

Uses and Administration

Pantoprazole is a proton pump inhibitor with actions and uses similar to those of omeprazole (p. 1867.2). It is given as the sodium salt but doses are expressed in terms of the base. Pantoprazole sodium 11.28 mg is equivalent to about 10 mg of pantoprazole.

In the treatment of **gastro-oesophageal reflux disease** (p. 1807.2), the usual oral dose is 20 to 40 mg once daily, which may be increased up to 80 mg daily. Treatment is usually given for 4 weeks, increased to 8 weeks if necessary; in the USA, up to 16 weeks of therapy is permitted for healing of erosive oesophagitis. For maintenance therapy, treatment can be continued with 20 to 40 mg daily. Alternatively, for recurring symptoms, an on-demand regimen of 20 mg daily may be given.

The usual dose for the treatment of **peptic ulcer disease** (p. 1813.2) is 40 mg once daily, increased up to 80 mg daily if needed. Treatment is usually given for 2 to 4 weeks for duodenal ulceration, or 4 to 8 weeks for benign gastric ulceration. For the eradication of *Helicobacter pylori* pantoprazole may be combined with two antibacterials in a 1-week **triple therapy** regimen. Effective regimens include pantoprazole 40 mg twice daily combined with clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily, or combined with clarithromycin 250 mg twice daily and metronidazole 400 mg twice daily.

Patients who require prophylaxis for **NSAID-associated ulceration** may take 20 mg daily.

In the treatment of pathological hypersecretory states such as the **Zollinger-Ellison syndrome** (p. 1814.3), the initial dose is 80 mg daily in a single dose or 2 divided doses, adjusted as required; up to 240 mg daily has been used. Daily doses greater than 80 mg should be given in 2 divided doses.

PARENTERAL DOSAGE.

Pantoprazole may also be given intravenously, as the sodium salt, over 2 to 15 minutes, either as a slow injection or a short-term infusion. For peptic ulceration or gastro-oesophageal reflux disease, the recommended dose is 40 mg

daily. A dose of 80 mg once or twice daily may be used for Zollinger-Ellison syndrome; up to 240 mg daily may be given in divided doses. Patients should be switched to oral therapy as soon as possible.

For use in children, see below. Doses of pantoprazole may need to be reduced in patients with hepatic impairment (see below).

The magnesium salt and *S*-isomer of pantoprazole have also been used.

Reviews.

5. Lehmann FS, Beglinger C. Role of pantoprazole in the treatment of gastro-oesophageal reflux disease. *Expert Opin Pharmacother* 2005; 6: 93–104.

Administration. Bioequivalence has been shown for pantoprazole granules (*Protonix, Wyeth*) given *orally* mixed with either apple juice or apple sauce, or when mixed with apple juice and given through a size 16 French nasogastric tube.[1]

The safety and tolerability profiles of *intravenous* pantoprazole given in 10 mL of sodium chloride 0.9% over 2 minutes were similar to those given over 15 minutes in 100 mL.[2]

A study[3] comparing two different infusion regimens of adjunctive pantoprazole for peptic ulcer bleeding found that clinical outcomes were similar if an intravenous bolus injection of pantoprazole 80 mg was followed by either a continuous intravenous infusion of 192 mg daily (given at 8 mg/hour which is usual practice), or 160 mg daily (given as 40 mg every 6 hours), both for 3 days.

2. Micalizzi M, *et al.* Comparative tolerability of 2-and 15-minute intravenous infusions of pantoprazole. *Am J Health-Syst Pharm* 2007; 64: 1822–6.
3. Hsu Y-C, *et al.* A randomized controlled trial comparing two different dosages of infusional pantoprazole in peptic ulcer bleeding. *Br J Clin Pharmacol* 2010; 69: 245–51.

Administration in children. Pantoprazole is licensed in the USA for oral use in children from 5 years of age with gastro-oesophageal reflux disease. Children weighing 15 kg up to 40 kg are given 20 mg once daily, and those weighing 40 kg and over are given 40 mg once daily, for up to 8 weeks for erosive oesophagitis.

For findings from a review regarding the efficacy and safety of proton pump inhibitors in infants, children, and adolescents, see Administration in Children, under Omeprazole, p. 1867.3.

Administration in hepatic impairment. Dosage of pantoprazole may need to be reduced in severe hepatic impairment. UK licensed product information recommends a maximum dose of 20 mg daily orally or intravenously; however, US licensed product information suggests that doses up to 40 mg daily can be used. Doses above 40 mg daily have not been studied in patients with hepatic impairment. Liver enzymes should be monitored during therapy, and pantoprazole should be stopped if elevations occur.

Administration in renal impairment. Most studies have not found the pharmacokinetics of pantoprazole to be altered in patients with renal impairment[1] and licensed product information in the UK and USA generally does not recommend dosage adjustment in this group; however some UK sources, including the *BNF*, suggest that a maximum oral dose of 40 mg daily should be observed.

1. Cheer SM, *et al.* Pantoprazole: an update of its pharmacological properties and therapeutic use in the management of acid-related disorders. *Drugs* 2003; 63: 101–132.

Adverse Effects and Precautions

As for Omeprazole, p. 1868.1. Dosage may need to be reduced in severe hepatic impairment; liver function should be monitored regularly, and therapy stopped if liver enzymes are elevated.

Incidence of adverse effects. In a postmarketing surveillance study of the 6-month period after the launch of pantoprazole in England (UK), the adverse effects reported most frequently were diarrhoea, nausea, and headache. Other effects included malaise or lassitude, rash, other gastrointestinal disturbances, myalgia, and oedema.[1]

1. Wilton LV, *et al.* The pharmacovigilance of pantoprazole: the results of postmarketing surveillance on 11 541 patients in England. *Drug Safety* 2003; 26: 121–32.

Effects on the blood. For a report of thrombocytopenia with pantoprazole, see under Omeprazole, p. 1868.2.

Effects on electrolytes. For mention of a fall in blood-electrolytes during treatment with proton pump inhibitors including pantoprazole, see Omeprazole, p. 1868.3.

Effects on the kidneys. For reports of interstitial nephritis associated with pantoprazole see p. 1869.1.

Effects on the skin. For mention of skin reactions to pantoprazole, see p. 1869.2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies pantoprazole as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Interactions

As for Omeprazole, p. 1870.3.

For reference to a lack of effect of pantoprazole on diazepam, see Gastrointestinal Drugs, p. 1069.3, and for a lack of effect on theophylline, see p. 1236.1. Licensed product information states that there are reports of increased prothrombin time in patients taking pantoprazole and warfarin, but for reports suggesting a lack of effect on warfarin, see p. 1534.1. For a report of severe generalised myalgia and bone pain attributed to the use of methotrexate with pantoprazole, see Gastrointestinal Drugs, p. 828.1. Proton pump inhibitors, including pantoprazole, may affect exposure to mycophenolate, see p. 1965.1.

Pharmacokinetics

Pantoprazole is rapidly absorbed and peak plasma-pantoprazole concentrations occur about 2 to 2.5 hours after an oral dose. The oral bioavailability is about 77% with the enteric-coated tablet formulation, and does not vary after single or multiple doses. Pantoprazole is about 98% bound to plasma proteins. It is extensively metabolised in the liver, primarily by the cytochrome P450 isoenzyme CYP2C19, to desmethylpantoprazole; small amounts are also metabolised by CYP3A4, CYP2D6, and CYP2C9. Metabolites are excreted mainly (about 80%) in the urine, with the remainder being excreted in faeces via the bile. The terminal elimination half-life is about 1 hour, and is prolonged in hepatic impairment; the half-life in patients with cirrhosis was 3 to 6 hours. Although the elimination half-life has been reported to be 3.5 to 10 hours in slow metabolisers (see also Metabolism under Omeprazole, p. 1871.2), minimal accumulation occurs with once-daily dosing.

Bioavailability. A suspension of pantoprazole in sodium bicarbonate solution was rapidly absorbed, and peak plasma concentrations were comparable to that of the tablet. However, bioavailability of the suspension was about 25% lower than that of the tablet; the amount of sodium bicarbonate used may affect the bioavailability.[1]

Pentaerythritol

Pentaeritritol; Tetramethylolmethane; Пентаэритритол.

2,2-Bis(hydroxymethyl)propane-1,3-diol.

$C_5H_{12}O_4$=136.1

CAS — 115-77-5.

ATC Vet — QA06AD14.

UNII — SU420W1S6N.

Profile

Pentaerythritol is an osmotic laxative used in the treatment of constipation (p. 1804.3) in oral doses of 5 to 15 g daily.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Fr.*: Auxitrans.

Peppermint Leaf

Black Mint; Borsosmentalevél; Hoja de Menta; Hortelã-Pimenta; List máty peprné; Liść mięty pieprzowej; Menta piperita, hoja de; Menth. Pip.; Mentha Piperita; Menthae Piperitae Folium; Menthe Poivrée; Menthe poivrée, feuille de; Pepparmyntblad; Peppermint; Pfefferminzblätter; Piparmintunlehti; Pipirmėčių lapai; White Mint; Листья Мяты Перечной.

ATC Herb — HA03AW5039 (Mentha x piperita: leaf).

UNII — A389O33LX6.

Pharmacopoeias. In *Eur.* (see p. vii), which also includes the dry extract. Also in *USNF.*

Ph. Eur. 8: (Peppermint Leaf). The whole or cut dried leaves of *Mentha X piperita*, containing not less than 1.2% v/w of essential oil if whole, or not less than 0.9% v/w if cut. It has a characteristic and penetrating odour and a characteristic aromatic taste. Protect from light.

USNF 31: (Peppermint). The dried leaf and flowering top of *Mentha piperita* (Labiatae). It has an aromatic, characteristic odour and a pungent taste, and produces a cooling sensation in the mouth.

Peppermint Oil

Aceite esencial de menta; Borsosmentaolaj; Essence de Menthe, Poivrée; Essência de Hortelã-Pimenta; Menta piperita, aceite esencial de; Menthae Piperitae Aetheroleum; Menthae Piperitae Etheroleum; Menthe poivrée, huile essentielle de; Minzöl; Nane Yağı; Ol. Menth. Pip.; Olejek miętowy; Oleum Menthae Piperitae; Pepparmyntolja; Pfefferminzöl; Piparminttuöljy; Pipirmėčių eterinis aliejus; Silice máty pepmé; Масло Мяты Перечной.

CAS — 8006-90-4.

ATC Herb — HD04AW5002 (Mentha x piperita: essential oil); HA03AW5038 (Mentha x piperita: essential oil).

UNII — AV092KU4JH.

Pharmacopoeias. In *Eur.* (see p. vii). Also in *USNF.*

Ph. Eur. 8: (Peppermint Oil). It is obtained by steam distillation from the fresh overground parts of the flowering plant of *Mentha X piperita*. It contains 30.0 to 55.0% menthol, 14.0 to 32.0% menthone, and 2.8 to 10.0% menthyl acetate, 3.5 to 8.0% 1,8-cineole, 1.5 to 10.0% isomenthone, 1.0 to 8.0% menthofuran, 1.0 to 3.5% limonene, not more than 3.0% pulegone, and not more than 1.0% carvone; the ratio of 1,8-cineole content to limonene content is not less than two.

It is a colourless, pale yellow, or pale greenish-yellow liquid with a characteristic odour and taste followed by a sensation of cold. Miscible with alcohol and with dichloromethane. Store in well-filled, airtight containers at a temperature not exceeding 25 degrees.

USNF 31: (Peppermint Oil). The volatile oil distilled with steam from the fresh overground parts of the flowering plant *Mentha piperita* (Labiatae), rectified by distillation, and neither partially nor wholly dementholised. It yields not less than 5% of esters calculated as menthyl acetate and not less than 50% of total menthol, free and as esters.

It is a colourless or pale yellow liquid with a strong, penetrating, characteristic odour and a pungent taste, followed by a sensation of cold when air is drawn into the mouth. Soluble 1 in 3 of alcohol (70%) with not more than slight opalescence. Store in airtight containers at a temperature not exceeding 40 degrees.

Storage. The Pharmaceutical Society of Great Britain's Department of Pharmaceutical Sciences found that PVC bottles softened and distorted fairly rapidly in the presence of peppermint oil, which should not be stored or dispensed in such bottles.[1]

1. Department of Pharmaceutical Sciences of the Pharmaceutical Society of Great Britain. Plastic medicine bottles of rigid PVC. *Pharm J* 1973; 210: 100.

Uses and Administration

Peppermint oil is an aromatic carminative that relaxes gastrointestinal smooth muscle and relieves flatulence and colic. Enteric-coated capsules containing peppermint oil are used for the relief of symptoms of the irritable bowel syndrome or gastrointestinal spasm secondary to other disorders. Usual oral doses are 0.2 mL three times daily, (increased to 0.4 mL three times daily if necessary) for up to 2 to 3 months. The capsules should be taken before food and swallowed whole, not chewed.

Peppermint oil is used as a flavour and with other volatile agents in preparations for respiratory-tract disorders. It is also used in aromatherapy.

Peppermint leaf, the source of the oil, has also been used for its carminative and flavouring properties.

Gastrointestinal disorders. Menthol (p. 2553.2), the major constituent of peppermint oil, has properties similar to those of calcium-channel blockers on smooth muscle such as that in the human gut.[1] *Reviews*[2,3] of the use of peppermint oil in irritable bowel syndrome (p. 1810.3) concluded that there was some evidence of its benefit.

The relaxant effect of peppermint oil on the gastrointestinal tract has been used to reduce spasm during endoscopy by giving solubilised peppermint oil directly into the lumen, through the accessory channel of the endoscope. It has been described as effective during colonoscopy[4] and may be more effective than intramuscular hyoscine butylbromide during upper gastrointestinal endoscopy.[5] Addition of peppermint oil to barium enema has also been tried and appears to reduce spasm[6,7] and the need for intravenous antispasmodics.[6]

2. Pittler MH, Ernst E. Peppermint oil for irritable bowel syndrome: a critical review and meta-analysis. *Am J Gastroenterol* 1998; 93: 1131–5.
3. Grigoleit H-G, Grigoleit P. Peppermint oil in irritable bowel syndrome. *Phytomedicine* 2005; 12: 601–6.
4. Asao T, *et al.* An easy method for the intraluminal administration of peppermint oil before colonoscopy and its effectiveness in reducing colonic spasm. *Gastrointest Endosc* 2001; 53: 172–7.
5. Hiki N, *et al.* Peppermint oil reduces gastric spasm during upper endoscopy: a randomized, double-blind, double-dummy controlled trial. *Gastrointest Endosc* 2003; 57: 475–82.
6. Sparks MJW, *et al.* Does peppermint oil relieve spasm during barium enema? *Br J Radiol* 1995; 68: 841–3.
7. Asao T, *et al.* Spasmolytic effect of peppermint oil in barium during double-contrast barium enema compared with Buscopan. *Clin Radiol* 2003; 58: 301–5.

Sore nipples. There is some evidence[1] that topical application of peppermint water after each feed may help prevent nipple cracks and soreness in breast-feeding mothers.

1. Sayyah Melli M, *et al.* Effect of peppermint water on prevention of nipple cracks in lactating primiparous women: a randomized controlled trial. *Int Breastfeed J* 2007; 2: 7.

Adverse Effects and Precautions

Peppermint oil can be irritant and may rarely cause hypersensitivity reactions. Reported reactions include erythematous skin rash, headache, bradycardia, muscle tremor, and ataxia. Heartburn has also been reported.

Effects on the cardiovascular system. Idiopathic atrial fibrillation occurred in 2 patients addicted to 'peppermints'. Normal rhythm was restored when peppermint-sucking ceased.[1]

1. Thomas JG. Peppermint fibrillation. *Lancet* 1962; i: 222.

Hypersensitivity. Exacerbation of asthma, with wheezing and dyspnoea, was associated with the use of paste-based toothpastes containing peppermint or wintergreen as a flavouring.[1]

1. Spurlock BW, Dailey TM. Shortness of (fresh) breath—toothpaste-induced bronchospasm. *N Engl J Med* 1990; 323: 1845–6.

Interactions

Adverse effects may be more likely if peppermint oil is taken with alcohol. Enteric-coated capsules containing peppermint oil should not be taken immediately after food or with antacids. There is some evidence that peppermint oil can inhibit the cytochrome P450 isoenzyme CYP3A4, and may affect the clearance of drugs whose metabolism is mediated by this enzyme.

Phenolphthalein *(BAN, rINN)*

Dihydroxyphthalophenone; Fenolftalein; Fenolftaleína; Fenolftaleinas; Fenoliftaleiini; Fenoloftaleína; Phénolphtaléine; Phenolphtaleinum; Phenolphthaleinum; Фенолфталеин.

3,3-Bis(4-hydroxyphenyl)phthalide.

$C_{20}H_{14}O_4$=318.3

CAS — 77-09-8.

ATC — A06AB04.

ATC Vet — QA06AB04.

UNII — 6QK969R2IF.

Pharmacopoeias. In *Chin.* and *Eur.* (see p. vii).

Ph. Eur. 8: (Phenolphthalein). A white or almost white powder. Practically insoluble in water; soluble in alcohol. Protect from light.

Uses and Administration

Phenolphthalein is a diphenylmethane stimulant laxative that has been used for the treatment of constipation (p. 1804.3) and for bowel evacuation before investigational procedures or surgery. It has been withdrawn in many countries because of concern over its carcinogenic potential after reports of tumours in *rodents*.

It has been given in pills or tablets, and as an emulsion with liquid paraffin. Yellow phenolphthalein, an impure form, has been used similarly.

Adverse Effects and Precautions

As for Bisacodyl, p. 1821.2. Hypersensitivity reactions, usually as skin rashes or eruptions, have occurred with phenolphthalein. Phenolphthalein may cause pink discoloration of alkaline urine.

Tumours have occurred in *rats* and *mice* given very high doses of phenolphthalein; there does not appear to be evidence of carcinogenicity in humans, but phenolphthalein-containing products have been withdrawn in many countries because of concerns about long-term safety.

Effects on the skin. Reports of skin reactions associated with phenolphthalein include fixed drug eruptions,[1,2] erythema multiforme reactions,[1,3] and toxic epidermal necrolysis.[4,5]

1. Baer RL, Harris H. Types of cutaneous reactions to drugs. *JAMA* 1967; 202: 710–13.
2. Savin JA. Current causes of fixed drug eruptions. *Br J Dermatol* 1970; 83: 546–9.
3. Shelley WB, *et al.* Demonstration of intercellular immunofluorescence and epidermal hysteresis in bullous fixed drug eruption due to phenolphthalein. *Br J Dermatol* 1972; 86: 118–25.
4. Kar PK, *et al.* Toxic epidermal necrolysis in a patient induced by phenolphthalein. *J Indian Med Assoc* 1986; 84: 189–93.
5. Artymowicz RJ, *et al.* Phenolphthalein-induced toxic epidermal necrolysis. *Ann Pharmacother* 1997; 31: 1157–9.

Overdosage. The most likely consequence of phenolphthalein overdosage is excessive purgation, which may require fluid and electrolyte replacement. However, a possible association with acute pancreatitis occurred in a 34-year-old man who inadvertently ingested phenolphthalein 2 g. There was complete recovery with no sequelae from the pancreatitis.[1] Widespread organ failure with disseminated intravascular coagulation, massive liver damage, pulmonary oedema, renal failure, and myocardial damage in a second patient[2] were attributed to self-poisoning with an unknown quantity of phenolphthalein-containing laxative, although the diagnosis was problematic. The patient died despite intensive support.

1. Lambrianides AL, Rosin RD. Acute pancreatitis complicating excessive intake of phenolphthalein. *Postgrad Med J* 1984; 60: 491–2.
2. Sidhu PS, *et al.* Fatal phenolphthalein poisoning with fulminant hepatic failure and disseminated intravascular coagulation. *Hum Toxicol* 1989; 8: 381–4.

Pharmacokinetics

Up to 15% of phenolphthalein given orally is subsequently excreted in the urine. Enterohepatic circulation occurs and the glucuronide is excreted in the bile. Elimination may take several days.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Fructines; *India*: Jaglax; *Israel*: Easylax; *S.Afr.*: Brooklax†; Dr Mackenzies Veinoids†; Laxador†; Laxene†; SB Strong-Lax†; Super-Tabs†; Surge†; *Thai.*: Phenolax; Regulim†; *Turk.*: Alin; Laksafenol.

Piperidolate Hydrochloride *(BANM, rINNM)*

Hidrocloruro de piperidolato; Pipéridolate, Chlorhydrate de; Piperidolati Hydrochloridum; Piperidolato, hidrocloruro de; Пиперидолата гидрохлорид.

1-Ethyl-3-piperidyl diphenylacetate hydrochloride.

$C_{21}H_{25}NO_2$,HCl=359.9

CAS — 82-98-4 (piperidolate); 129-77-1 (piperidolate hydrochloride).

ATC — A03AA30.

ATC Vet — QA03AA30.

UNII — 57UA660ILV.

Profile

Piperidolate hydrochloride is a tertiary amine antimuscarinic with effects similar to those of atropine (p. 1312.1). It has been given in the symptomatic treatment of smooth muscle spasm associated with gastrointestinal disorders.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Dactiran; *Mex.*: Dactil OB.

Multi-ingredient Preparations. *Braz.*: Dactil OB.

Pipethanate Ethobromide *(rINNM)*

Ethylpipethaniate Bromide; Etobromuro de pipetanato; Piperilate Ethobromide; Pipetanato, etobromuro de; Pipéthanate, Ethobromure de; Pipethanati Ethobromidum; Пипетаната этобромид.

1-(2-Benziloyloxyethyl)-1-ethylpiperidinium bromide.

$C_{23}H_{30}BrNO_3$=448.4

CAS — 4546-39-8 (pipethanate); 23182-46-9 (pipethanate ethobromide).

Profile

Pipethanate ethobromide is an antimuscarinic with actions similar to those of atropine (p. 1312.1). It has been used in the symptomatic treatment of visceral spasms in oral doses of up to 160 mg daily in divided doses. Pipethanate ethobromide has been given intramuscularly or intravenously in doses of 10 to 20 mg daily; it has also been given rectally.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Chile*: Nospasmin; *Ital.*: Spasmodil; *Venez.*: Flespan.

Pirenzepine Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de pirenzepina; LS-519 (pirenzepine); LS-519-Cl2; Pirentsepiinidihydrokloridimonohydraatti; Pirenzepina, hidrocloruro de; Pirenzepin-dihidrokloridmonohidrát; Pirenzepin-dihydrochlorid monohydrát; Pirenzepindihydrokloridmonohydrat; Pirenzépine, Chlorhydrate de; Pirenzépine (dichlorhydrate de) monohydraté; Pirenzepini dihydrochloridum monohydricum; Pirenzepini Hydrochloridum; Pirenzepino dihidrochloridas monohidratas; Пирензепина гидрохлорид.

5,11-Dihydro-11-(4-methylpiperazin-1-ylacetyl)pyrido[2,3-*b*][1,4]benzodiazepin-6-one dihydrochloride monohydrate.

$C_{19}H_{21}N_5O_2$,2HCl,H_2O=442.3

CAS — 28797-61-7 (pirenzepine); 29868-97-1 (pirenzepine hydrochloride).

ATC — A02BX03.

ATC Vet — QA02BX03.

UNII — 10YM403FLS.

Pharmacopoeias. In *Eur.* (see p. vii) and *Jpn.*

Ph. Eur. 8: (Pirenzepine Dihydrochloride Monohydrate; Pirenzepine Hydrochloride BP 2014). A white or yellowish crystalline powder. Freely soluble in water; very slightly soluble in dehydrated alcohol; practically insoluble in dichloromethane; slightly soluble in methyl alcohol. A 10% solution in water has a pH of 1.0 to 2.0. Protect from light.

Uses and Administration

Pirenzepine is a selective M_1 tertiary amine antimuscarinic that displays a preferential action on the gastric mucosa thus causing a reduction in the secretion of gastric acid; it also reduces the secretion of pepsin. At therapeutic doses it has few other antimuscarinic actions.

Pirenzepine hydrochloride has been used in the management of peptic ulcer disease (p. 1813.2) in a usual oral dose of 50 mg two or three times daily for 4 to 6 weeks. It has also been given by slow intravenous or intramuscular injection in a dose of 10 mg every 12 hours.

Myopia. Pirenzepine ophthalmic gel has been investigated[1-4] in children for its potential in slowing the progression of myopia. In a study[3] involving 353 children with myopia, pirenzepine 2% gel given once or twice daily into the lower eyelid for 1 year was associated with reduced progression: at 12 months myopia had progressed by a mean of 0.7 and 0.47 dioptres in children assigned to once and twice daily dosage respectively, compared with 0.84 dioptres in those given placebo. The gel was generally well tolerated, the most frequent adverse effects being development of papillae or follicles, or abnormalities of accommodation such as mydriasis or cycloplegia. Of 55 patients who failed to complete the study, 31 did so as a result of adverse effects.

1. Bartlett JD, *et al.* A tolerability study of pirenzepine ophthalmic gel in myopic children. *J Ocul Pharmacol Ther* 2003; 19: 271–9.
2. Siatkowski RM, *et al.* US Pirenzepine Study Group. Safety and efficacy of 2% pirenzepine ophthalmic gel in children with myopia: a 1-year, multicenter, double-masked, placebo-controlled parallel study. *Arch Ophthalmol* 2004; 122: 1667–74.
3. Tan DTH, *et al.* Asian Pirenzepine Study Group. One-year multicenter, double-masked, placebo-controlled, parallel safety and efficacy study of 2% pirenzepine ophthalmic gel in children with myopia. *Ophthalmology* 2005; 112: 84–91.
4. Siatkowski RM, *et al.* U.S. Pirenzepine Study Group. Two-year multicenter, randomized, double-masked, placebo-controlled, parallel safety and efficacy study of 2% pirenzepine ophthalmic gel in children with myopia. *J AAPOS* 2008; 12: 332–9.

Adverse Effects and Precautions

Antimuscarinic adverse effects such as dry mouth and blurred vision have been reported but are less common with pirenzepine than with atropine (see p. 1312.1). Pirenzepine should be used with caution in patients with renal impairment, particularly those with end-stage renal failure.

Effects on the blood. Thrombocytopenia in one patient and agranulocytosis in another was probably associated with the use of pirenzepine.[1]

1. Stricker BHC, *et al.* Blood disorders associated with pirenzepine. *BMJ* 1986; 293: 1074.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

Pharmacokinetics

Pirenzepine is absorbed from the gastrointestinal tract but the bioavailability is reported to be only about 20 to 30%, and is decreased to about 10 to 20% when taken with food. Very little pirenzepine is metabolised. About 10% of an oral dose is excreted unchanged in the urine, the remainder being excreted in the faeces.

Pirenzepine has an elimination half-life of about 12 hours and is about 12% bound to plasma proteins. Diffusion across the blood-brain barrier is poor and only minimal amounts are present in breast milk.

Renal impairment. The renal clearance and total plasma clearance of pirenzepine may be significantly reduced in patients with renal impairment,[1,2] with clearance decreasing proportionately with the degree of renal impairment. The half-life of pirenzepine is increased with reported values ranging from 14 to 20 hours.[1-3] Plasma concentrations of pirenzepine may be reduced by up to about 50% during haemodialysis.[2,3]

1. Krakamp B, *et al.* Steady-state intravenous pharmacokinetics of pirenzepine in patients with hepatic insufficiency and combined renal- and hepatic insufficiency. *Eur J Clin Pharmacol* 1989; 36: 71–3.

3. MacGregor T, *et al.* Oral pharmacokinetics of pirenzepine in patients with chronic renal insufficiency, failure, and maintenance haemodialysis. *Eur J Clin Pharmacol* 1990; 38: 405–6.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Austria*: Gastrozepin; *Ger.*: Gastrozepin; *Gr.*: Gastrozepin; Threptin; *Jpn*: Gastrozepin; *Rus.*: Gastrozepin (Гастроцепин); *Thai.*: Cevanil; *Ukr.*: Gastrozepin (Гастроцепин).

Platyphylline Acid Tartrate

Platyphylline Bitartrate; Platyphyllini Hydrotartras; Платифиллина битартрат.

1,2-Dihydro-12-hydroxysenecionan-11,16-dione hydrogen tartrate.

$C_{18}H_{27}NO_5$,$C_4H_6O_6$=487.5

CAS — 480-78-4 (platyphylline); 1257-59-6 (platyphylline acid tartrate).

UNII — 6SXK0Y9D98.

Profile

Platyphylline acid tartrate is a pyrrolizidine alkaloid occurring in *Senecio platyphyllus* and other *Senecio* spp. It has antimuscarinic actions and has been given alone or with papaverine in antispasmodic preparations.

Plaunotol (rINN)

CS-684; Plaunotolum; Плаунотол.
(2*Z*,6*E*)-2-[(3*E*)-4,8-Dimethyl-3,7-nonadienyl]-6-methyl-2,6-octadiene-1,8-diol.
$C_{20}H_{34}O_2$=306.5
CAS — 64218-02-6.
UNII — MV715X4634.

Profile

Plaunotol is a complex aliphatic alcohol extracted from the Thai medicinal plant plau-noi (*Croton sublyratus* (Euphorbiaceae)). It is reported to possess cytoprotective properties and has been used in the treatment of gastritis and peptic ulcer disease in an oral dose of 80 mg three times daily.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Kelnac; *Thai.*: Kelnac†.

Polaprezinc (rINN)

Polaprézinc; Polaprezincum; Z-103; Zinc-L-carnosine; Полапрезинк.
catena-Poly[zinc-μ-[β-alanyl-L-histidinato(2-)-*N*,*N*$^{\pi}$,*O*:*N*$^{\tau}$]].
$(C_9H_{12}N_4O_3Zn)_n$
CAS — 107667-60-7.

Profile

Polaprezinc is a cytoprotective agent used in the treatment of peptic ulcer disease and as a zinc supplement. It is under investigation as a treatment for taste disorders.

Poldine Metilsulfate (BAN, pINN)

IS-499; McN-R-726-47; Metilsulfato de poldina; Poldina, metilsulfato de; Poldine Methosulphate; Poldine Methylsulfate (USAN); Poldine Methylsulphate; Poldine, Métilsulfate de; Poldini Metilsulfas; Польдина Метилсульфат.
(*RS*)-2-Benziloyloxymethyl-1,1-dimethylpyrrolidinium methylsulphate.
$C_{21}H_{26}NO_3.CH_3O_4S$=451.5
CAS — 596-50-9 (poldine); 545-80-2 (poldine metilsulfate).
ATC — A03AB11.
ATC Vet — QA03AB11.
UNII — 564C0W9848.

Pharmacopoeias. In *Br.*

BP 2014: (Poldine Metilsulfate). A white odourless or almost odourless crystalline powder. Freely soluble in water; soluble in alcohol; slightly soluble in chloroform. A 1% solution in water has a pH of 5.0 to 7.0.

Profile

Poldine metilsulfate is a quaternary ammonium antimuscarinic with peripheral actions similar to those of atropine (p. 1312.1) and has been used in the management of gastrointestinal disorders, including peptic ulcer disease.

Preparations

Pharmacopoeial Preparations
BP 2014: Poldine Tablets.

Polycarbophil (BAN, rINN)

Policarbofilo; Polycarbophile; Polycarbophilum; Поликарбофил.
CAS — 9003-97-8.
UNII — W25LM17A4W.

Pharmacopoeias. In *US.*

USP 36: (Polycarbophil). It is polyacrylic acid cross-linked with divinyl glycol. White to creamy-white granules, with a characteristic, ester-like odour. Swells in water to a range of volumes, depending primarily on the pH. Insoluble in water, in common organic solvents, and in dilute acids and alkalis. A 1% mixture in water has a pH of not more than 4.0. Store in airtight containers.

Polycarbophil Calcium (BANM, rINNM)

AHR-3260B; Calcii Polycarbophilum; Calcium Polycarbophil (USAN); HSR-237; Policarbofilo cálcico; Polycarbophile Calcique; Polycarbophilum Calcii; Polykarbofiilikalsium; Polykarbofilkalcium; Polykarbophilum Calcicum; WI-140; Кальций Поликарбофил.
CAS — 126040-58-2.
ATC — A06AC08.
ATC Vet — QA06AC08.
UNII — 8F049NKY49.

Pharmacopoeias. In *US.*

USP 36: (Calcium Polycarbophil). A white to creamy-white powder. Insoluble in water, in common organic solvents, and in dilute acids and alkalis. It loses not more than 10% of its weight on drying and contains not less than 18% and not more than 22% of calcium, calculated on the dried basis. Store in airtight containers.

Uses and Administration

Polycarbophil calcium has similar properties to ispaghula (p. 1849.2) and is used as a bulk laxative and for adjusting faecal consistency. After ingestion calcium ions are replaced by hydrogen ions from gastric acid and the resultant polycarbophil exerts a hydrophilic effect in the intestines.

It is given orally in a usual dose equivalent to 1 g of polycarbophil up to four times daily, as necessary. Doses should be taken with at least 250 mL of water.

Polycarbophil is used topically as a vaginal moisturiser and as an ocular lubricant.

References.

2. Toskes PP, *et al.* Calcium polycarbophil compared with placebo in irritable bowel syndrome. *Aliment Pharmacol Ther* 1993; 7: 87–92.
3. Chiba T, *et al.* Colonic transit, bowel movements, stool form, and abdominal pain in irritable bowel syndrome by treatments with calcium polycarbophil. *Hepatogastroenterology* 2005; 52: 1416–20.

Adverse Effects and Precautions

As for Ispaghula, p. 1849.2. Polycarbophil calcium releases calcium ions in the gastrointestinal tract and should be avoided by patients who must restrict their calcium intake.

There is a risk of intestinal or oesophageal obstruction and faecal impaction, especially if such bulk laxatives are swallowed dry. Therefore, they should always be taken with sufficient fluid and should not be taken immediately before going to bed. They should be avoided by patients who have difficulty swallowing.

Interactions

The calcium component of polycarbophil calcium may produce interactions typical of calcium salts (p. 1786.1), such as reducing the absorption of tetracyclines from the gastrointestinal tract; it should not be taken within 2 hours of the antibacterial. Polycarbophil calcium has also been reported to decrease the absorption of ciprofloxacin and mycophenolate mofetil.

Preparations

Proprietary Preparations (details are given in Volume B)

Potassium Acid Tartrate

E336; Hydrogenvinan draselný; Kalii Hydrogenotartras; Kaliovandenilio tartratas; Kalium Hydrotartaricum; Káliumhidrogén-tartarát; Kaliumhydrogentartrat; Kaliumvätetartrat; Kaliumvetytartraatti; Potassium Bitartrate (USAN); Potassium Hydrogen Tartrate; Potassium, hydrogénotartrate de; Potasu wodorowinian; Purified Cream of Tartar; Tartarus Depuratus; Tartrato ácido de potasio; Weinstein; Кислый Виннокислый Калий.
$C_4H_5KO_6$=188.2
CAS — 868-14-4.
ATC — A12BA03.
ATC Vet — QA12BA03.
UNII — NPT6P8P3UU.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Potassium Hydrogen Tartrate). A white or almost white, crystalline powder or colourless crystals. Slightly soluble in water; practically insoluble in alcohol. It dissolves in dilute solutions of mineral acids and alkali hydroxides.

USP 36: (Potassium Bitartrate). Colourless or slightly opaque crystals or a white, crystalline powder. Slightly soluble in water; soluble in boiling water; very slightly soluble in alcohol. A saturated solution is acid to litmus. Store in airtight containers.

Profile

Potassium acid tartrate is given with sodium bicarbonate as a suppository for the treatment of constipation (p. 1804.3) and for bowel evacuation before investigational procedures or surgery. Carbon dioxide gas is produced in the rectum, which stimulates defaecation within 5 to 30 minutes.

Potassium acid tartrate is used as a food additive and pharmaceutical aid.

Potassium acid tartrate has been used as an ingredient of preparations for potassium supplementation, although other potassium salts are usually preferred. For the general properties of potassium salts, see p. 1793.1.

Preparations

Proprietary Preparations (details are given in Volume B)

Multi-ingredient Preparations. *Austria*: Lecicarbon; *Ital.*: Potassion; *Jpn*: Circanetten; *Mon.*: Eductyl; *Swed.*: Relaxit; *Thai.*: Circanetten; *USA*: Ceo-Two.

Homoeopathic Preparations. *Ger.*: Phonix Silybum spag; Phonix Urtica-Arsenicum spag.

Pharmacopoeial Preparations
BPC 1968: Effervescent Potassium Tablets.

Potassium Sodium Tartrate

E337; Kalii Natrii Tartras; Kalio-natrio tartratas; Kalium Natrium Tartaricum; Kálium-nátrium-tartarát; Kaliumnatriumtartraatti; Kaliumnatriumtartrat; Potassium et de sodium, tartrate de; Rochelle Salt; Seignette Salt; Sodii et Potassii Tartras; Sodium Potassium Tartrate; Sodu potasu winian; Tartarus Natronatus; Tartrato de potasio y de sodio; Vinan draselno-sodný; Виннокислый Калий-натрий.
$C_4H_4KNaO_6.4H_2O$=282.2
CAS — 304-59-6 (anhydrous sodium potassium tartrate); 6381-59-5 (sodium potassium tartrate tetrahydrate); 6100-16-9 (sodium potassium tartrate tetrahydrate).
UNII — QH257BPV3J.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Potassium Sodium Tartrate Tetrahydrate). A white or almost white, crystalline powder or colourless transparent crystals. Very soluble in water; practically insoluble in alcohol.

USP 36: (Potassium Sodium Tartrate). Colourless crystals or a white, crystalline powder, with a cooling, saline taste. It effloresces slightly in warm dry air, the crystals often being coated with a white powder. Soluble 1 in 1 of water; practically insoluble in alcohol. Store in airtight containers.

Profile

Potassium sodium tartrate has been used as an osmotic laxative (p. 1804.1). It is also used as a food additive.

For the general properties of potassium salts, see p. 1793.1, and of sodium salts, see p. 1795.1.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Gr.*: Trigolax; Trilax.

Multi-ingredient Preparations. *Austria*: Laxalpin†; *Denm.*: Samarin; *Fr.*: Romarene†; *Hung.*: Samarin; *Philipp.*: Castoria; *Swed.*: Samarin; Samarin; *UK*: Jaaps Health Salt.

Prifinium Bromide (rINN)

Bromuro de prifinio; PDB; Prifinii Bromidum; Prifinio, bromuro de; Prifinium, Bromure de; Pyrodifenium Bromide; Прифиния Бромид.
3-Diphenylmethylene-1,1-diethyl-2-methylpyrrolidinium bromide.
$C_{22}H_{28}BrN$=386.4
CAS — 10236-81-4 (prifinium); 4630-95-9 (prifinium bromide).
ATC — A03AB18.
ATC Vet — QA03AB18.
UNII — 3B7O9ZC520.

Profile

Prifinium bromide is a quaternary ammonium antimuscarinic with peripheral effects similar to those of atropine (p. 1312.1). It is structurally related to diphemanil metilsulfate (p. 2494.3).

Prifinium bromide is used to relieve smooth muscle spasms. Oral doses usually range from 90 to 180 mg daily in 3 divided doses. It can also be given by subcutaneous, intramuscular, or intravenous injection in a dose of 15 mg given 2 to 4 times daily. It has been given rectally.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Ital.*: Riabal; *Jpn*: Padrin; *Mex.*: Anespas†; *Rus.*: Riabal (Рябал); *Ukr.*: Riabal (Рябал).

Proglumide *(BAN, USAN, rINN)*

CR-242; Proglumida; Proglumidum; W-5219; Xylamide; Проглумид.

(±)-4-Benzamido-*N*,*N*-dipropylglutaramic acid.

$C_{18}H_{26}N_2O_4$=334.4

CAS — 6620-60-6.

ATC — A02BX06.

ATC Vet — QA02BX06.

UNII — EPL8W5565D.

Pharmacopoeias. In *Chin.* and *Jpn.*

Profile

Proglumide is a cholecystokinin antagonist with an inhibitory effect on gastric secretion. It has been given orally or by intramuscular or intravenous injection in the treatment of peptic ulcer disease (p. 1813.2) and other gastrointestinal disorders.

Propantheline Bromide *(BAN, rINN)*

Bromuro de propantelina; Propantelinibromidi; Propantelin Brom ür; Propantelina, bromuro de; Propantelinbromid; Propantelin-bromid; Propantelino bromidas; Propanthelin-bromid; Propanthéline, Bromure de; Propanthelini bromidum; Propanthelinii Bromidum; Propanthelinium-bromid; Пропантелина Бромид.

Di-isopropylmethyl[2-(xanthen-9-ylcarbonyloxy)ethyl] ammonium bromide.

$C_{23}H_{30}BrNO_3$=448.4

CAS — 298-50-0 (propantheline); 50-34-0 (propantheline bromide).

ATC — A03AB05.

ATC Vet — QA03AB05.

UNII — UX9Z118X9F.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Propantheline Bromide). A white or yellowish-white, slightly hygroscopic powder. Very soluble in water, in alcohol, and in dichloromethane. Store in airtight containers.

USP 36: (Propantheline Bromide). White or practically white, odourless, crystals. Very soluble in water, in alcohol, and in chloroform; practically insoluble in ether and in benzene.

Uses and Administration

Propantheline bromide is a quaternary ammonium antimuscarinic with peripheral effects similar to those of atropine (p. 1312.1). It has been used as an antispasmodic (p. 1803.3) for conditions associated with gastrointestinal spasm, and as an adjunct in the treatment of peptic ulcer disease (p. 1813.2). The usual initial oral dose is 15 mg three times daily, 30 to 60 minutes before meals, and 30 mg at bedtime; doses of up to 120 mg daily may be needed in some patients. In elderly patients, doses of 7.5 mg three times daily may be sufficient. For doses in children, see below.

Propantheline bromide has been used in the treatment of adult enuresis or urinary incontinence, and in hyperhidrosis (see below), in doses similar to those given above.

Administration in children. Propantheline bromide is used in children for the symptomatic relief of gastrointestinal smooth muscle spasm. The *BNPC* suggests children from 1 month to 12 years may be given an oral dose of 300 micrograms/kg (maximum 15 mg) three or four times daily, at least 1 hour before food. Older children may be given the adult dose, see above.

Hyperhidrosis. Some antimuscarinics, including propantheline, have been applied topically in the treatment of hyperhidrosis (p. 1685.1). Adverse effects of antimuscarinics given orally generally preclude their use by this route, although oral propantheline was used successfully to control excessive sweating in 2 patients with spinal cord injuries,[1] and it is sometimes used in palliative care to control night sweats. The *BNF* notes that propantheline may be used for gustatory sweating in patients with diabetic neuropathy.

1. **Canaday BR, Stanford RH.** Propantheline bromide in the management of hyperhidrosis associated with spinal cord injury. *Ann Pharmacother* 1995; 29: 489–92.

Urinary incontinence. In the UK, guidelines issued by NICE suggest that propantheline should not be recommended for the treatment of urinary incontinence (p. 2349.2) or overactive bladder in women; other antimuscarinics are preferred.[1]

1. **NICE.** Urinary incontinence: the management of urinary incontinence in women (issued October 2006). Available at: http://www.nice.org.uk/nicemedia/pdf/CG40fullguideline.pdf (accessed 03/07/08)

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p. 1312.1 and p. 1312.2. Contact dermatitis has been reported after topical application of propantheline bromide.

Buccal and oesophageal ulceration. Severe buccal mucosal ulceration has been reported[1] in a 95-year-old woman as a result of retaining emepronium bromide tablets in her mouth, and recurred on giving propantheline bromide tablets.

1. **Buston GJ, *et al.*** Anticholinergic drugs, buccal ulceration and mucosal potential difference. *Postgrad Med J* 1978; 54: 331–2.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p. 1312.3).

Pharmacokinetics

Propantheline bromide is incompletely absorbed from the gastrointestinal tract and bioavailability is reported to be reduced by food; it is extensively metabolised in the small intestine before absorption. The plasma elimination half-life after a single oral dose has been reported to be about 2 to 3 hours. Propantheline is eliminated mainly in the urine as metabolites and less than 10% as unchanged drug. The duration of action is about 6 hours.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Austral.*: Pro-Banthine; *Canad.*: Pro-Banthine†; *Denm.*: Ercoril; *Gr.*: Pro-Banthine; *Hong Kong*: Panbro†; *India*: Pro-Banthine; *Indon.*: Pro-Banthine†; *Irl.*: Pro-Banthine; *NZ*: Pro-Banthine; *S.Afr.*: Pro-Banthine; *Singapore*: Panbro; Pro-Banthine; *UK*: Pro-Banthine; *USA*: Pro-Banthine†.

Prucalopride *(BAN, USAN, rINN)*

Prucaloprida; Prucalopridum; R-093877 (prucalopride or prucalopride hydrochloride); Прукалоприд.

4-Amino-5-chloro-2,3-dihydro-*N*-[1-(3-methoxypropyl)-4-piperidyl]-7-benzofurancarboxamide.

$C_{18}H_{26}ClN_3O_3$=367.9

CAS — 179474-81-8.

ATC — A06AX05.

ATC Vet — QA06AX05.

UNII — 0A09IUW5TP.

Prucalopride Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de prucalopride; Prucalopride, Chlorhydrate de; Prucalopridi Hydrochloridum; R-093877 (prucalopride or prucalopride hydrochloride); R-93877; Прукалоприда Гидрохлорид.

4-Amino-5-chloro-2,3-dihydro-*N*-[1-(3-methoxypropyl)-4-piperidyl]-7-benzofurancarboxamide hydrochloride.

$C_{18}H_{26}ClN_3O_3$,HCl=404.3

CAS — 179474-80-7.

ATC — A06AX05.

ATC Vet — QA06AX05.

UNII — M8IYX9Z79V.

Prucalopride Succinate *(BAN, USAN, rINNM)*

Prucalopride, Succinate de; Prucalopridi Succinas; R-108512; Succinato de prucalopride; Прукалоприда Сукцинат.

4-Amino-5-chloro-2,3-dihydro-*N*-[1-(3-methoxypropyl)-4-piperidyl]-7-benzofurancarboxamide succinate (1:1).

$C_{18}H_{26}ClN_3O_3$,$C_4H_6O_4$=486.0

CAS — 179474-85-2.

ATC — A06AX05.

ATC Vet — QA06AX05.

UNII — 4V2G75E1CK.

Uses and Administration

Prucalopride is a selective 5-HT$_4$ receptor agonist with prokinetic properties that is used in the treatment of women with chronic constipation where laxatives have failed to provide relief; efficacy in men has not been established. It is given as the succinate but doses are expressed as the base prucalopride succinate 1.32 mg is equivalent to about 1 mg of prucalopride. The usual oral dose in women aged over 18 years is prucalopride 2 mg once daily. In elderly patients aged over 65 years, an initial dose of 1 mg once daily can be given, increased up to 2 mg once daily if required. For doses of prucalopride in hepatic and renal impairment, see below.

Administration in hepatic impairment. Due to a lack of data in patients with hepatic impairment, licensed product information for prucalopride recommends a reduced oral dose of 1 mg once daily in those with severe impairment (defined as Child-Pugh class C); no dose adjustments are considered necessary for those with mild to moderate impairment.

Administration in renal impairment. The main route of excretion of prucalopride is renal. Although no dosage adjustments are considered necessary in patients with mild to moderate renal impairment, licensed product information recommends a reduced oral dose of prucalopride 1 mg once daily in those with severe impairment (defined as a glomerular filtration rate of less than 30 mL/minute per 1.73 m^2). Prucalopride is not recommended for those on dialysis.

Adverse Effects and Precautions

The most frequently reported adverse effects during prucalopride treatment are headache and gastrointestinal disturbances such as abdominal pain, nausea, or diarrhoea. These usually occur at the start of therapy and resolve within a few days of continued treatment. Other common adverse effects include dizziness, pollakiuria (the frequent passing of small quantities of urine), and fatigue. Tremors, palpitations, anorexia, and fever have also been reported.

Due to a lack of study data, prucalopride should be used cautiously in patients with significant unstable comorbidities, particularly arrhythmias or ischaemic heart disease. It is not recommended in those with intestinal perforation or obstruction.

Interactions

In vitro data indicate that prucalopride does not affect the cytochrome P450 isoenzyme system, but may be a weak substrate of P-glycoprotein; ketoconazole, a potent P-glycoprotein inhibitor, increases exposure to prucalopride by about 40%, although this is not considered clinically relevant.

Pharmacokinetics

Oral prucalopride is rapidly absorbed and peak plasma concentrations occur after 2 to 3 hours. Absolute bioavailability is greater than 90%, and is not affected by food. Prucalopride is extensively distributed with low plasma-protein binding (about 30%). Metabolism in the liver is very slow and the main metabolite accounts for less than 4% of an excreted dose. Renal excretion of unchanged drug involves both passive filtration and active secretion. About 60% of a dose is excreted as unchanged drug via the urine and at least 6% via the faeces. Terminal elimination half-life is about 1 day. Prucalopride is excreted into breast milk.

Rabeprazole Sodium

(BANM, USAN, rINNM)

E-3810; LY-307640; Natrii Rabeprazolum; Rabeprazol sódico; Rabeprazol Sodyum; Rabéprazole Sodique; Rabeprazolum natricum; Sodium Pariprazole; Натрий Рабепразол.

2-({[4-(3-Methoxypropoxy)-3-methyl-2-pyridyl]methyl}sulfinyl)-1*H*-benzimidazole sodium.

$C_{18}H_{20}N_3NaO_3S$=381.4

CAS — 117976-89-3 (rabeprazole); 117976-90-6 (rabeprazole sodium).

ATC — A02BC04.

ATC Vet — QA02BC04.

UNII — 3L36P16U4R.

Uses and Administration

Rabeprazole is a proton pump inhibitor with actions and uses similar to those of omeprazole (p. 1867.2). It is given orally as rabeprazole sodium in the form of enteric-coated tablets. It is normally taken in the morning.

In the treatment of severe (erosive or ulcerative) **gastro-oesophageal reflux disease** (p. 1807.2), the usual dose of rabeprazole sodium is 20 mg once daily for 4 to 8 weeks; in the USA, a further 8-week course is permitted for healing of erosive oesophagitis. Thereafter, maintenance therapy can be continued with 10 or 20 mg daily depending on the response. For symptomatic disease without erosive or ulcerative oesophagitis a dose of 10 or 20 mg may be given once daily for 4 weeks; in the USA, a further 4-week course is permitted. Once symptoms have resolved, a dose of 10 mg once daily may be given as necessary.

For the treatment of active **peptic ulcer disease** (p. 1813.2), 20 mg daily is given for 4 to 8 weeks for duodenal ulcer and 6 to 12 weeks for gastric ulcer. For the eradication of *Helicobacter pylori* rabeprazole sodium may be combined with two antibacterials in a 1-week **triple therapy** regimen. Effective regimens include 20 mg twice daily combined with clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily, or combined with clarithromycin 250 mg twice daily and metronidazole 400 mg twice daily.

For **Zollinger-Ellison syndrome** (p. 1814.3), the starting dose is 60 mg once daily, adjusted according to response. Doses up to 120 mg daily have been given; when the daily dose is more than 100 mg it should be given in 2 divided doses.

For doses in children, see below.

Dexrabeprazole, the dextrorotatory isomer of rabeprazole, and its sodium salt have also been used.

Reviews.

5. Pallotta S, *et al.* Rabeprazole: a second-generation proton pump inhibitor in the treatment of acid-related disease. *Expert Rev Gastroenterol Hepatol* 2008; 2: 509–22.
6. Dadabhai A, Friedenberg FK. Rabeprazole: a pharmacologic and clinical review for acid-related disorders. *Expert Opin Drug Safety* 2009; 8: 119–26.
7. Baldwin CM, Keam SJ. Rabeprazole: a review of its use in the management of gastric acid-related diseases in adults. *Drugs* 2009; 69: 1373–1401.

Administration in children. Rabeprazole sodium is licensed for use in children in the USA. For short-term treatment of gastro-oesophageal reflux disease, oral doses are given according to age and weight:

- 1 to 11 years and < 15 kg: 5 mg once daily, increased up to 10 mg once daily if needed, for up to 12 weeks
- 1 to 11 years and ≥ 15 kg: 10 mg once daily for up to 12 weeks
- 12 years and older: 20 mg once daily for up to 8 weeks

Adverse Effects and Precautions

As for Omeprazole, p. 1868.1.

Effects on the endocrine system. For cases of gynaecomastia associated with rabeprazole see Omeprazole, p. 1868.3.

Effects on the kidneys. For reports of interstitial nephritis associated with rabeprazole see p. 1869.1.

Effects on the nervous system. For a report of neuropsychiatric symptoms associated with rabeprazole, see p. 1869.2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies rabeprazole as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Interactions

As for Omeprazole (p. 1870.3) but because the cytochrome P450 isoenzyme system is a minor route of metabolism for rabeprazole, clinically significant interactions with diazepam, phenytoin, theophylline, or warfarin have not been found in healthy subjects.

Pharmacokinetics

Rabeprazole is rapidly absorbed and peak plasma concentrations occur about 3.5 hours after an oral dose. The oral bioavailability is about 52% with the enteric-coated tablet formulation, because of first-pass metabolism, and does not appear to vary after single or repeated doses. Rabeprazole is about 97% bound to plasma proteins. It is mainly metabolised via nonenzymatic reduction and, to a lesser extent, via the cytochrome P450 isoenzymes CYP2C19 and CYP3A4. Metabolites are excreted principally in the urine (about 90%) with the remainder in the faeces. The plasma half-life is about 1 to 2 hours, increased at least two to threefold in hepatic impairment, 1.6 times in CYP2C19 slow metabolisers (see also Metabolism under Omeprazole, p. 1871.2), and by 30% in the elderly.

Racecadotril *(BAN, rINN)*

Acetorphan; Racécadotril; Racecadotrilo; Racecadotrilum; Рацекадотрил.

(±)-*N*-(2-[(Acetylthio)methyl]-1-oxo-3-phenylpropyl)glycine phenylmethyl ester; *N*-[(*R,S*)-3-acetylthio-2-benzylpropanoyl]glycine benzyl ester; (±)-*N*-[α-(Mercaptomethyl)hydrocinnamoyl]glycine benzyl ester acetate.

$C_{23}H_{25}NO_4S$=385.5

CAS — 81110-73-8.

ATC — A07XA04.

ATC Vet — QA07XA04.

UNII — 76K53XP4TO.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Racecadotril). A white or almost white powder. Practically insoluble in water; freely soluble in methyl alcohol and in dichloromethane.

Profile

Racecadotril is an enkephalinase inhibitor that inhibits the breakdown of endogenous opioids, thus reducing intestinal secretions. It is given orally in doses of 100 mg three times daily before meals for up to 7 days for the symptomatic management of acute diarrhoea (p. 1805.2).

The *S*-form of racecadotril (sinorphan, ecadotril—see Natriuretic Peptides, p. 1444.1) has been investigated for hypertension and heart failure.

$C_{17}H_{17}N_3O.HCl$=315.8

CAS — 132036-88-5 (ramosetron); 132907-72-3 (ramosetron hydrochloride).

UNII — 9551LHD87E.

Profile

Ramosetron is a 5-HT_3 antagonist with general properties similar to those of ondansetron (p. 1872.1). Ramosetron hydrochloride is given for its antiemetic properties in the management of nausea and vomiting induced by cancer chemotherapy in a usual oral dose of 100 micrograms once daily. Alternatively, it may be given intravenously in a usual dose of 300 micrograms once daily; an additional dose of 300 micrograms may be given if needed, to a maximum daily dose of 600 micrograms. Ramosetron is also under

investigation in the management of diarrhoea-predominant irritable bowel syndrome.

Diarrhoea. Ramosetron has been tried with some success in a case of diabetic diarrhoea that had not responded to conventional antidiarrhoeals.[1]

Uses and Administration

Ranitidine is a histamine H_2-antagonist with actions and uses similar to those of cimetidine (p. 1827.2).

Ranitidine may be given orally or parenterally by the intravenous or intramuscular routes. Although most preparations contain ranitidine hydrochloride, strengths and doses are expressed in terms of the base. Ranitidine hydrochloride 111.6 mg is equivalent to about 100 mg of ranitidine. Doses of ranitidine may need to be adjusted in patients with renal impairment, and in children. For discussion of dosage in children and renal impairment, see below.

In the management of benign **gastric and duodenal ulceration** (p. 1813.2) a single daily oral dose of 300 mg at bedtime or 150 mg twice daily (in the morning and at bedtime) is given initially for at least 4 weeks. Up to 300 mg twice daily may be used if necessary. Where appropriate a maintenance dose of 150 mg daily may be given at bedtime. To treat ulcers associated with NSAID therapy, ranitidine 150 mg twice daily or 300 mg at bedtime may be given for 8 to 12 weeks; for duodenal ulcers, a higher dose of 300 mg twice daily for 4 weeks has also been used. (To *prevent* NSAID-associated ulcers, UK licensed product information recommends an oral dose of 150 mg twice daily given with NSAID treatment; although unlicensed, the *BNF* suggests a higher dose of 300 mg twice daily may be used.)

For duodenal ulcer associated with *Helicobacter pylori* infection, ranitidine in a usual oral dose of 300 mg once daily at bedtime or 150 mg twice daily may be given as part of triple therapy with amoxicillin 750 mg and metronidazole 500 mg, both given orally, three times daily, for 2 weeks. Therapy with ranitidine should then be continued for a further 2 weeks.

In **gastro-oesophageal reflux disease** (p. 1807.2) the oral dose is 150 mg twice daily or 300 mg at bedtime for up to 8 weeks or, if required, 12 weeks. This may be increased to 150 mg four times daily for up to 12 weeks in severe cases. In the maintenance of healing erosive oesophagitis, a dose of 150 mg twice daily may be used. In pathological hypersecretory conditions, such as the **Zollinger-Ellison syndrome**, (p. 1814.3) the initial oral dose is usually 150 mg twice or three times daily and may be increased if necessary; doses of up to 6 g daily have been used. Alternatively, an intravenous infusion may be given, initially at a rate of 1 mg/kg per hour; the rate may be increased by increments of 500 micrograms/kg per hour, beginning after 4 hours, if required. Intravenous doses up to 2.5 mg/kg per hour and infusion rates up to 220 mg/hour have been used.

For the management of patients at risk from **stress ulceration** of the upper gastrointestinal tract, parenteral therapy may be given as a slow intravenous injection of a 50-mg priming dose followed by a continuous intravenous infusion of 125 to 250 micrograms/kg per hour. Oral doses of 150 mg twice daily may be given once oral feeding is resumed.

In patients at risk of developing the **acid aspiration syndrome** (p. 1804.2) during general anaesthesia, an oral dose of 150 mg may be given 2 hours before the induction of anaesthesia and preferably also 150 mg the previous evening. Alternatively, a dose of 50 mg may be given by intramuscular or slow intravenous injection 45 to 60 minutes before the induction of anaesthesia. In obstetric patients at the start of labour, an oral dose of 150 mg may be given and may be repeated at intervals of 6 hours if required.

In patients with chronic episodic **dyspepsia** (p. 1806.3), a dose of 150 mg twice daily orally for up to 6 weeks may be given. For the short-term symptomatic relief of dyspepsia a dose of 75 mg, repeated if necessary up to a maximum of 4 doses daily, may be taken. Treatment should be restricted to a maximum of 2 weeks of continuous use at one time.

PARENTERAL DOSAGE.

The usual dose of ranitidine by intramuscular or intravenous injection is 50 mg, which may be repeated every 6 to 8 hours; the intravenous injection should be given slowly over not less than 2 minutes and should be diluted to contain 50 mg in 20 mL. For an intermittent intravenous infusion the recommended dose in the UK is 25 mg/hour given for 2 hours which may be repeated every 6 to 8 hours. A rate of 6.25 mg/hour has been suggested for continuous intravenous infusion although higher rates may be used for conditions such as Zollinger-Ellison syndrome or in patients at risk from stress ulceration (see above).

Administration in children. Ranitidine is used in children to heal duodenal and gastric ulcers and to prevent stress ulceration in critically ill patients. It is licensed in children, although indications, age ranges, and doses may vary from country to country. When given orally, ranitidine is licensed from ages 3 to 11 years and over 30 kg bodyweight in the UK, and from 1 month to 16 years in the USA.

In the treatment of duodenal and gastric ulcers, a usual oral dose of 4 to 8 mg/kg daily in 2 divided doses is given, to a maximum of 300 mg ranitidine daily, for 4 to 8 weeks. For maintenance US licensed product information recommends a dose of 2 to 4 mg/kg daily, to a maximum of 150 mg ranitidine daily.

In the treatment of gastro-oesophageal reflux disease, a usual oral dose of 5 to 10 mg/kg daily in 2 divided doses is given, to a maximum of 600 mg daily.

The *BNFC* suggests the same oral doses for 3 to 12 year olds as those licensed in the UK, but includes doses for younger children, for any indication:

- neonates: 2 mg/kg three times daily, although absorption can be unreliable, and a maximum dose of 3 mg/kg three times daily
- 1 to 6 months: 1 mg/kg three times daily; maximum 3 mg/kg three times daily
- 6 months to 3 years: 2 to 4 mg/kg twice daily

It also suggests adult doses for children aged 12 to 18 years, see Uses and Administration above.

Ranitidine may also be given intravenously to children when oral treatment is not possible. UK licensed product information recommends the following doses in children aged 6 months to 11 years:

Treatment of peptic ulcer and gastro-oesophageal reflux disease:

- initially 2 or 2.5 mg/kg (maximum 50 mg) as a slow intravenous injection over 10 minutes followed by intermittent infusion of 1.5 mg/kg every 6 to 8 hours *or*
- a loading dose of 450 micrograms/kg as a slow intravenous injection over at least 2 minutes followed by a continuous infusion of 150 micrograms/kg per hour

Prophylaxis of stress ulceration:

- 1 mg/kg (maximum 50 mg) as a slow intravenous injection over at least 2 minutes, every 6 to 8 hours *or*
- 125 to 250 micrograms/kg per hour as a continuous infusion

The *BNFC* also suggests intravenous doses for children according to age, for all indications:

- neonate: 0.5 to 1 mg/kg by slow intravenous injection every 6 to 8 hours
- 1 month to 18 years: 1 mg/kg (to a maximum of 50 mg) every 6 to 8 hours, either by slow intravenous injection or by intermittent infusion at a rate of 25 mg/hour

In the USA, ranitidine is given intravenously to treat children from 1 month to 16 years of age with duodenal ulcer. A dose of 2 to 4 mg/kg daily in 3 or 4 divided doses at 6 to 8 hourly intervals (maximum of 50 mg per dose) is given either by slow intravenous injection over 5 minutes, or by intermittent infusion over 20 minutes.

Administration in renal impairment. A study in patients with varying degrees of renal impairment[1] found that the mean terminal half-life of ranitidine was increased from 2.09 hours in subjects with normal renal function to between 4.23 and 8.45 hours in patients with renal impairment, the degree of prolongation being proportional to the degree of impairment as measured by glomerular filtration rate. As a result of these findings it was recommended that the dose of ranitidine should be halved in patients with a glomerular filtration rate of 20 mL/minute or less. Licensed product information therefore recommends that dosage of ranitidine be reduced in patients with severe renal impairment.

For patients with a creatinine clearance of less than 50 mL/minute, an *oral* dose of 150 mg daily at bedtime is recommended. This may be cautiously increased to 150 mg every 12 hours if needed and reduced back to 150 mg daily if maintenance treatment is required.

For *parenteral* use, licensed recommendations vary between countries. In the UK, individual doses may be reduced to 25 mg, while the frequency is adjusted in the USA to give a recommended usual dose of 50 mg every 18 to 24 hours, which may be cautiously increased to every 12 hours or more often if necessary.

Ranitidine 150 mg daily provided adequate serum concentrations without excessive accumulation in 20 patients undergoing regular haemodialysis.[2] The serum-ranitidine concentrations fell by about 50% during a 4-hour haemodialysis session but less than 3% of the dose was removed and supplemental doses after dialysis were considered unnecessary. Licensed product information in the UK and USA recommends that the timing of doses is adjusted so that they are given at the end of dialysis.

2. Comstock TJ, *et al.* Ranitidine accumulation in patients undergoing chronic hemodialysis. *J Clin Pharmacol* 1988; 28: 1081–5.

Cystic fibrosis. A comparative study involving 29 patients with cystic fibrosis (p. 177.2) found that ranitidine was more effective than cisapride in improving dyspeptic symptoms and gastric emptying and distension.[1] Antisecretory drugs are also used in this condition to decrease the inactivation of oral pancreatic enzyme therapy.

1. Cucchiara S, *et al.* Ultrasound measurement of gastric emptying time in patients with cystic fibrosis and effect of ranitidine on delayed gastric emptying. *J Pediatr* 1996; 128: 485–8.

Immunomodulation. Like cimetidine (see p. 1827.3), ranitidine has been proposed to have immunoregulatory effects. However, ranitidine 300 mg twice daily had no effect on absolute CD4 cell counts or plasma HIV RNA in patients with HIV infection in a placebo-controlled study.[1] Similarly, ranitidine had no significant benefit in patients with gastric cancer (see Malignant Neoplasms, p. 1828.1).

1. Bartlett JA, *et al.* A placebo-controlled trial of ranitidine in patients with early human immunodeficiency virus infection. *J Infect Dis* 1998; 177: 231–4.

Skin disorders. As with cimetidine (p. 1828.2), ranitidine has been tried in various skin disorders. Oral ranitidine 300 mg twice daily for up to 16 weeks has been reported to be of benefit as an adjuvant to local treatment with corticosteroids and a moisturising ointment in patients with *atopic dermatitis*.[1] There are reports of improvements in *psoriasis* after use of ranitidine,[2-4] although this is a field that is notoriously difficult to evaluate because of the chronic relapsing and remitting nature of the disease, and others have failed to show benefit.[5]

1. Veien NK, *et al.* Ranitidine treatment of hand eczema in patients with atopic dermatitis: a double-blind placebo-controlled trial. *J Am Acad Dermatol* 1995; 32: 1056–7.

3. Smith KC. Ranitidine useful in the management of psoriasis in a patient with acquired immunodeficiency syndrome. *Int J Dermatol* 1994; 33: 220–1.
4. Kristensen JK, *et al.* Systemic high-dose ranitidine in the treatment of psoriasis: an open prospective clinical trial. *Br J Dermatol* 1995; 133: 905–8.
5. Çetin L, *et al.* High-dose ranitidine is ineffective in the treatment of psoriasis. *Br J Dermatol* 1997; 137: 1021–2.

Adverse Effects

As for Cimetidine, p. 1828.3. Unlike cimetidine, ranitidine has little or no anti-androgenic effect, despite isolated reports of gynaecomastia and impotence.

General references.

1. Wormsley KG. Safety profile of ranitidine: a review. *Drugs* 1993; 46: 976–85.
2. Mills JG, *et al.* The safety of ranitidine in over a decade of use. *Aliment Pharmacol Ther* 1997; 11: 129–37.

Meningitis. A 30-year-old man developed aseptic meningitis on 3 occasions after use of ranitidine.[1] In each case symptoms resolved rapidly on withdrawal of the drug.

Precautions

As for Cimetidine, p. 1830.2.

Allergy testing. For mention of the effect of ranitidine on allergy testing, see Cimetidine, p. 1830.2.

Helicobacter pylori testing. For reference to the effect of ranitidine on the urea breath test for *Helicobacter pylori*, see p. 1830.2.

Hepatic impairment. For a report of increased resistance to H_2-antagonists in patients with liver cirrhosis, see Cimetidine, p. 1830.3.

Porphyria. Although licensed product information recommends that ranitidine should be avoided in patients with a history of acute porphyria, reports of porphyria associated with its use have been rare and inconclusive. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies ranitidine as probably not porphyrinogenic: it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pregnancy. For information on the use of H_2-antagonists during pregnancy, see Cimetidine, p. 1830.3.

Renal impairment. For evidence of reduced clearance of ranitidine in patients with renal impairment see Administration in Renal Impairment, p. 1882.3.

Interactions

Unlike cimetidine (p. 1830.3), ranitidine does not seem to affect cytochrome P450 isoenzymes to any great extent, and therefore is considered to have little effect on drugs metabolised by this route. However, like other H_2-antagonists, its effects on gastric pH may alter the absorption of drugs whose absorption is dependent on an acid gastric pH.

A review comparing the drug interactions of ranitidine with those of cimetidine.[1]

1. Smith SR, Kendall MJ. Ranitidine versus cimetidine: a comparison of their potential to cause clinically important drug interactions. *Clin Pharmacokinet* 1988; 15: 44–56.

Alcohol. Any interaction between H_2-antagonists and alcohol is generally thought unlikely to be clinically significant (see p. 1735.2).

Antacids. For discussion of the effect of antacids on the bioavailability of H_2-antagonists, see Cimetidine, p. 1831.1.

Cisapride. For mention of the effect of cisapride on the bioavailability of ranitidine, see Cimetidine, p. 1831.1.

Sucralfate. For information on the effect of sucralfate on the bioavailability of H_2-antagonists, see Cimetidine, p. 1831.1.

Pharmacokinetics

Ranitidine is readily absorbed from the gastrointestinal tract with peak concentrations in plasma occurring about 2 to 3 hours after oral doses. Food does not significantly impair absorption. The bioavailability of ranitidine after oral doses is about 50%. Ranitidine is rapidly absorbed after intramuscular injection, with peak plasma concentrations occurring in about 15 minutes. It is weakly bound, about 15%, to plasma proteins.

The elimination half-life is about 2 to 3 hours and is increased in renal impairment. A small proportion of ranitidine is metabolised in the liver to the *N*-oxide, the *S*-oxide, and desmethylranitidine; the *N*-oxide is the major metabolite but accounts for only about 4 to 6% of a dose. About 30% of an oral dose and 70% of an intravenous dose is excreted unchanged in the urine in 24 hours, primarily by active tubular secretion; there is some excretion in the faeces. Ranitidine crosses the placental barrier and is distributed into breast milk.

Distribution into breast milk. A study in a mother given multiple doses of ranitidine showed higher concentrations in breast milk than in serum; the minimum milk concentration occurred between 1 and 2 hours after a dose and the highest concentration was towards the end of the 12-hour dosing interval.[1] The amount that would be ingested by the infant could not be reliably estimated because of the variable milk to serum ratio.

1. Kearns GL, *et al.* Appearance of ranitidine in breast milk following multiple dosing. *Clin Pharm* 1985; 4: 322–4.

Enterohepatic recycling. Some individuals have a second peak in the plasma concentration of ranitidine, which could be due to enterohepatic recirculation. However, only 0.7 to 2.6% and 0.3 to 1.0% of a dose of ranitidine was excreted into the bile of 3 patients in 24 hours after 50 mg given intravenously or 300 mg given orally respectively, indicating that significant recirculation did not occur.[1]

1. Klotz U, Walker S. Biliary excretion of H_2-receptor antagonists. *Eur J Clin Pharmacol* 1990; 39: 91–2.

Neonates. Renal function is limited in the first month of life, and reduced clearance of ranitidine would be expected. Blood samples taken from 27 full-term neonates given a single intravenous dose of ranitidine 2.4 mg/kg revealed the following pharmacokinetic data: elimination half-life, 3.45 hours; total volume of distribution, 1.52 litres/kg; total plasma clearance, 5.02 mL/kg per minute.[1] None of the infants had renal or hepatic impairment. In another study[2] in 13 full-term neonates undergoing extracorporeal membrane oxygenation, the elimination half-life was increased to 6.61 hours after an intravenous dose of 2 mg/kg ranitidine. A sustained increase in gastric pH was seen with this dose, and the authors suggested that a dosage interval of 12 hours or longer may be sufficient for intermittent intravenous use in this population. Alternatively, a continuous infusion of ranitidine 2 mg/kg daily was recommended to maintain the initial increase in pH. See also Administration in Children, p. 1882.2.

Ranitidine Bismuth Citrate *(BAN, USAN)*

GR-122311X; Ranitidin Bizmut Sitrat; Ranitidin Bizmutreks; Ranitidina y bismuto, citrato de; Ranitidine Bismutrex; Ранитидин Висмут Цитрат.

N-[2-{[5-[(Dimethylamino)methyl]furfuryl]thio}-ethyl]-*N'*-methyl-2-nitro-1,1-ethenediamine, compound with bismuth (3+) citrate (1:1).

$C_{13}H_{22}N_4O_3S,C_6H_5BiO_7$=712.5

CAS — 128345-62-0.

ATC — A02BA07.

ATC Vet — QA02BA07.

UNII — 7AJ51I17KG.

Profile

Ranitidine bismuth citrate is a combination of ranitidine and a bismuth citrate complex, which dissociates in the stomach and releases ranitidine and bismuth; it therefore possesses both the actions of the bismuth compounds (p. 1822.2) and of ranitidine (p. 1882.1). It has been used in the management of peptic ulcer disease (p. 1813.2), and has

been given with antibacterials for the eradication of *Helicobacter pylori* infection and the prevention of relapse of peptic ulcer disease.

Blackening of the tongue and faeces is common with ranitidine bismuth citrate, and gastrointestinal disturbances, headache, mild anaemia, and altered liver enzyme values have been reported. Rarely, hypersensitivity reactions (including anaphylaxis), have occurred. It was not suitable for long-term or maintenance therapy because of the risk of bismuth accumulation.

Reviews.

2. Chiba N, *et al.* Ranitidine bismuth citrate. *Can J Gastroenterol* 2001; 15: 389–98.

Peptic ulcer disease. Although proton pump inhibitor-based *Helicobacter pylori* eradication regimens are more commonly used (see p. 1813.2), regimens containing ranitidine bismuth citrate have also been tried as alternatives with some success.[1]

Rebamipide *(rINN)*

Rebamipida; Rébamipide; Rebamipidum; Ребамипид.
(±)-α-(*p*-Chlorobenzamido)-1,2-dihydro-2-oxo-4-quinolinepropionic acid.
$C_{19}H_{15}ClN_2O_4$=370.8
CAS — 90098-04-7; 111911-87-6.

Profile

Rebamipide is stated to possess cytoprotective properties and is used in the treatment of peptic ulcer disease (p. 1813.2) and gastritis in usual oral doses of 100 mg three times daily. It has also been used rectally for the treatment of intestinal inflammation. Rebamipide eye drops are under investigation in the treatment of dry eye.

Rhubarb

Chinese Rhubarb; Korzeń rzewienia; Rabarbarų šaknys; Rabarbaro; Rabarberrot; Raparperinjuuri; Ravent; Rebarbaragyökértörzs; Reveňový kořen; Rhabarber; Rhabarberwurzel; Rhei Radix; Rhei Rhizoma; Rheum; Rhubarb Rhizome; Rhubarbe; Ruibarbo; Ревень Аптечный.
ATC Herb — HA06AB5015 (Rheum palmatum: root).
UNII — A47JP5ZG9M (Rheum officinale root).

Description. Indian rhubarb (Himalayan rhubarb) consists of the dried rhizome and roots of *Rheum emodi, R. webbianum,* or some other related species of *Rheum.*

Rhapontic rhubarb (Chinese rhapontica) consists of the dried rhizomes of *R. rhaponticum.* It may occur as an adulterant of rhubarb, and pharmacopoeias specify a test to confirm its absence. Garden rhubarb, of which the leafstalks are used as food, is derived from *R. rhaponticum.*

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *Jpn. Chin.* and *Jpn* also permit *Rheum tanguticum,* and *Jpn* also permits *R. coreanum.*

Ph. Eur. 8: (Rhubarb). The whole or cut, dried underground parts of *Rheum palmatum* or of *R. officinale* or of hybrids of these two species or of a mixture. The underground parts are often divided; the stem and most of the bark with the rootlets are removed. It contains not less than 2.2% of hydroxyanthracene derivatives, expressed as rhein ($C_{15}H_8O_6$ = 284.2), calculated with reference to the dried drug. Protect from light.

Uses and Administration

Rhubarb is an anthraquinone stimulant laxative used similarly to senna (p. 1885.2). It also exerts an astringent action due to the presence of gallic acid derivatives and tannins.

Homoeopathy

Rhubarb has been used in homoeopathic medicines under the following names: Rheum; Rhei radix; Rheum palmatum; Rheum officinale.

Adverse Effects and Precautions

As for Senna, p. 1885.3.

Roxatidine Acetate Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de acetato de roxatidina; Hoe-062 (roxatidine); Hoe-760; Pifatidine Hydrochloride; Roxatidina, hidrocloruro de acetato de; Roxatidine, Acétate Chlorhydrique de; Roxatidini Acetati Hydrochloridum; TZU-0460; Роксатидина Ацетат Гидрохлорид.
N-[3-[(α-Piperidino-*m*-tolyl)oxy]propyl]glycolamide acetate monohydrochloride.
$C_{17}H_{26}N_2O_3.C_2H_2O_2.HCl$=384.9
CAS — 78273-80-0 (roxatidine); 97900-88-4 (roxatidine hydrochloride); 78628-28-1 (roxatidine acetate); 93793-83-0 (roxatidine acetate hydrochloride).
ATC — A02BA06.
ATC Vet — QA02BA06.
UNII — 60426GOR1E.

Pharmacopoeias. In *Jpn.*

Stability. The stability of roxatidine acetate hydrochloride in parenteral nutrition solutions was influenced by storage temperature and amino acid content and composition.[1]

1. Oh J, *et al.* Stability of roxatidine acetate in parenteral nutrient solutions containing different amino acid formulations. *Am J Health-Syst Pharm* 2005; 62: 289–91.

Uses and Administration

Roxatidine acetate hydrochloride is an H_2-antagonist with actions and uses similar to those of cimetidine (p. 1827.2).

In the management of **peptic ulcer disease** the oral dose is 150 mg at bedtime or 75 mg twice daily for 4 to 6 weeks. Where appropriate a maintenance dose of 75 mg at bedtime may be given to prevent the recurrence of ulcers. In **gastro-oesophageal reflux disease** the recommended dose is 150 mg at bedtime or 75 mg twice daily for 6 to 8 weeks. Gastritis has been managed with 75 mg once daily in the evening, and a dose of 75 mg twice daily has been used for **Zollinger-Ellison** syndrome.

When used as a **pre-anaesthetic** medication, a dose of roxatidine acetate hydrochloride 75 mg is given 1 hour before anaesthesia by slow intravenous injection. Alternatively, an oral dose of 75 mg is given in the evening on the day before surgery and repeated 2 hours before the induction of anaesthesia; alternatively a single dose of 150 mg may be given the night before surgery.

Roxatidine acetate hydrochloride may also be given intravenously for the treatment of **upper gastrointestinal tract haemorrhage** in a dose of 75 mg twice daily by slow intravenous injection or by intravenous infusion.

For dosage in renal impairment, see below.

Reviews.

1. Murdoch D: Roxatidine acetate: a review of its pharmacodynamic and pharmacokinetic properties, and its therapeutic potential in peptic ulcer disease and related disorders. *Drugs* 1991; 42: 240–60.

Administration in renal impairment. The dosage of roxatidine acetate hydrochloride should be reduced in patients with renal impairment. Suggested oral doses for peptic ulcer disease or gastro-oesophageal reflux disease are based on creatinine clearance (CC):

- CC 20 to 50 mL/minute: 75 mg once daily
- CC less than 20 mL/minute: 75 mg every 2 days

However, results in 6 patients with chronic renal failure and CC less than 20 mL/minute indicated that giving the recommended dose of roxatidine acetate hydrochloride, 75 mg every other day, was inadequate to maintain gastric pH above 4 for more than 6 hours. Subsequent study in 8 patients showed that a dose of 75 mg daily was well tolerated and effective.[1]

For prophylaxis of peptic ulcers, the following oral doses have been suggested based on CC:

- CC 20 to 50 mL/minute: 75 mg every 2 days
- CC less than 20 mL/minute: 75 mg twice weekly

1. Gladziwa U, *et al.* Pharmacokinetics and pharmacodynamics of roxatidine in patients with renal insufficiency. *Br J Clin Pharmacol* 1995; 39: 161–7.

Adverse Effects and Precautions

As for Cimetidine, p. 1828.3. Unlike cimetidine, roxatidine has little or no anti-androgenic effect, despite isolated reports of reductions in libido.

Interactions

Unlike cimetidine (p. 1830.3) roxatidine does not appear to affect cytochrome P450 isoenzymes, and therefore is considered to have little effect on drugs metabolised by this route. However, like other H_2-antagonists its effects on gastric pH may alter the absorption of drugs whose absorption is dependent on an acid gastric pH.

Pharmacokinetics

Roxatidine acetate hydrochloride is rapidly and almost completely absorbed from the gastrointestinal tract with peak concentrations in plasma occurring about 1 to 4 hours after oral doses. It is rapidly hydrolysed to the active desacetyl metabolite, roxatidine, by esterases in the liver, small intestine, and serum.

Over 90% of a dose is excreted in the urine as roxatidine and other metabolites. The elimination half-life of roxatidine is about 4 to 6 hours and is prolonged in renal impairment.

Roxatidine crosses the placenta and small amounts have been reported to be distributed into breast milk.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Gr.*: Roxane; *India*: Rotane; *Ital.*: Gastralgin; Neo H2: Roxit; *Jpn*: Altat; *Spain*: Zarocs†.

Senna

Alexandrian senna (senna pods, Alexandrian); Alexandrian senna (senna leaf); Alexandrian senna pods; Alexandrian senna, senna leaf; Alexandrian senna, senna pods; Alexandrian senna leaf;

inflammatory bowel disease. Prolonged use should generally be avoided.

Although anthraquinone derivatives may be distributed into breast milk the concentration achieved after usual maternal dosage is thought to be insufficient to affect the nursing infant (see also below).

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving senna, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*: 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 21/11/06)

Colonic perforation. There were early reports of colonic perforation with faecal peritonitis,[1,2] in one case fatal,[1] after use of a senna preparation containing total sennosides 142 mg for bowel preparation before barium enema. In 1985, the strength of the UK preparation was halved to contain 72 mg of total sennosides; it was subsequently withdrawn, although a similar preparation, at the higher strength, remains available in some countries. To reduce the risk of colonic perforation, patients with suspected stricture, inflammatory bowel disease, or impending obstruction should not receive a bowel stimulant.[2]

2. Cave-Bigley D. Faecal peritonitis after laxative preparation for barium enema. *BMJ* 1982; 284: 740.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies senna as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pregnancy. A retrospective case-control study involving 22 843 infants with congenital abnormalities and 38 151 healthy matched controls (of whom 506 and 937 respectively had mothers who had taken senna for constipation during pregnancy) found no association between abnormality and maternal use of senna.[1]

1. Ács N, *et al.* Senna treatment in pregnant women and congenital abnormalities in their offspring—a population-based case-control study. *Reprod Toxicol* 2009; 28: 100–4.

Pharmacokinetics

There is some absorption of anthraquinone laxatives after oral doses. Absorbed anthraquinones are metabolised in the liver. Unabsorbed senna is hydrolysed in the colon by bacteria to release the active free anthraquinones. Anthraquinones are excreted in urine and faeces and distributed into breast milk.

Simeticone *(BAN, rINN)*

Activated Dimethicone; Activated Dimethylpolysiloxane; Activated Dimeticone; Antifoam A; Antifoam AF; Simethicone (USAN); Simeticon; Simeticona; Siméticone; Simeticonum; Simetikon; Simetikonas; Simetikoni; Szimetikon; Симетикон.

CAS — 8050-81-5.

NOTE. Do not confuse with Dimeticone (p. 2209.3).

Compounded preparations of simeticone may be represented by the following names:

- Co-simalcite *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of simeticone and hydrotalcite respectively.

Pharmacopoeias. In *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Simeticone). It is prepared by incorporation of 4 to 7% silica into poly(dimethylsiloxane) with a degree of polymerisation between 20 and 400. It contains 90.5 to 99.0% of poly(dimethylsiloxane). It is a greyish-white, opalescent, viscous liquid. Practically insoluble in water and in methyl alcohol; very slightly soluble to practically insoluble in dehydrated alcohol; partly miscible with dichloromethane, with ethyl acetate, with methyl ethyl ketone, and with toluene.

USP 36: (Simeticone). A mixture of fully methylated linear siloxane polymers containing repeating units of the formula $[-(CH_3)_2SiO-]_n$ stabilised with trimethylsiloxy end-blocking units of the formula $[(CH_3)_3SiO-]$, and silicon dioxide. It contains not less than 90.5% and not more than 99% of polydimethylsiloxane and not less than 4% and not more than 7% of silicon dioxide. A translucent, grey, viscous fluid. Insoluble in water, in alcohol, and in dehydrated alcohol; the liquid phase is soluble 1 in 10 of chloroform, of ether, and of benzene, leaving a residue of silicon dioxide. Store in airtight containers.

Profile

Simeticone is a mixture of liquid dimeticones containing finely divided silicon dioxide to enhance the defoaming properties of the silicone. It lowers surface tension and when given orally causes bubbles of gas in the gastrointestinal tract to coalesce, thus aiding their dispersion.

Simeticone is used for the relief of flatulence and abdominal discomfort due to excess gastrointestinal gas in disorders such as dyspepsia (p. 1806.3) and gastro-oesophageal reflux disease (p. 1807.2). Doses of 100 to 250 mg three or four times daily have been given. For many gastrointestinal disorders, it is given with an antacid.

For doses in children, see below

Simeticone is also used as a defoaming agent in radiography or endoscopy of the gastrointestinal tract.

Administration in children. Simeticone can be given orally to infants to relieve symptoms of colic (see Gastrointestinal Spasm, p. 1807.1); 20 to 40 mg is given before feeds.

Gastrointestinal disorders. A brief review of the use of simeticone for gastrointestinal symptoms concluded that although it was commonly prescribed with an antacid, there was no good evidence that this provided additional benefit. When used alone simeticone probably helped to relieve minor postoperative and postprandial symptoms and was a useful aid in upper gastrointestinal endoscopy.[1] However, some considered there was no convincing evidence that simeticone, alone or with antacids, was effective for the treatment of eructation, flatulence, or other signs or symptoms of excess gastrointestinal gas.[2]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies silicones when used for gastrointestinal disorders as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

Smectites

Смектиты.
ATC — A07BC05 (diosmectite).
ATC Vet — QA07BC05 (diosmectite).

Profile

Smectites are natural mineral clays composed mainly of aluminium silicates and include aluminium magnesium silicate (p. 2168.2), bentonite (p. 2170.3), and Fuller's earth (p. 1553.2). They have adsorbent properties and some, such as dioctahedral smectite (diosmectite), have been used in the management of diarrhoea. They are also used as pharmaceutical excipients and in industry.

Azulene Sodium Sulfonate; Azulene Soluble; Guaiazulene Sodium Sulphonate; Guaiazulene Soluble; Gualénate de Sodium; Gualenate Sodium; Gualenato de sodio; Natrii Gualenas; Натрия гуаленат.
Sodium 5-isopropyl-3,8-dimethyl-1-azulene sulfonate.
$C_{15}H_{17}NaO_3S$=300.3
CAS — 6223-35-4.
UNII — 19WSH095WP.

Profile

Sodium gualenate is the 3-sodium sulfonate salt of guaiazulene, a substance isolated from chamomile oil. Sodium gualenate has anti-inflammatory effects and is used orally, usually with glutamine, to treat peptic ulcer disease and gastritis. Sodium gualenate hydrate is used as an oral rinse or gargle to treat mouth and throat disorders including pharyngitis, tonsillitis, stomatitis, gingivitis, and glossitis. Sodium gualenate hydrate eye drops are used to treat eye disorders including conjunctivitis, keratitis, blepharitis, and scleritis.

ATC — A06AB08.
ATC Vet — QA06AB08.
UNII — LR57574HN8.

Pharmacopoeias. In *Eur.* (see p. vii) and *Jpn.*

Ph. Eur. 8: (Sodium Picosulfate). A white or almost white, crystalline powder. Freely soluble in water; slightly soluble in alcohol.

Uses and Administration

Sodium picosulfate is a stimulant laxative related to bisacodyl (p. 1821.1) used for the treatment of constipation (p. 1804.3) and for evacuation of the colon before investigational procedures or surgery. When taken orally it is metabolised by colonic bacteria to an active form that stimulates bowel movements. It is usually effective within 6 to 12 hours although when used with magnesium citrate for bowel evacuation an effect may be seen within 3 hours.

For constipation it is given as a single oral dose of 5 to 10 mg, usually at bedtime. (For doses in children see below.)

For bowel evacuation, a dose of sodium picosulfate 10 mg with magnesium citrate (p. 1857.1) is given in the morning and again in the afternoon of the day before examination.

References.
1. Hoy SM, *et al.* Sodium picosulfate/magnesium citrate: a review of its use as a colorectal cleanser. *Drugs* 2009; 69: 123–36.

Administration in children. In the UK, the following oral doses of sodium picosulfate have been recommended for children in the treatment of constipation; the dose is usually given at night:

- 1 month to 4 years: 250 micrograms/kg (maximum 5 mg)
- 4 to 10 years: 2.5 to 5 mg
- over 10 years: 5 to 10 mg

Most UK licensed product information gives similar doses to those above for bowel cleansing. Alternatively, some recommend that children may be given the following doses of a sachet containing sodium picosulfate 10 mg (with magnesium citrate):

- 1 to 2 years: ¼ sachet in the morning and ¼ sachet in the afternoon
- 2 to 4 years: ½ sachet in the morning and ½ sachet in the afternoon
- 4 to 9 years: 1 sachet in the morning and ½ sachet in the afternoon
- over 9 years: 1 sachet in the morning and 1 sachet in the afternoon

Adverse Effects and Precautions

As for Bisacodyl, p. 1821.2.

Bowel evacuation. The National Patient Safety Agency in the UK released a warning[1] about oral bowel cleansing preparations after reports of fatalities and harm from the improper use of these products. Particularly highlighted were electrolyte imbalance or dehydration due to inappropriate fluid intake or use of these products despite a clinical contra-indication. In Australia, the Adverse Drug Reactions Advisory Committee has also warned that low volume sodium picosulfate solutions may cause marked dehydration, hyponatraemia, other electrolyte abnormalities, and associated complications. Patients at particular risk include infants, the elderly, the frail, and those with congestive heart failure or with renal impairment.[2] It may be appropriate to carry out bowel preparation in hospital for those at risk.[1,3,4] Accumulation of magnesium may occur in patients with severe renal impairment given some magnesium-containing preparations, and an alternative should be used. Bowel cleansing preparations may affect the absorption of oral medicines given at the same time. Caution is also advised when these preparations are given with other medicines that affect fluid and electrolyte balance.[1]

A grand mal seizure in a 64-year-old female given sodium picosulfate with magnesium citrate was assumed to have been caused by hyponatraemia; the patient had normal electrolyte concentrations in the period before taking the bowel preparation. Care is needed when sodium picosulfate solutions are used in those with a low seizure threshold or potential sodium depletion.[5]

Although caution is advised with the use of bowel cleansing preparations in patients with inflammatory bowel disease, sodium picosulfate with magnesium citrate was considered a safe and effective bowel cleansing agent in adults[6] and children[7] with these problems. They tolerated the preparation as well as patients with other colonic disorders with no adverse effect on their disease symptoms. Patients should be kept well hydrated and this treatment should not be used in suspected toxic dilatation of the colon.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sodium picosulfate as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Pharmacokinetics

Like bisacodyl (p. 1821.2), sodium picosulfate is metabolised by colonic bacteria to the active compound bis(*p*-hydroxyphenyl)pyridyl-2-methane. Only a small amount of sodium picosulfate is absorbed after an oral dose; this is subsequently excreted in the urine.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Agarol; Chicle; Cirulaxia; Dagol; Dulcolax; Factor Laxante; Feen-A-Mint; Gotalax; Granulax; Kritel; Laxamin; Modaton; Opalino; Rapilax; Trali; Verilax; Yodolin; *Austral.*: Dulcolax SP; *Austria*: Agaffin; Agiopic†; Guttalax; Laxasan; *Belg.*: Dulcolax Picosulphate; Fructines; Laxoberon; Picolaxine; *Braz.*: Cronoplex; Diltin; Forlax†; Guttalax; Rapilax; *Chile*: Aguala; Cronolax; Dulcolax; Guttalax; Laxantil; Laxoberal†; *Cz.*: Agiolax Pico†; Guttalax; Laxygal; Progut†; Regulax Pikosulfat; *Denm.*: Actilax; Laxoberal; Picolon; *Fin.*: Laxoberon; *Fr.*: Fructines; *Ger.*: Agiolax Pico; Darmol Pico; Dulcolax NP; Laxans-ratiopharm Pico; Laxoberal; Liquidepur mit Natriumpicosulfat†; Regulax Picosulfat; *Gr.*: Guttalax; Laxatol; *Hong Kong*: Sur-Lax; *Hung.*: Guttalax; Laxygal; *India*: Asilax Plus; Colax; Coso; Cremalax; Dyrset-Eze; Laxatab; Laxicare; Laxkair; Laxopic; Laxsure; Novalax Plus; Oslax; *Indon.*: Laxoberon; *Irl.*: Agiolax Pico†; Dulcolax; Laxoberal†; *Ital.*: Buchessina GM; Falquigut; Gocce Lassative Aicardi; Guttalax; *Jpn*: Laxoberon; *Mex.*: Anara; Laxoberon; Motilaxil; *Neth.*: Dulcodruppels; Dulcopearls; Pico-Salax; *Norw.*: Laxoberal; *Philipp.*: Dulcolax SP; Laxoberal†; *Port.*: Dulcogotas; Fructines; Guttalax; Laxodal; Picolax; *Rus.*: Guttalax (Гутталакс); Laxigal (Лакигал); Regulax Picosulphate (Регулакс Пикосульфат); Slabicap (Слабикап); Slabilen (Слабилен); *Spain*: Contumax; Evacuol; Ezor; Gutalax†; Lubrilax; Skilax†; *Swed.*: Cilaxoral; Laxoberal; *Switz.*: Dulcolax Picosulfat; Fructines; Laxoberon; *Turk.*: Dulcolax; *UK*: Dulcolax; *Ukr.*: Agiolax Pico (Агиолакс Пико)†; Guttalax (Гутталакс); Picolax (Пиколакс); *Venez.*: Lasoberon.

CAS — 7757-82-6.

ATC — A06AD13; A12CA02.

ATC Vet — QA06AD13; QA12CA02.

UNII — 36KCS0R750.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, and *Viet.*

US includes a single monograph for both the anhydrous form and the decahydrate.

Ph. Eur. 8: (Sodium Sulfate, Anhydrous). A white or almost white, hygroscopic powder. Freely soluble in water. Store in airtight containers.

USP 36: (Sodium Sulfate). It contains 10 molecules of water of hydration or is anhydrous. The decahydrate loses between 51 and 57% of its weight on drying and the anhydrous form loses not more than 0.5% of its weight. Large, colourless, odourless, transparent crystals or a granular powder. It effloresces rapidly in air, liquefies in its water of hydration at about 33 degrees, and loses all of its water of hydration at about 100 degrees. Freely soluble in water; insoluble in alcohol; soluble in glycerol. Store in airtight containers, preferably at a temperature not exceeding 30 degrees.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, and *Viet.*

US includes a single monograph for both the anhydrous form and the decahydrate.

Ph. Eur. 8: (Sodium Sulfate Decahydrate; Sodium Sulfate BP 2014). A white or almost white, crystalline powder or colourless, transparent crystals. Freely soluble in water; practically insoluble in alcohol. It partly dissolves in its own water of crystallisation at about 33 degrees. It loses between 52.0 and 57.0% of its weight on drying.

USP 36: (Sodium Sulfate). It contains 10 molecules of water of hydration or is anhydrous. The decahydrate loses between 51 and 57% of its weight on drying and the anhydrous form loses not more than 0.5% of its weight. Large, colourless, odourless, transparent crystals or a granular powder. It effloresces rapidly in air, liquefies in its water of hydration at about 33 degrees, and loses all of its water of hydration at about 100 degrees. Freely soluble in water; insoluble in alcohol; soluble in glycerol. Store in airtight containers, preferably at a temperature not exceeding 30 degrees.

Profile

Sodium sulfate has been used as an osmotic laxative (p. 1804.1). It is also given in dilute solution (about 0.5%) with a high molecular weight macrogol for prompt bowel evacuation before investigational procedures or surgery (see Macrogols, p. 2548.1).

Sodium sulfate is also used as an additive in foods.

For the general properties of sodium salts, see p. 1795.1.

Sterculia

E416; Goma esterculia; Goma Karaya; Indian Tragacanth; Karaya; Karaya Gum; Sterculia Gum; Sterkúlia; Tragacante Indio; Камедь Карайи; Стеркулия Жгучая (*Sterculia urens*).

CAS — 9000-36-6.

ATC — A06AC03.

ATC Vet — QA06AC03.

ATC Herb — HA06AC5011 (Sterculia urens: *gum*).

UNII — 73W9IQY50Q.

Pharmacopoeias. In *Br.* and *Fr.*

BP 2014: (Sterculia). The gum obtained from *Sterculia uren.* and other species of *Sterculia*. Irregular or vermiform pieces greyish-white with a brown or pink tinge, with an odour resembling that of acetic acid. It contains not less than 14.0% of volatile acid (or not less than 10.0% if supplied in powdered form), calculated as acetic acid. Sparingly soluble in water, but swells into a homogeneous, adhesive, gelatinous mass; practically insoluble in alcohol. Store at a temperature not exceeding 25 degrees.

Uses and Administration

Sterculia is used similarly to ispaghula (p. 1849.2) as a bulk laxative and for adjusting faecal consistency. It has also been used as an aid to appetite control in the management of obesity (p. 2315.1) but there is little evidence of efficacy. It is usually taken in the form of granules containing sterculia 62%; the dose is 1 to 2 sachets or 1 to 2 heaped 5 mL spoonfuls orally once or twice daily after meals. (For a dose in children see below.) The granules are washed down without chewing with plenty of water. They may also be taken sprinkled onto soft foods such as yogurt.

Sterculia is used topically, as a paste or powder, for skin protection and sealing in the fitting of ileostomy and colostomy appliances. It has also been used in dental fixative powders, and as an emulsifier and stabiliser in foods.

Administration in children. In the UK, the recommended oral dose of granules, containing sterculia 62%, for constipation in children aged 6 to 12 years is ½ to 1 sachet, or ½ to one 5 mL spoonful, once or twice daily after meals. Children over 12 years may be dosed as for adults, see Uses and Administration, above. The granules are washed down without chewing with plenty of water. They may also be taken sprinkled onto soft foods such as yogurt.

Adverse Effects and Precautions

As for Ispaghula, p. 1849.2. There is a risk of intestinal or oesophageal obstruction and faecal impaction, especially if such compounds are swallowed dry. Therefore they should always be taken with sufficient fluid and should not be taken immediately before going to bed. They should be avoided by patients who have difficulty swallowing.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sterculia as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

Sucralfate (BAN, USAN, rINN)

Sucralfato; Sucralfatum; Sukralfaatti; Sükralfat; Sukralfat; Сукральфат.

Sucrose hydrogen sulphate basic aluminium salt; Sucrose octakis(hydrogen sulphate), aluminium complex; β-D-Fructofuranosyl-α-D-glucopyranoside octakis (hydrogen sulphate) aluminium complex.

$C_{12}H_mAl_{16}O_nS_8$.

CAS — 54182-58-0.

ATC — A02BX02.

ATC Vet — QA02BX02.

UNII — XX73205DH5.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Sucralfate). A white or almost white, amorphous powder. Practically insoluble in water, in alcohol, and in dichloromethane. It dissolves in dilute solutions of mineral acids and alkali hydroxides.

USP 36: (Sucralfate). The hydrous basic aluminium salt of sucrose octasulfate. Store in airtight containers.

Uses and Administration

Sucralfate is a cytoprotective drug that, under acid gastrointestinal conditions, forms an adherent complex with proteins that coats the gastric mucosa and is reported to have a special affinity for ulcer sites. It also inhibits the action of pepsin and adsorbs bile salts.

Sucralfate has been used in the treatment of peptic ulcer disease (p. 1813.2) and chronic gastritis. It is given orally and should be taken on an empty stomach before meals and at bedtime. The usual dose is 1 g four times daily or 2 g twice daily for 4 to 8 weeks; if necessary the dose may be increased to a maximum of 8 g daily. If longer-term therapy is required sucralfate may be given for up to 12 weeks. Where appropriate a maintenance dose of 1 g twice daily may be given to prevent the recurrence of duodenal ulcers.

For prophylaxis of gastrointestinal haemorrhage from stress ulceration the usual dose of sucralfate is 1 g six times daily; a dose of 8 g daily should not be exceeded. For children's doses see below.

Administration in children. Although sucralfate is not licensed in the UK for use in children under 15 years, the *BNFC* recommends the following oral doses for the treatment of peptic ulcer disease, or the prophylaxis of stress ulceration in children in intensive care (but see also under Bezoar Formation, below):

- 1 month to 2 years: 250 mg four to six times daily
- 2 to 12 years: 500 mg four to six times daily
- 12 to 15 years: 1 g four to six times daily
- 15 to 18 years: adult doses may be given, see above

The oral suspension blocks fine-bore feeding tubes and tablets should be crushed and dispersed in water instead.

Gastrointestinal bleeding. Sucralfate is an effective drug for the prophylaxis and management of stress-induced gastrointestinal bleeding in severely ill patients but whether it should be chosen over an H_2-antagonist has been subject to debate. One study suggested it might reduce the risk of late-onset pneumonia compared with ranitidine.[1] Another study[2] found ranitidine to be more effective than sucralfate in reducing the risk of gastrointestinal bleeding; while there was a trend towards a lower rate of pneumonia among patients receiving sucralfate, the difference was not significant. However, meta-analyses[3] found an increased risk of pneumonia with ranitidine compared with sucralfate, but no difference in the rate of pneumonia with sucralfate and placebo; insufficient data were available to conduct a meta-analysis of sucralfate's efficacy in terms of rates of bleeding, and a reassessment of recommendations for the prophylaxis of stress ulcers was called for. Later guidelines[4] concluded that the use of sucralfate did not influence the incidence of ventilator-associated pneumonia compared with placebo. For further discussion of stress ulceration and bleeding, including the use of sucralfate, see under Peptic Ulcer Disease, p. 1813.2. There is also some evidence from a study[5] that sucralfate reduces gastrointestinal bleeding associated with NSAID use, although it does not prevent drug-induced gastric erosion.

In a study to assess whether oral prophylactic sucralfate could ameliorate the symptoms of acute radiation proctitis, sucralfate was found to increase the incidence of rectal bleeding compared with placebo; the cause of this increased bleeding was unclear.[6]

Gastro-oesophageal reflux disease. Although sucralfate has been tried for gastro-oesophageal reflux disease (p. 1807.2) the results of studies have been inconsistent.[1-3] However, if lifestyle or dietary measures prove insufficient for the management of heartburn in pregnancy, sucralfate may be considered for first-line therapy.

3. Simon B, *et al.* Sucralfate gel versus placebo in patients with non-erosive gastro-oesophageal reflux disease. *Aliment Pharmacol Ther* 1996; 10: 441–6.

Mouth ulceration. Sucralfate has been investigated as a mouth rinse in the treatment and prophylaxis of stomatitis induced by cancer chemotherapy[1-3] although evidence of benefit for any drug is ambiguous (see Mucositis, p. 732.1). One study[2] in 40 patients found a significant reduction in symptoms among 23 evaluable patients given sucralfate prophylactically. Seven patients withdrew due to aggravation of chemotherapy-induced nausea. It was suggested that to overcome this problem, the suspension should have a neutral taste, should not be swallowed after rinsing, and that rinsing should not be started until nausea had stopped. However, another study[4] involving 80 patients treated with fluorouracil for colorectal cancer found no significant difference in self-reported mucositis symptoms between patients given sucralfate suspension and those given placebo.

Sucralfate has also been reported to be of benefit in patients with recurrent aphthous stomatitis (mouth ulceration—p. 1811.2). A study involving 21 such patients over 2 years found that topical application of sucralfate suspension 4 times daily was superior to treatment with an antacid (aluminium hydroxide with magnesium hydroxide) or placebo.[5]

In patients with Behçet's syndrome (p. 1601.1), topical sucralfate suspension significantly decreased the frequency, healing time, and pain of oral ulceration, as well as the healing time and pain of genital ulceration,[6] when compared with placebo.

Skin ulceration. Sucralfate is of interest for its actions on epithelial wound healing,[1] and has reportedly been applied topically with some success to treat bleeding skin ulcers (p. 1690.1) associated with malignancy,[2] and to promote the healing of chronic venous ulcers.[3,4] It has been suggested that sucralfate promotes angiogenesis by binding to, and preventing degradation of, basic fibroblast growth factor (bFGF).[3] Topical sucralfate 7% cream was also reported to decrease pain and speed healing of the wound after open surgical removal of haemorrhoids.[5]

Adverse Effects and Precautions

Constipation is the most frequently reported adverse effect of sucralfate although diarrhoea, nausea, vomiting, flatulence, or gastric discomfort may also occur. Other adverse effects include dry mouth, dizziness, drowsiness, headache, vertigo, back pain, and skin rashes. Hypersensitivity reactions such as pruritus, oedema, urticaria, respiratory difficulty, rhinitis, laryngospasm, and facial swelling have been reported.

Great caution is needed in patients with renal impairment (below) as absorption and accumulation of aluminium may cause adverse effects.

Bezoar formation. As of March 1999, the UK CSM was aware of 7 reports worldwide of bezoar formation associated with sucralfate use in intensive care patients.[1] It advised caution in the use of sucralfate in seriously ill patients because of the risks of bezoar formation and intestinal obstruction.[1] Patients with delayed gastric emptying or receiving concomitant enteral feeds may be at increased risk. A report by the French Pharmacovigilance System at about the same time made similar recommendations but also contra-indicated the use of sucralfate in premature and immature neonates.[2]

2. Guy C, Ollagnier M. Sucralfate et bézoard: bilan de l'enquête officielle de pharmacovigilance et revue de la littérature. *Therapie* 1999; 54: 55–8.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sucralfate as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 06/10/11)

Renal impairment. Sucralfate under acid conditions can release aluminium ions that may be absorbed systemically. Significant increases in the urinary excretion of aluminium have been seen in healthy subjects given sucralfate 4 g daily,[1,2] reflecting gastrointestinal absorption of aluminium; aluminium concentrations in serum and urine were significantly higher in patients with chronic renal impairment than in subjects with normal renal function,[3] and similar serum increases have been seen in children with acute renal failure.[4] Aluminium toxicity in patients with normal renal function receiving sucralfate would not be expected, but seizures, muscle weakness, bone pain,[1] and severe aluminium encephalopathy[5] have been reported in patients with end-stage renal disease requiring dialysis. Sucralfate should be used with caution in patients with renal impairment, especially if other aluminium-containing agents are also taken, and such patients should be monitored for signs of aluminium toxicity.[4,6]

Interactions

Sucralfate may interfere with the absorption of other drugs and it has been suggested that there should be an interval of 2 hours between giving sucralfate and other non-antacid medication. Some of the drugs reported to be affected by sucralfate include cimetidine, ranitidine, digoxin, fluoroquinolone antibacterials, ketoconazole, levothyroxine, phenytoin, tetracycline, quinidine, theophylline, and possibly warfarin. The recommended interval between sucralfate and antacids is 30 minutes. An interval of 1 hour should elapse between giving sucralfate and enteral feeding.

Pharmacokinetics

Sucralfate is only slightly absorbed from the gastrointestinal tract after oral doses. However, there can be some release of aluminium ions and of sucrose sulfate; small quantities of sucrose sulfate may then be absorbed and excreted, primarily in the urine; some absorption of aluminium may also occur (see Renal Impairment, above).

Preparations

Multi-ingredient Preparations. *Arg.*: Cicalfate; *Chile*: Cicalfate; *Fr.*: Cicalfate; *Gr.*: Profenil Complex; *India*: Acicot-O; Adcral-O; Acral-O; Alcocid; Crasia-O; Daffocid-O; Erocot-O; Esfate-O; Focri-O; Greycid; Kulent-O; Kulfi; Lacrate-O; Lorcus-O; Oxefate-O.

Used as an adjunct in:. *Gr.*: Vofen; *Ital.*: Ketodol.

Pharmacopoeial Preparations
USP 36: Sucralfate Tablets.

Sulfasalazine *(BAN, USAN, rINN)*

Salatsosulfapyridiini; Salazosulfapyridin; Salazosulfapyridine; Salazosulfapyridinum; Salicylazosulfapyridine; SI-88; Sulfasalatsiini; Sülfasalazin; Sulfasalazin; Sulfasalazina; Sulfasalazinas; Sulfasalazinum; Sulfasalazyna; Sulphasalazine; Szulfaszalazin; Сульфасалазин.

4-Hydroxy-4′-(2-pyridylsulphamoyl)azobenzene-3-carboxylic acid.

$C_{18}H_{14}N_4O_5S$=398.4

CAS — 599-79-1.

ATC — A07EC01.

ATC Vet — QA07EC01.

UNII — 3XC8GUZ6CB.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Sulfasalazine). A bright yellow or brownish-yellow, fine powder. Practically insoluble in water and in dichloromethane; very slightly soluble in alcohol; dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 36: (Sulfasalazine). A fine odourless bright yellow or brownish-yellow powder. Practically insoluble in water, in chloroform, in ether, and in benzene; soluble 1 in 2900 of alcohol, and 1 in 1500 of methyl alcohol; soluble in aqueous solutions of alkali hydroxides. Store in airtight containers. Protect from light.

Uses and Administration

Sulfasalazine is a compound of a sulfonamide, sulfapyridine, with 5-aminosalicylic acid (mesalazine). Its activity is generally considered to lie in the 5-aminosalicylic acid moiety, which is released in the colon by bacterial metabolism, although intact sulfasalazine has some anti-inflammatory properties in its own right.

In inflammatory bowel disease (p. 1808.3) it is used alone or as an adjunct to corticosteroids in the treatment of active ulcerative colitis and is effective in maintaining remission. Sulfasalazine may also be effective in the treatment of active Crohn's disease, particularly of the colon, but it does not appear to be of value in maintaining remissions. Sulfasalazine is also used as a disease modifying drug in the treatment of severe or progressive rheumatoid arthritis (below).

In **inflammatory bowel disease** the usual initial dose of sulfasalazine is 1 to 2 g orally 4 times daily in the UK. However, doses over 4 g daily are associated with an increased risk of toxicity, and in the USA, therefore, the usual dose is 1 g given 3 or 4 times daily, and an initial dose of 500 mg every 6 to 12 hours may be recommended to lessen gastrointestinal adverse effects. Enteric-coated tablets are also claimed to reduce the incidence of adverse gastrointestinal effects. The overnight interval between doses should not exceed 8 hours. On remission the dose in patients with ulcerative colitis is gradually reduced to 2 g daily and then generally continued indefinitely.

Sulfasalazine is also given rectally, as suppositories, initially at a dose of 1 g at night and in the morning. After three weeks the dosage is gradually reduced according to response. Rectal sulfasalazine can be given as 0.5 to 1 g night and morning as an adjunct to treatment by mouth.

In **rheumatoid arthritis** treatment is usually started with an oral dose of 500 mg daily, as enteric-coated tablets, for the first week; dosage is then increased by 500 mg daily each week to a maximum of 3 g daily given in 2 to 4 divided doses according to tolerance and response.

For doses in children, see below.

Administration in children. In children with inflammatory bowel disease, sulfasalazine can be used alone or as an adjunct to corticosteroids to treat active ulcerative colitis and to maintain remission. Sulfasalazine may also be used to treat active Crohn's disease, particularly of the colon, but it does not appear to be of value in maintaining remissions. Sulfasalazine is also used as a disease modifying drug in the treatment of juvenile rheumatoid arthritis.

To treat active **inflammatory bowel disease**, children 2 years of age or older may be given oral sulfasalazine 40 to 60 mg/kg daily in divided doses. This can be reduced to 20 to 30 mg/kg daily to maintain remission in ulcerative colitis.

Sulfasalazine can also be given rectally as suppositories; the *BNFC* suggests the following doses for children according to age:

- 5 to 8 years: 500 mg twice daily
- 8 to 12 years: 500 mg in the morning and 1 g at night
- 12 to 18 years: 0.5 to 1 g twice daily

Sulfasalazine has also been used for polyarticular **juvenile rheumatoid arthritis** (see also below). US licensed product information recommends that children aged 6 years and older who have not responded adequately to salicylates or other NSAIDs may be given an oral dose of 30 to 50 mg/kg daily in two divided doses, to a maximum of 2 g daily. To reduce adverse gastrointestinal effects, an enteric-coated tablet is used and the initial dose should be a quarter to a third of the planned maintenance; it is then increased weekly to reach the maintenance dose after one month.

Although sulfasalazine is not licensed for juvenile rheumatoid arthritis in the UK, the *BNFC* suggests that children aged 2 to 18 years may be given an initial oral dose of 5 mg/kg twice daily for 1 week. The dose is then increased to 10 mg/kg twice daily for 1 week, then 20 mg/kg twice daily for 1 week, and maintained on a dose of 20 to 25 mg/kg twice daily. For children aged 2 to 12 years the maximum dose suggested is 2 g daily, and 3 g daily for children aged 12 to 18 years.

Psoriasis. In a double-blind placebo-controlled study involving 50 patients with moderate to severe plaque-type psoriasis (p. 1688.1), sulfasalazine 3 to 4 g daily produced a significantly greater clinical improvement than placebo after 4 weeks of treatment with a further improvement at 8 weeks.[1]

Rheumatoid arthritis. Sulfasalazine is considered to be a useful disease-modifying antirheumatic drug (DMARD) in the treatment of rheumatoid arthritis (p. 13.2). Studies have found a beneficial clinical effect of sulfasalazine, compared with placebo, on tender and swollen joints, pain, and erythrocyte sedimentation rate.[1,2] Meta-analyses[3,4] of generally short-term comparative studies suggest that sulfasalazine is roughly comparable in efficacy to methotrexate, intramuscular gold (sodium aurothiomalate), and penicillamine. Other reviews[2,5] have also suggested that it may have similar efficacy to hydroxychloroquine and leflunomide. Although there are regional differences in the prescription of DMARDs, sulfasalazine has been widely used for initial therapy, especially of less severe disease.[5] In an open study[6] of 200 patients with rheumatoid arthritis who were randomly allocated to treatment with sulfasalazine or auranofin, 31% of the sulfasalazine recipients were still taking the drug after 5 years compared with 15% of auranofin recipients. Improvement over baseline was still significant at 5 years for those patients receiving sulfasalazine but not in those treated with auranofin. Although one study[7] failed to find convincing evidence that using sulfasalazine with methotrexate was more effective than either drug alone, other studies have shown that combination treatment with sulfasalazine plus methotrexate and hydroxychloroquine was more effective than methotrexate alone or with sulfasalazine or hydroxychloroquine or the combination of sulfasalazine with hydroxychloroquine.[8–10] A review of sulfasalazine use in the management of rheumatoid arthritis concluded that combination therapy may be of benefit in patients with early or advanced rheumatoid arthritis but that there is still a need for studies to determine the efficacy and tolerability of various combinations.[5]

JUVENILE IDIOPATHIC ARTHRITIS. Juvenile idiopathic arthritis (p. 12.1) is generally managed similarly to rheumatoid arthritis, but there is limited experience with the use of some antirheumatic drugs in children. Sulfasalazine has produced significant improvement in studies of patients with juvenile chronic arthritis; a literature review found that it was consistently reported to be of benefit.[1] Adverse effects were reported to be similar to those in adults, with the exception of a serum-sickness-like reaction which was mostly seen in systemic onset patients and may be unique to juvenile rheumatoid arthritis.[1] For doses see Administration in Children, above.

1. Brooks CD. Sulfasalazine for the management of juvenile rheumatoid arthritis. *J Rheumatol* 2001; **28**: 845–53.

Spondyloarthropathies. *ANKYLOSING SPONDYLITIS.* Sulfasalazine has been found to be effective[1] in the treatment of active ankylosing spondylitis (p. 14.3), but there is evidence that it is more useful in the treatment of active disease and peripheral articular manifestations than in the management of chronic long-standing disease.[2–4] The active moiety appears to be sulfapyridine rather than mesalazine.[5] Sulfasalazine was no better than placebo for the treatment of inflammatory back pain due to undifferentiated spondyloarthritis and early ankylosing spondylitis, but it was more effective than placebo in a subgroup of patients with no peripheral arthritis.[6]

PSORIATIC ARTHRITIS. A systematic review[1] of interventions for psoriatic arthritis (see Spondyloarthropathies, p. 14.3) concluded that sulfasalazine was one of only two drugs with published evidence of well proven efficacy in psoriatic arthritis (the other being high-dose parenteral methotrexate).

See also under Psoriasis, above.

1. Jones G, *et al.* Interventions for treating psoriatic arthritis. Available in The Cochrane Database of Systematic Reviews, Issue 3. Chichester: John Wiley; 2000 (accessed 29/04/05).

Adverse Effects and Precautions

Since sulfasalazine is metabolised to sulfapyridine and 5-aminosalicylic acid (mesalazine), its adverse effects and precautions are similar to those of sulfonamides (see Sulfamethoxazole, p. 365.3) and of mesalazine (p. 1860.1). Many adverse effects have been attributed to the sulfapyridine moiety and appear to be more common if serum-sulfapyridine concentrations are greater than 50 micrograms/mL, if the daily dose of sulfasalazine is 4 g or more, or in slow acetylators of sulfapyridine.

The most commonly reported adverse effects include nausea and vomiting, abdominal discomfort, anorexia, headache, fever, and skin rash.

Adverse effects can be broadly divided into 2 groups:

- dose-related effects are dependent on acetylator phenotype, and largely predictable; this group includes nausea and vomiting, headache, haemolytic anaemia, and methaemoglobinaemia

- hypersensitivity reactions are essentially unpredictable and usually occur at the start of treatment; this group includes aplastic anaemia, hepatic and pulmonary dysfunction, vasculitis, auto-immune haemolysis, and rash such as toxic epidermal necrolysis, Stevens-Johnson syndrome, and drug rash with eosinophilia and systemic symptoms (DRESS).

Oligospermia, reversible on withdrawal of sulfasalazine, has also been reported. Sulfasalazine treatment may result in yellow-orange discoloration of skin, urine, and other body fluids. Some soft contact lenses may be stained. Adverse effects on the CNS include insomnia, depression, hallucinations, vertigo, convulsions, aseptic meningitis, ataxia, encephalopathy, peripheral neuropathy, and tinnitus.

Sulfasalazine should not be given to patients with a history of sensitivity to *sulfonamides or salicylates. Use in* children under 2 years of age is contra-indicated because of the risk of kernicterus. Use in children with juvenile rheumatoid arthritis may result in a serum sickness-like reaction. Caution is required when used in patients with severe allergy or asthma.

Blood counts should be performed at the start of therapy and frequently thereafter, particularly during the first 3 months of treatment. If a blood dyscrasia is suspected treatment should be stopped immediately and a blood count performed. Patients or their carers should be told how to recognise signs of blood toxicity and should be advised to seek immediate medical attention if symptoms such as fever, sore throat, jaundice, bruising or bleeding develop. Care is advisable in patients with G6PD deficiency because of the risk of haemolytic anaemia.

Sulfasalazine should be used with caution in hepatic or renal impairment. Liver function tests should be carried out at monthly intervals for the first 3 months of treatment. Periodic monitoring of kidney function has also been recommended.

The adverse effects associated with the use of *sulfasalazine in patients with inflammatory bowel disease*[1] or rheumatoid arthritis have been reviewed.[2,3] The type and incidence of adverse effects appear to be similar in both groups of patients.[2] Although most reactions are minor and patients may continue therapy at the same or reduced dosage, some patients stop treatment because of adverse effects and in these cases a hyposensitisation regimen may be considered.[1,4,5] **Hyposensitisation** should not be attempted in patients with a history of a serious adverse effect such as agranulocytosis, toxic epidermal necrolysis, erythema multiforme, frank haemolysis, or a severe hypersensitivity reaction.[1,4,5] An alternative to hyposensitisation in patients with inflammatory bowel disease who cannot tolerate sulfasalazine is to try a drug that supplies the active 5-aminosalicylic acid component without sulfapyridine, as the latter is thought to be responsible for many of the adverse effects. Examples include balsalazide, mesalazine, and olsalazine; however, some patients still experience hypersensitivity, see under Mesalazine, p. 1860.1.

Breast feeding. Small amounts of sulfasalazine and its sulfapyridine metabolites are excreted in breast milk; the concentrations of sulfasalazine and total sulfapyridine may be up to 30% and 50% of maternal serum concentrations respectively.[1] Bloody diarrhoea in a breast-fed infant whose mother was taking sulfasalazine 3 g daily has been reported.[2] The mother was a slow acetylator with a relatively high blood concentration of sulfapyridine, which contributed to the appearance of the drug in the infant's blood. Based on this report, the American Academy of Pediatrics[3] considers that sulfasalazine should be given with caution to breast-feeding mothers. However, others consider that continued treatment with sulfasalazine can generally be recommended to breast-feeding mothers of healthy infants.[4] A small study initially involving 17 mother-child pairs concluded sulfasalazine treatment could continue throughout pregnancy and lactation. The study found negligible amounts of sulfasalazine, and its main metabolite sulfapyridine, were transferred to the child via breast feeding. The authors did however warn that this conclusion could not be applied to a prematurely born child or a child with haemolytic disease.[5]

Effects on the blood. Blood disorders constitute 19% of all reactions reported with sulfasalazine.[1] As of June 1993 the UK CSM was aware of 191 reports of neutropenia, leucopenia, or agranulocytosis (22 fatal), 44 reports of bone marrow depression or aplastic anaemia (13 fatal) and 30 reports of thrombocytopenia (1 fatal).[1]

Although blood dyscrasias were initially thought to be caused by the sulfapyridine moiety, subsequent experience has shown that the aminosalicylates can also cause haematological reactions (see Mesalazine, p. 1860.2). The risk of blood dyscrasias with sulfasalazine has been estimated at 0.6 per 1000 in those given the drug for inflammatory bowel disease, but about 10 times greater in patients receiving sulfasalazine for rheumatoid arthritis.[2]

Sulfasalazine inhibits folic acid absorption, interferes with its metabolism, and can increase folic acid requirements through haemolysis of red blood cells.[3,4] These effects are not usually significant in patients with inflammatory bowel disease unless there are additional factors causing folate deficiency, such as intercurrent illness or an exacerbation of bowel disease.[3,4] However, clinical folate deficiency with macrocytosis, megaloblastic anaemia, or pancytopenia has been reported rarely.[3,4] Macrocytic anaemia associated with sulfasalazine may occur more commonly in patients with rheumatoid arthritis; it was found in 7 of 50 patients within 3 to 4 months of starting treatment with sulfasalazine.[5] The effects of sulfasalazine on folic acid metabolism appear to be dose-related and respond to withdrawal or dosage reduction, and folic acid supplements;[3-5] intravenous folinic acid may sometimes be needed.[4] Although the effects may be potentially serious, they are not a contra-indication to continuing sulfasalazine treatment.[4,5]

Patients with a history of leucopenia associated with gold therapy for rheumatoid arthritis should not be given sulfasalazine since a similar reaction may occur.[6]

Effects on the cardiovascular system. Reports include Raynaud's syndrome with sulfasalazine[1] and myocarditis with sulfasalazine and with mesalazine.[2] Myocarditis leading to fatal cardiogenic shock has been reported in a patient receiving mesalazine and it has been recommended that sulfasalazine or mesalazine should be replaced by glucocorticoids if cardiac symptoms arise.[3] See also under Mesalazine, p. 1860.2, and under Balsalazide, p. 1820.3.

3. Kristensen KS, *et al.* Fatal myocarditis associated with mesalazine. *Lancet* 1990; **335**: 605.

Effects on fertility. Although successful pregnancies have been reported in the partners of men taking sulfasalazine,[1,2] male infertility is a well recognised complication of sulfasalazine treatment. Untreated inflammatory bowel disease is not associated with abnormal seminal quality or infertility, but oligospermia, reduced sperm motility, and an increase in morphological abnormalities are seen after treatment with sulfasalazine which may lead to infertility.[1-4] Oligospermia has been reported in 86% of men with inflammatory bowel disease treated with sulfasalazine.[1] Seminal characteristics and fertility return to normal within 2 to 3 months of withdrawing sulfasalazine and successful pregnancies have been reported after withdrawal.[1-3] The mechanism involved is thought to be a direct toxic effect on immature and developing spermatozoa, possibly due to the sulfapyridine moiety.[2-4] Improvement in seminal characteristics and successful pregnancies have been reported following substitution of mesalazine[4,5] or balsalazide[6] for sulfasalazine in patients with ulcerative colitis. However, reversible infertility, similar to that caused by sulfasalazine, has also been reported with mesalazine.[7]

Effects on the gastrointestinal tract. Sulfasalazine-induced exacerbations of ulcerative colitis have been reported[1,2] and are probably caused by the salicylate moiety rather than sulfapyridine.[3] Other reported effects include intestinal villous atrophy.[4]

1. Schwartz AG, *et al.* Sulfasalazine-induced exacerbation of ulcerative colitis. *N Engl J Med* 1982; **306**: 409–12.

Effects on the hair. Alopecia occurred on 2 occasions[1] after starting sulfasalazine 2 or 3 g daily in a patient with ulcerative colitis. On both occasions normal hair growth returned after treatment was stopped, and the patient was later successfully desensitised. However, alopecia that developed in another patient during sulfasalazine treatment did not recur on rechallenge.[2] In this case postpartum alopecia was considered to be the cause and these authors doubted whether sulfasalazine causes alopecia at all. Hair loss has been reported in 2 patients receiving mesalazine enemas.[3] However, remission of alopecia universalis has been reported during sulfasalazine treatment of rheumatoid arthritis.[4]

4. Jawad ASM, Scott DGI. Remission of alopecia universalis during sulphasalazine treatment for rheumatoid arthritis. *BMJ* 1989; **298**: 675.

Effects on the kidneys. UK licensed product information advises that adequate fluid intake and avoidance of urinary acidifiers may reduce the incidence of crystalluria and stone formation. For reports of nephrotic syndrome and of interstitial nephritis associated with sulfasalazine treatment, see under Mesalazine, p. 1860.3.

Effects on the pancreas. The UK CSM had received 6 reports of pancreatitis associated with sulfasalazine as of February 1994.[1] There had been further reports associated with mesalazine (see p. 1860.3). However, a large Danish population-based case-control study concluded neither sulfasalazine nor mesalazine was associated with an increased risk of pancreatitis, and that any increased risk might be associated with inflammatory bowel disease itself.[2]

1. CSM/MCA. Drug-induced pancreatitis. *Current Problems* 1994; **20**: 2–3. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024457&RevisionSelectionMethod=LatestReleased (accessed 02/07/08)

Effects on the respiratory system. Although one study reviewed 50 cases of sulfasalazine-induced pulmonary complications, pulmonary toxicity remains a rare adverse effect.[1] Most reports include dyspnoea, cough, pulmonary infiltrates, fever, and eosinophilia, usually developing in the first few months of treatment although they may occur after several years.[1-3] Symptoms are generally readily reversible on withdrawal of sulfasalazine, although death due to fibrosing alveolitis has been reported,[2] and the need for corticosteroid therapy remains debatable.[1] These effects have also occurred with mesalazine, p. 1861.1; they have been reported in patients with a history of sensitivity to salicylates, sulfonamides, or with no known sensitivity to these drugs.[2,3] Bronchiolitis obliterans organising pneumonia has been reported in a patient with rheumatoid arthritis receiving sulfasalazine;[4] clinical improvement occurred after sulfasalazine was stopped and corticosteroid therapy started.

4. Ulubaş B, *et al.* Bronchiolitis obliterans organizing pneumonia associated with sulfasalazine in a patient with rheumatoid arthritis. *Clin Rheumatol* 2004; **23**: 249–51.

Effects on taste. Metallic taste has occurred in patients taking sulfasalazine for ulcerative colitis,[1] although diseases causing changes in gastrointestinal absorption may lead to zinc deficiency, which has itself been associated with a metallic taste. There has also been a report of two patients developing a reversible taste dysfunction, while taking sulfasalazine for rheumatoid arthritis.[2]

2. Marcus RW. Sulfasalazine induced taste disturbances. *J Rheumatol* 1991; 18: 634–5.

Lupus. A study in 11 patients with sulfasalazine-induced lupus found that induction of disease was more likely in patients who were slow acetylators of sulfapyridine, and who had HLA haplotypes associated with idiopathic SLE.[1] Furthermore, the risk of developing persistent SLE and lupus nephritis increased with duration of treatment and cumulative dose of sulfasalazine. Lupus-like syndrome has also occurred with mesalazine (p. 1861.1).

1. Gunnarsson L *et al.* Predisposing factors in sulphasalazine-induced systemic lupus erythematosus. *Br J Rheumatol* 1997; 36: 1089–94.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sulfasalazine as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 03/10/11)

Pregnancy. Sulfasalazine and its sulfapyridine metabolites readily cross the placenta resulting in similar concentrations in the cord serum and maternal serum at delivery.[1,2] The concentration of the 5-aminosalicylic acid component of sulfasalazine in both cord serum and maternal serum is negligible.[1] There have been isolated reports of congenital abnormalities associated with use of sulfasalazine during pregnancy including coarctation of the aorta with a ventricular septal defect,[3,4] and genito-urinary disorders.[4] There is also a theoretical risk of kernicterus in the neonate if sulfasalazine is given close to delivery (see p. 366.2). However, given the concentrations of sulfasalazine and its metabolites found in cord blood, the risk of kernicterus from maternal use is considered minimal.[2] There have been many successful and uncomplicated pregnancies during sulfasalazine therapy and the general consensus favours continuing sulfasalazine throughout pregnancy when indicated.[1,3–6] (See also Mesalazine, p. 1861.1.) The minimum effective dose should be used and since sulfasalazine may precipitate folate deficiency (see Effects on the Blood, p. 1891.2), folic acid supplements are recommended.[7]

Interactions

Giving sulfasalazine with antibacterial therapy may reduce conversion of sulfasalazine to its active metabolite (see below).

Sulfasalazine has been reported to interfere with the absorption of digoxin (p. 1357.3) or folic acid (see Effects on the Blood, p. 1891.2) from the gastrointestinal tract.

Antibacterials. Since the effects of sulfasalazine depend on release of 5-aminosalicylic acid by bacterial metabolism in the gut, any drug that reduces the intestinal microflora may rednce the production of active metabolite. Evidence for this has been seen in patients also given *rifampicin* and *ethambutol*,[1] or in subjects also given *ampicillin*.[2] However, a decrease in clinical effect does not seem to have been seen.

1. Shaffer JL, Houston JB. The effect of rifampicin on sulphapyridine plasma concentrations following sulphasalazine administration. *Br J Clin Pharmacol* 1985; 19: 526–8.
2. Houston JB *et al.* Azo reduction of sulphasalazine in healthy volunteers. *Br J Clin Pharmacol* 1982; 14: 395–8.

Antineoplastics. For mention of 5-aminosalicylates such as sulfasalazine inhibiting the metabolism of thiopurine antineoplastics, and increasing their toxicity, see Gastrointestinal Drugs, p. 822.1.

Pharmacokinetics

About 15% of an oral dose of sulfasalazine is absorbed from the small intestine, although some of this is subsequently returned to the intestine in bile via enterohepatic circulation. The great majority of the dose reaches the colon where the azo bond is cleaved by the action of the intestinal flora, producing sulfapyridine and 5-aminosalicylic acid (mesalazine). Results in patients who have undergone colectomy suggest that between 60 and 90% of the total dose is metabolised in this way, but the degree of metabolism depends both on the activity of the intestinal flora and the speed of intestinal transit; colonic metabolism is reduced in patients with diarrhoea (for example, in active inflammatory bowel disease).

The small amount of intact sulfasalazine that is absorbed is extensively protein bound and subsequently excreted unchanged in urine. It crosses the placenta and is found in breast milk.

After cleavage of the sulfasalazine molecule about 60 to 80% of available sulfapyridine is absorbed, and undergoes extensive metabolism by acetylation, hydroxylation, and glucuronidation. Peak steady-state concentrations of sulfapyridine are higher in slow acetylators than fast acetylators after similar doses and the former are 2 to 3 times more likely to have adverse effects. Some 60% of the original dose of sulfasalazine is excreted in urine as sulfapyridine and its metabolites. As with sulfasalazine, absorbed sulfapyridine crosses the placenta and is found in breast milk.

The 5-aminosalicylic acid (5-ASA) moiety is much less well absorbed. About one-third of liberated 5-ASA is absorbed and almost all of this is acetylated and excreted in urine. For further details of the pharmacokinetics of 5-aminosalicylic acid see under Mesalazine, p. 1861.2.

Teduglutide *(BAN, USAN, rINN)*

ALX-0600; [2-Glycine]-1-33-glucagon-like Peptide II; Teduglutida; Téduglutide; Teduglutidum; Тедуглутид.

$C_{164}H_{252}N_{44}O_{55}S$=3752.1.

CAS — 287714-30-1.

UNII — 7M19191IKG.

Uses and Administration

Teduglutide is an analogue of endogenous human glucagon-like peptide 2 (GLP-2) that acts as an agonist at GLP-2 receptors in the distal intestine. It increases intestinal and portal blood flow, inhibits gastric acid secretion, decreases intestinal motility, and promotes repair of the intestinal mucosa. Teduglutide is used in the management of patients with short bowel syndrome. A dose of 50 micrograms/kg is given by subcutaneous injection once daily. This initial dose may be titrated to a lower dose if necessary to improve tolerability. Doses should be reduced in moderate to severe renal impairment, see Administration in Renal Impairment, below.

Teduglutide is under investigation in Crohn's disease.

References.

2. Norholt LM, *et al.* Treatment of adult short bowel syndrome patients with teduglutide. *Expert Opin Pharmacother* 2012; 13: 235–43.
3. Burness CB, McCormack PL. Teduglutide: a review of its use in the treatment of patients with short bowel syndrome. *Drugs* 2013; 73: 935–47.

Administration in renal impairment. Exposure to teduglutide is increased in renal impairment and the usual dose (see Uses and Administration, above) should be reduced by 50% in patients with moderate to severe impairment (creatinine clearance < 50 mL/minute) or end-stage renal disease.

Adverse Effects and Precautions

The most common adverse effects associated with teduglutide include injection site reactions, abdominal pain and distension, nausea and vomiting, headaches, peripheral oedema, and upper respiratory-tract infections. Other adverse effects include flatulence, hypersensitivity reactions, changes to appetite, sleep disturbances, cough, skin haemorrhage, arthralgia, renal colic, chest pain, and night sweats. Patients with a stoma reported a higher incidence of stoma complications. Teduglutide enhances fluid absorption, and fluid overload and congestive heart failure have been seen during treatment. Intestinal obstruction has been reported; teduglutide should be withheld until it has resolved.

Teduglutide has the potential to cause hyperplastic changes including neoplasia and should not be used in patients with active gastrointestinal malignancy. In those at increased risk of malignancy or with an active non-gastrointestinal malignancy, the benefits and risks of treatment should be considered. Patients should be monitored for small bowel neoplasia. Colorectal polyps may develop during teduglutide therapy; before starting treatment a colonoscopy should be carried out and any polyps removed. Subsequently, a colonoscopy should be carried out at least every 5 years.

Cholecystitis, cholangitis, and cholelithiasis have been reported, and there have been adverse effects on the pancreas such as pancreatitis. Monitoring of the function of the gallbladder and pancreas should be carried out before and during treatment.

Antibodies to teduglutide have developed in some patients, and may cross-react with endogenous glucagon-like peptide-2. Concentrations of C-reactive protein increased when teduglutide therapy was started and then gradually declined with ongoing treatment. The long term impact of these changes is unknown.

Interactions

Teduglutide can increase the absorption of other drugs such as benzodiazepines; increased concentrations of prazepam were noted when teduglutide was started, which led to

deterioration of mental status. Caution is required when teduglutide is used with drugs that require titration or have a narrow therapeutic index.

Pharmacokinetics

Subcutaneous injection of teduglutide has an absolute bioavailability of 88% in healthy subjects, with peak plasma concentrations reached between 3 to 5 hours after a dose. No accumulation is seen after repeated doses. The metabolic pathway of teduglutide is unknown, but it is expected to be degraded into small peptides and amino acids via catabolic pathways, in a similar manner to endogenous glucagon-like peptide-2. Teduglutide is mainly cleared by the kidneys; plasma clearance has a similar value to the glomerular filtration rate. The mean terminal half-life is about 2 hours in healthy subjects and 1.3 hours in patients with short bowel syndrome. Exposure to teduglutide is reduced in patients with moderate hepatic impairment. In those with moderate to severe renal impairment or end-stage renal disease, exposure to teduglutide increases with the degree of impairment. Exposure is increased by a factor of 2.6 in patients with end-stage renal disease compared with healthy subjects.

Tegaserod Maleate *(BANM, USAN, rINNM)*

HTF-919; Maleato de tegaserod; SDZ-HTF-919; Tégasérod, Maléate de; Tegaserod, maleato de; Tegaserodi Maleas; Teracepoda Maneat.

1-[[(5-Methoxyindol-3-yl)methylene]amino]-3-pentylguanidine maleate.

$C_{16}H_{23}N_5O.C_4H_4O_4$=417.5

CAS — 145158-71-0 (tegaserod); 189188-57-6 (tegaserod maleate).

ATC — A06AX06.

ATC Vet — QA06AX06.

UNII — E5XNT3RF5A.

Stability and compatibility. Crushed tablets of tegaserod were found to be stable in water, and apple juice; the latter may mask the taste of the drug. Orange juice, milk, or yogurt were not recommended as vehicles because of incomplete dissolution or uncertainty about stability.[1]

1. Carrier M-N, *et al.* Stability and compatibility of tegaserod from crushed tablets mixed in beverages and foods. *Am J Health-Syst Pharm* 2004; **61**: 1135–42.

Uses and Administration

Tegaserod is a partial agonist at 5-HT_4 receptors and has prokinetic properties. Although it has been withdrawn in most countries because of an apparent high incidence of cardiovascular ischaemic events (see Effects on the Heart, below), it is still licensed in some for use in women below the age of 55 for the short-term treatment of irritable bowel syndrome (p. 1810.3), particularly the constipation-predominant form. It is also used for the treatment of chronic idiopathic constipation (p. 1804.3) in women less than 55 years of age. Efficacy in men and the elderly has not been established.

Tegaserod is given orally as the maleate but doses are expressed in terms of the base; 8.31 mg of tegaserod maleate is equivalent to about 6 mg of tegaserod. It is given in a dose of 6 mg twice daily before food. For irritable bowel syndrome, it is given for a maximum of 12 weeks; treatment should be stopped if no response is seen after 4 weeks.

References.

1. Evans BW, *et al.* Tegaserod for the treatment of irritable bowel syndrome and chronic constipation. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2007 (accessed 17/03/08).

Adverse Effects and Precautions

The most common adverse effects of tegaserod have been gastrointestinal disturbances including abdominal pain, diarrhoea, nausea, vomiting, and flatulence. Diarrhoea generally occurs within the first week of treatment and is usually transient but may be severe. Ischaemic colitis has been reported. Headache, dizziness, migraine, insomnia, fatigue, leg or back pain, and arthropathy have also been commonly reported.

Serious and sometimes fatal cardiovascular ischaemic events such as myocardial infarction, unstable angina pectoris, and stroke have occurred with tegaserod, and have led to its withdrawal from the market in most of the world. Cardiovascular adverse effects may also include hypotension and arrhythmias. Other adverse effects have included effects on the nervous system such as depression, and other gastrointestinal effects including cholelithiasis and dyspepsia.

Treatment has been contra-indicated in patients with a history of cardiovascular disease, bowel obstruction or biliary disease, abdominal adhesions, or diarrhoea, as well as in those with severe renal or moderate to severe hepatic impairment.

Effects on the gastrointestinal tract. Severe diarrhoea, leading to hypovolaemia, hypotension, and syncope has been seen occasionally in patients receiving tegaserod. Some patients required hospitalisation for rehydration, and patients should be advised to stop taking the drug and seek medical attention if severe diarrhoea or associated dizziness or lightheadedness develop. In addition, ischaemic colitis has been reported rarely, and the drug should be stopped immediately in patients who develop symptoms such as rectal bleeding, bloody diarrhoea, or new and worsening abdominal pain.[1] The FDA noted that it had received 20 reports of ischaemic colitis in patients taking tegaserod between August 2002 and March 2004; in 3 cases, the effect only developed after several months (7 to 13) of therapy.[2] However, in reply the manufacturer (*Novartis*) suggested that there was no evidence from post-marketing surveillance to support an increased rate of ischaemic colitis over that normally seen in patients with irritable bowel syndrome, who are at increased risk of this diagnosis, nor any obvious pharmacological mechanism for such an adverse effect.[3]

Effects on the heart. In an analysis of pooled data from 29 studies, 13 out of 11 614 patients taking tegaserod had serious cardiovascular ischaemic events, compared with 1 out of 7031 patients taking placebo. Events included unstable angina pectoris, stroke, and myocardial infarction, one of which was fatal.[1-3] Most of these patients had at least one cardiovascular risk factor, but for some, no cardiovascular disease or risk had been diagnosed at the onset of treatment with tegaserod.[2] Patients taking tegaserod should seek medical attention if they have severe chest pain, dyspnoea, dizziness, sudden onset of weakness, difficulty walking or talking, or any other symptoms suggestive of myocardial infarction or stroke.[1] However, a large observational cohort study[4] involving over 55 000 patients in US general practice could not find any increased risk of cardiovascular event or stroke in users of tegaserod compared with matched controls.

4. Loughlin J, *et al.* Tegaserod and the risk of cardiovascular ischemic events: an observational cohort study. *J Cardiovasc Pharmacol Ther* 2010; **15**: 151–7.

Pharmacokinetics

Tegaserod is rapidly absorbed from the gastrointestinal tract and peak plasma levels occur after about 1 hour. The absolute bioavailability of an oral dose is 10%; this is reduced by the presence of food. Tegaserod is widely distributed into the tissues and is about 98% bound to plasma proteins. Presystemic acid-catalysed hydrolysis in the stomach, and then oxidation and glucuronidation, produces the main metabolite, which is inactive; direct systemic glucuronidation also occurs. Two-thirds of an oral dose is excreted unchanged in the faeces and one-third excreted in the urine primarily as the main metabolite. The terminal half-life of tegaserod is about 11 hours.

$C_{19}H_{27}NO_6S_2$=429.5

CAS — 6504-57-0.

Profile

Tiemonium iodide and tiemonium metilsulfate are quaternary ammonium antimuscarinics with peripheral effects similar to those of atropine (p. 1312.1) and are used in the relief of visceral spasms.

Tiemonium metilsulfate is given in an oral dose of 100 to 300 mg daily in divided doses. It has also been given by intramuscular or slow intravenous injection or rectally as a suppository.

Tiemonium iodide has been used similarly.

UNII — 8R9E4766V4.

Pharmacopoeias. In *Jpn.*

Profile

Timepidium bromide is a quaternary ammonium antimuscarinic with peripheral actions similar to those of atropine (p. 1312.1). It has been given for the symptomatic treatment of visceral spasms in usual oral doses of 30 mg three times daily. It has also been given by subcutaneous, intramuscular, and intravenous injection in a dose of 7.5 mg.

Urinary metabolites of timepidium may cause a reddish coloration of the urine.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Indon.*: Sesden; *Jpn*: Sesden; *Singapore*: Sesden†.

Tiquizium Bromide *(pINN)*

Bromuro de tiquizio; HSR-902; Tiquizii Bromidum; Tiquizio, bromuro de; Tiquizium, Bromure de; Тихизия бромид.

trans-3-(Di-2-thienylmethylene)octahydro-5-methyl-2*H*-quinolizinium bromide.

$C_{19}H_{24}BrNS_2$=410.4

CAS — 71731-58-3.

UNII — 659K6049SF.

Profile

Tiquizium bromide is an antimuscarinic with actions similar to those of atropine (p. 1312.1). It is used as an antispasmodic (p. 1803.3) in the treatment of gastrointestinal spasm, biliary tract disease, and urolithiasis; a suggested oral dose is 5 to 10 mg three times daily.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Jpn*: Thiaton.

Tropisetron *(BAN, rINN)*

Tropisetrón; Tropisétron; Tropisetroni; Tropisetronum; Трописетрон.

CAS — 105826-92-4.

ATC — A04AA03.

ATC Vet — QA04AA03.

UNII — A19338Q2YO.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Tropisetron Hydrochloride). A white or almost white powder. Freely soluble or soluble in water; sparingly soluble in alcohol; very slightly soluble in dichloromethane.

Uses and Administration

Tropisetron is a 5-HT_3 antagonist with an antiemetic action similar to that of ondansetron (p. 1872.2). It is used in the prevention of nausea and vomiting induced by cytotoxic therapy and in the treatment and prevention of postoperative nausea and vomiting (p. 1811.3).

Tropisetron is given as the hydrochloride by slow intravenous injection or infusion, or orally. Doses are expressed in terms of tropisetron base; 5.64 mg of tropisetron hydrochloride is equivalent to about 5 mg of tropisetron base.

For the *prophylaxis* of acute **nausea and vomiting** associated with cytotoxic **chemotherapy** a single dose of 5 mg may be given by slow intravenous injection or infusion on the day of treatment, shortly before chemotherapy. The injection is given over not less than 1 minute; it may be given into a running infusion. For infusion, it is diluted into 100 mL of a suitable infusion fluid (such as sodium chloride 0.9% or glucose 5%), and given over 15 minutes. Subsequent doses of 5 mg daily are given orally, in the morning at least one hour before food, for a further 5 days.

For the *treatment* of **postoperative** nausea and vomiting 2 mg may be given by slow intravenous injection (over not less than 30 seconds), or by infusion (over 15 minutes), within 2 hours of the end of anaesthesia. For *prophylaxis*, the same dose may be given shortly before induction of anaesthesia.

For doses in children, see below.

Administration in children. Tropisetron hydrochloride is used in children to prevent nausea and vomiting induced by cytotoxic chemotherapy; doses are expressed in terms of tropisetron base. Children over 2 years of age have been given tropisetron 200 micrograms/kg (maximum dose 5 mg) before chemotherapy, by intravenous injection over at least 1 minute, or by infusion (at a concentration of 50 micrograms/mL in a suitable infusion fluid, over about 15 minutes). In children weighing less than 25 kg the same dose may be given intravenously once daily for up to a further 4 days as required. In those weighing more than 25 kg, a dose of 5 mg may be given orally once daily for up to a further 5 days; if oral dosage is not possible, 5 mg may be given intravenously.

Fatigue. Tropisetron has been reported to be of benefit in patients with chronic fatigue, see under Uses and Administration of Ondansetron, p. 1873.1.

Pain. For reference to the use of tropisetron in various painful syndromes, see under Uses and Administration of Ondansetron, p. 1873.1.

Pruritus. Tropisetron and other 5-HT_3 antagonists have been investigated for the management of pruritus (see under Ondansetron, p. 1873.1).

Adverse Effects and Precautions

As for Ondansetron, p. 1873.2. Fatigue, abdominal pain, and diarrhoea may also occur. Visual hallucinations, and an increase in blood pressure in patients with pre-existing hypertension, have been noted at high repeated doses. ECG changes such as prolongation of QT interval have been noted with high-dose intravenous tropisetron. The drug should therefore be used with caution in patients with cardiac rhythm or conduction disturbances. Care should be taken when driving or operating machinery. No dosage reduction is considered necessary in renal or hepatic impairment despite possible reductions in clearance.

Carcinogenicity. The manufacturer (*Novartis, UK*) has reported an increased incidence of hepatic neoplasms in male *mice* given high doses of tropisetron but it is suggested that these effects are both species and sex specific.

Effects on the cardiovascular system. For a discussion of the effects of 5-HT_3 antagonists on the cardiovascular system, see under Ondansetron, p. 1873.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies tropisetron as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 07/10/11)

Interactions

Drugs that induce or inhibit hepatic enzymes may affect plasma concentrations of tropisetron. Licensed product information considers that any changes are usually unlikely to be clinically relevant with the recommended doses.

Tropisetron should be used with caution with antiarrhythmics, beta blockers, or drugs likely to prolong the QT interval, including those likely to cause electrolyte disturbances (see Ondansetron, p. 1874.2).

Pharmacokinetics

Tropisetron is well absorbed after oral doses. Peak plasma concentrations occur within 3 hours. Absolute bioavailability depends on the dose since first-pass metabolism is saturable. It is 71% bound to plasma proteins. Tropisetron is metabolised by hydroxylation and conjugation, and metabolites are excreted mainly in the urine with a small amount in the faeces. The cytochrome P450 isoenzyme CYP2D6 is involved in tropisetron metabolism, and shows genetic polymorphism. The elimination half-life is about 8 hours in extensive metabolisers and up to 45 hours in poor metabolisers. Clearance is also reduced in patients with renal impairment.

Preparations

Troxipide *(rINN)*

Troxipida; Troxipidum; Троксипид.

(±)-3,4,5-Trimethoxy-*N*-3-piperidylbenzamide.

$C_{15}H_{22}N_2O_4$=294.4

CAS — 30751-05-4.

ATC — A02BX11.

ATC Vet — QA02BX11.

UNII — W6QJX1Q00Z.

Profile

Troxipide is used for its cytoprotective properties in the treatment of gastritis and peptic ulcer disease (p. 1813.2) in a usual oral dose of 100 mg three times daily, after food.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *China*: Ke Fen Qi (科芬奇); Shuqi (殊奇); *Jpn*: Aplace.

Urogastrone

Anthelone; EGF-URO; Epidermal Growth Factor; Murodermina; Uroanthelone; Uroenterone; Urogastrona; Уроластрон.

CAS — 9010-53-1.

UNII — TZK30RF92W.

Pharmacopoeias. *Chin.* includes monographs for recombinant human epidermal growth factor suitable for external use.

Profile

Urogastrone is a polypeptide first isolated from human urine. Two forms have been identified, β and γ urogastrone. The β form consists of 53 amino acids and is distinguishable from the γ form by an additional terminal arginine residue. The β form is reported to be identical to human epidermal growth factor and this term is widely used in the literature.

Urogastrone inhibits gastric acid secretion and has been tried in the treatment of peptic ulcer disease and other gastrointestinal disorders but its rapid destruction in the stomach has limited its clinical use.

It is a potent stimulator of cellular proliferation and has also been used as an aid to wound healing.

Reviews.
1. Granul-Bilska AT, *et al.* Wound healing: the role of growth factors. *Drugs Today* 2003; 39: 787–800.
2. Klenkler B, Sheardown H. Growth factors in the anterior segment: role in tissue maintenance, wound healing and ocular pathology. *Exp Eye Res* 2004; 79: 677–88.

Gastrointestinal disorders. Intravenous infusion of urogastrone 250 nanograms/kg over 1 hour has been reported[1,2] to reduce the secretion of gastric acid in patients with duodenal ulcer (p. 1813.2) or the Zollinger-Ellison syndrome (p. 1814.3). Ulcer pain was relieved 30 to 60 minutes after the start of the infusion.[2] A dose of 100 nanograms/kg per hour by intravenous infusion has been used with partial success in an infant with microvillous atrophy[3] and was apparently beneficial in an infant with necrotising enteritis.[4]

Human epidermal growth factor has also shown some promise in the treatment of active ulcerative colitis. In a small study,[5] patients received daily enemas containing either recombinant human epidermal growth factor (5 micrograms in 100 mL) or placebo; all patients also received oral mesalazine. Ten of the 12 patients in the urogastrone group were in remission after 2 weeks treatment compared with 1 of the 12 patients in the placebo group, and this benefit was maintained for up to 12 weeks.

Wound healing. For a general discussion of the management of wounds and ulcers, see p. 1690.1.

In a randomised double-blind study in 61 patients with diabetic foot ulcers, adding human epidermal growth factor 0.04% to an ulcer cream containing protein-free bovine blood extract was shown to significantly enhance wound healing and reduce healing time compared with either the cream alone or the cream plus human epidermal growth factor 0.02%.[1] Topical application of recombinant human epidermal growth factor 0.02% has also been reported to reduce pain and promote healing of exfoliated skin lesions in a patient with drug-induced Stevens-Johnson syndrome.[2]

The effect on the rate of wound healing of a cream containing sulfadiazine silver plus recombinant human epidermal growth factor (10 micrograms/mL) was compared with sulfadiazine silver alone in 12 patients each requiring skin grafts at 2 donor sites.[3] The cream containing epidermal growth factor accelerated the rate of epidermal regeneration in all patients and reduced the average time to 100% healing by about 1.5 days. Patients were followed up for a maximum of 1 year after cessation of therapy and no complications or clinical evidence of neoplasia at the healed donor sites occurred.

In contrast, recombinant human epidermal growth factor as an ophthalmic solution containing 30 or 100 micrograms/mL was investigated in patients who had undergone keratoplasty, but the weaker solution had no effect on the rate of re-epithelialisation, and the more concentrated one was actually associated with slower healing.[4]

CGS-9343B (zaldaride maleate); Zaldarida; Zaldaridum; Зальдарид.

(±)-1-[1-[(4-Methyl-4*H*,6*H*-pyrrolo[1,2-*a*][4,1]benzoxazepin-4-yl)methyl]-4-piperidyl]-2-benzimidazolinone.

$C_{26}H_{28}N_4O_2$=428.5

CAS — 109826-26-8 (zaldaride); 109826-27-9 (zaldaride maleate).

UNII — GH66PET6S3.

Profile

Zaldaride is a calmodulin antagonist that has been investigated as the maleate for the treatment of diarrhoea.

Diarrhoea. Studies in patients with travellers' diarrhoea (p. 1805.2) have indicated that zaldaride in oral doses of 20 mg as the maleate four times daily is an effective antidiarrhoeal.[1,2] It was somewhat less effective than loperamide when given without a loading dose,[2] but a regimen of 40 mg initially, followed by 20 mg, about every 6 hours was as effective as loperamide 4 mg initially followed by 2 mg after each unformed stool.[3]

General Anaesthetics

This chapter includes drugs used for the induction and maintenance of general anaesthesia. General anaesthetics are given either by inhalation or by intravenous or occasionally intramuscular injection (see Table 1, below).

Table 1. Classification of general anaesthetics.

Injectable	Inhalational
Barbiturate	*Halogenated*
Methohexital	Chloroform
Thiamylal	Desflurane
Thiopental	Enflurane
	Halothane
Miscellaneous	Isoflurane
Alfadolone	Methoxyflurane
Alfaxolone	Sevoflurane
Etomidate	Trichloroethylene
Ketamine	*Miscellaneous*
Propanidid	Cyclopropane
Propofol	Anaesthetic Ether
Sodium Oxybate	Nitrous Oxide
Tiletamine	Xenon

Uses of General Anaesthetics

General anaesthetics depress the CNS and cause loss of consciousness associated with an inability to perceive pain. An ideal anaesthetic would produce unconsciousness, analgesia, and muscle relaxation suitable for all surgical procedures and would be metabolically inert and rapidly eliminated. No anaesthetic fulfils all these requirements in safe concentrations and it is customary to use several drugs to achieve the required conditions while minimising the risk of toxicity.

The activity of any anaesthetic is dependent on its ability to reach the brain. With inhalational anaesthetics there has to be a transfer from the alveolar space to the blood, then to the brain; recovery is a function of the removal of the anaesthetic from the brain. With injectable anaesthetics their activity is similarly dependent on their ability to penetrate the blood-brain barrier and recovery in turn is governed by their redistribution and excretion. The potency of inhalational anaesthetics is often expressed in terms of *minimum alveolar concentrations*, known as MAC values. The MAC of an anaesthetic is the concentration at 1 atmosphere that will produce immobility in 50% of subjects exposed to a noxious stimulus. Values given under the individual monographs are based on use without nitrous oxide as the latter can reduce the MAC. Other factors including age, body temperature, and concurrent medication such as premedicants and opioid analgesics can also affect MAC values.

Anaesthesia. Many drugs are involved in achieving and maintaining conditions suitable for surgery. Conventional general anaesthesia may be divided into several stages including:

- premedication
- induction
- muscle relaxation and intubation
- maintenance
- analgesia
- reversal

A brief outline of the drugs typically used in each stage follows.

For **premedication**, benzodiazepines such as diazepam, lorazepam, midazolam, or temazepam, and some phenothiazines such as promethazine or alimemazine, may be given to sedate and relieve *anxiety* in apprehensive patients. Butyrophenones such as droperidol have also been used. The benzodiazepines have useful amnestic and muscle-relaxant properties and short-acting oral forms are common in current regimens. The phenothiazines and butyrophenones are rarely used now although their antiemetic actions may be useful to control *postoperative nausea and vomiting* (p. 1811.3). Cloral hydrate is still used in some countries for pre-operative sedation, particularly in children. The use of barbiturates has largely ceased. For sedation of children the oral route is often preferred to injections, or the rectal route may be used in exceptional circumstances.

Antimuscarinics such as atropine, glycopyrronium, and hyoscine may be given to inhibit excessive *bronchial* and *salivary secretions* induced by intubation, upper airway surgery, and some anaesthetics, although such use is less common nowadays. Antimuscarinics are also given as premedicants to reduce the intra-operative bradycardia and hypotension induced by drugs such as suxamethonium, halothane, or propofol or by vagal stimulation. Hyoscine also provides some degree of amnesia.

Opioids, including morphine and its derivatives, papaveretum and pethidine, have been widely used before surgery to reduce anxiety, smooth induction of anaesthesia, reduce overall anaesthetic requirements, and provide pain relief during and after surgery. The routine use of opioids as premedicants is now rare and generally restricted to patients already in pain. However, they continue to find a role at induction (below).

Patients may also be given drugs that reduce the danger from regurgitation and *aspiration* of gastric contents (see Aspiration Syndromes, p. 1804.2), such as the histamine H_2-antagonists, cimetidine and ranitidine, and the proton pump inhibitor, omeprazole. Other drugs used include sodium citrate to neutralise gastric acidity and metoclopramide to stimulate gastric emptying. Cardiovascular drugs may be needed during surgery to control *blood pressure* and counteract *arrhythmias*.

The aim of **induction** is to produce anaesthesia rapidly and smoothly. Induction may be achieved with intravenous or inhalational anaesthetics but intravenous induction may be more pleasant for the patient. Intravenous drugs used include the barbiturate thiopental, the benzodiazepine midazolam, and other anaesthetics such as etomidate, propofol, or ketamine. Small doses of short-acting opioids, for example alfentanil, fentanyl, or remifentanil, given before or at induction allow the use of smaller induction doses of some drugs used for anaesthesia, and this technique is particularly suitable for poor-risk patients.

After induction, **muscle relaxation** with a rapidly acting depolarising neuromuscular blocker such as suxamethonium aids **intubation** of the patient. Longer acting, competitive neuromuscular blockers may then be given to allow procedures such as abdominal surgery to be carried out under lighter anaesthesia. For more detail, see Anaesthesia, p. 2028.1.

Maintenance of anaesthesia may be achieved with an inhalational anaesthetic, an intravenous anaesthetic, or an intravenous opioid, either alone or in combination.

Opioid analgesics may also be given for **analgesia** as supplements during general anaesthesia (see also Balanced Anaesthesia, under Anaesthetic Techniques, below). Long-acting opioids such as morphine or papaveretum may cause postoperative respiratory depression. The short-acting opioid fentanyl, and its congeners alfentanil and sufentanil, appear to produce fewer circulatory changes and may be preferred to other opioids, especially in cardiovascular surgery; remifentanil may be valuable for its very short duration of action. Various combinations of analgesic techniques, including the use of pre-emptive analgesia, are used or are being investigated for the management of surgical pain (see Postoperative Analgesia, p. 6.1).

At the end of surgery drugs are sometimes given to accelerate recovery by **reversal** of the effects of the various agents used during anaesthesia. The *neuromuscular block* produced by competitive neuromuscular blockers may be reversed with anticholinesterases such as neostigmine and edrophonium but atropine or glycopyrronium are also needed to prevent bradycardia and other muscarinic actions developing. The selective relaxant binding agent, sugammadex, is also used for the reversal of neuromuscular blockade induced by rocuronium or vecuronium. The opioid antagonist naloxone has been given to reverse opioid-induced *respiratory depression*. However, it may antagonise the analgesic effects of the opioids in the control of postoperative pain and the increasing use of short-acting intravenous opioid analgesics should reduce the need for its use. Flumazenil is a benzodiazepine antagonist that is used to reverse the *central sedative effects* of benzodiazepines in anaesthetic procedures.

ANAESTHETIC TECHNIQUES. A balanced combination of drugs with different actions is often used to provide the various components of general anaesthesia including unconsciousness, muscle relaxation, and analgesia. This technique, termed **balanced anaesthesia**, has been reported to minimise intra-operative cardiovascular depression, to facilitate a rapid return of consciousness, and to have a low incidence of postoperative adverse effects such as nausea and vomiting, and excitation. Typically an opioid is given before or with induction and anaesthesia is induced using nitrous oxide and an intravenous barbiturate such as thiopental. The opioid is then given in small incremental doses to achieve and maintain adequate analgesia during surgery. Opioid analgesics commonly used in this technique include morphine, fentanyl, sufentanil, and alfentanil; buprenorphine and nalbuphine have also been used.

In **total intravenous anaesthesia** (TIVA), induction and maintenance of anaesthesia is achieved with one or more anaesthetics given intravenously. This allows high inspired oxygen concentrations in situations where hypoxaemia may otherwise occur, and is advantageous in surgery where delivery of inhaled anaesthetic may be difficult (for example in bronchoscopy). Combinations used in TIVA include propofol with alfentanil or fentanyl, and midazolam with alfentanil. Neuromuscular blockers are given to produce muscle relaxation but there can be difficulty in assessing the depth of anaesthesia in patients who are paralysed for mechanical ventilation, and there have been reports of awareness during procedures under TIVA (see also Intraoperative Awareness, under Precautions, p. 1897.3). Target-controlled infusion (TCI) systems are used in some countries to control the speed of induction and depth of anaesthesia by specifying target blood concentrations.

Although now largely obsolete, use of a neuroleptic with an opioid analgesic produces an altered state of consciousness known as **neuroleptanalgesia** in which the patient is calm and indifferent to the surroundings yet is responsive to commands. The technique was used for diagnostic or therapeutic procedures such as minor surgery, endoscopy, and changing dressings. Neuroleptanalgesia can be converted to **neuroleptanaesthesia** by the concurrent administration of nitrous oxide in oxygen; a muscle relaxant may also be included. Neuroleptanaesthesia is particularly useful if the patient's cooperation is required, as consciousness soon returns once the nitrous oxide is stopped. The neuroleptic most commonly used was droperidol and it was usually given with fentanyl although other opioids have also been used. These procedures have since evolved into **conscious sedation** and **monitored anaesthesia care** techniques using newer drugs such as propofol or remifentanil, with or without midazolam.

Ketamine used alone can produce a state of **dissociative anaesthesia** similar to that of neuroleptanalgesia in which the patient may appear to be awake but is unconscious. Marked analgesia and amnesia are produced, but there may be an increase in muscle tone and emergence reactions. Dissociative anaesthesia is considered suitable for use in various diagnostic procedures, dressing changes, and in minor surgery not requiring muscle relaxation.

Techniques using **local anaesthetics** are discussed on p. 1977.2.

Adverse Effects of General Anaesthetics and their Treatment

The complex regimens used in general anaesthesia may produce complications both during and after the procedure. Adverse effects that may occur with general anaesthesia include involuntary muscle movements, hiccup, coughing, bronchospasm, laryngospasm, apnoea, respiratory depression, hypotension, cardiac arrhythmias, and mild hypothermia. Regurgitation and aspiration of gastric contents (Mendelson's syndrome) is a potential cause of morbidity

and mortality associated with general anaesthesia, especially in obstetrics and in emergency surgery (see Aspiration Syndromes, p. 1804.2).

After general anaesthesia many patients will be drowsy and mental performance may be impaired for at least 24 hours. Postoperative nausea with or without vomiting is common in the absence of antiemetic prophylaxis; nausea may last for 2 days but vomiting seldom persists beyond the first day (for details of postoperative vomiting and its management, see p. 1811.3). Other relatively common postanaesthetic effects include anorexia, malaise, fatigue, dizziness, and headache. Delirium has been noted in at least 10% of elderly general surgical patients and in up to 50% of elderly patients undergoing hip fracture repair.

Sore throat is frequent in patients who have been intubated or have had a throat pack inserted. Dry mouth as a result of premedication can add to the patient's discomfort. Manipulations for the maintenance of a clear airway may result in postoperative jaw pain.

Muscle pain, typically involving the neck, shoulders, and upper abdomen, may occur if the neuromuscular blocker suxamethonium has been given. It is usually worse on the second postoperative day and may last up to 6 days. Shoulder ache after laparoscopy resolves after 24 hours; it is due to accumulation of carbon dioxide under the diaphragm. Backache may occur after epidural or spinal anaesthesia. Urinary retention may follow regional block, cystoscopic or gynaecological surgery, or when there is prostatism.

Malignant hyperthermia (malignant hyperpyrexia—see under Dantrolene, p. 2024.1) is a rare but potentially fatal complication of general anaesthesia that may be induced by inhalational anaesthetics (mainly halogenated hydrocarbons).

Hepatotoxicity may occur in patients who are sensitised to halogenated anaesthetics; halothane has been associated with severe hepatotoxicity and is largely superseded by newer agents.

Sensitisation of the myocardium to beta-adrenergic stimulation occurs with some anaesthetics.

There has been concern over the possible danger to anaesthetists, dentists, and other personnel from exposure to volatile anaesthetics.

Effects on neurodevelopment. There has been some concern[1,2] that exposure to anaesthetics might have adverse effects on neurological and cognitive development of neonates and young children. Results of studies have been conflicting, and further research is needed; however, it has been suggested that elective procedures using general anaesthesia should be avoided below the age of 3 years.[2]

Hypersensitivity. Type I hypersensitivity reactions related to various aspects of the procedure have occurred during general anaesthesia.[1–4] In most patients the release of histamine and other mediators such as prostaglandins and leukotrienes is of no clinical importance but in a few susceptible individuals anaphylaxis may result; the mortality rate is estimated to range from 3 to 9%. Anaphylaxis may occur at any time, with 90% of reactions appearing at induction of anaesthesia.[4]

Neuromuscular blockers are associated with the highest (50 to 70%) incidence of anaphylaxis, followed by latex (12 to 20%) and antibacterials (15%).[4,5] (For details of hypersensitivity reactions associated with neuromuscular blockers, see under Adverse Effects of Suxamethonium, p. 2038.2.) Anaphylactic reactions to the general anaesthetics thiopental and propofol are uncommon, with an estimated incidence of 1 in 30 000 and 1 in 60 000, respectively; reactions to etomidate and ketamine are very rare and there appear to be no published reports associated with halogenated volatile anaesthetics.[3–6] Other agents used during general anaesthesia that are rarely associated with anaphylaxis include local anaesthetics, opioid analgesics, NSAIDs, colloids, contrast media, and disinfectants.[3–6]

Many factors to identify those at risk have been proposed over the years along with suggested modifications for anaesthetic management. Routine prophylaxis with histamine H_1- and histamine H_2-antagonists has been advocated by some as part of anaesthetic management but others recommend such use only in susceptible patients with known risk factors;[7] however, there is no evidence that prophylactic treatment with H_1-and H_2-antagonists and corticosteroids actually decreases the severity of anaphylaxis.[5,7,8] Preventing re-exposure to implicated agents and avoiding other known causes of histamine release are the mainstay of prophylaxis in susceptible patients.[5,8]

Nausea and vomiting. For a discussion on postoperative nausea and vomiting and its management, see p. 1811.3.

Shivering and its treatment. Postoperative shivering, also referred to as spontaneous postanaesthetic tremor, can occur in up to 65% of patients recovering from general anaesthesia;[1,2] its aetiology and relationship to thermoregulation is unclear.[1,3,4] Postoperative shivering may be part of a more generalised neurological disturbance associated with anaesthesia.[1] It also occurs after regional anaesthesia, especially when given epidurally, but this is probably produced by different mechanisms.[3] Muscular activity during shivering greatly increases metabolic rate, oxygen consumption, and cardiac output and may cause complications in patients with cardiac or respiratory disorders. It can also strain surgical sutures, raise intra-ocular pressure, and impede haemodynamic monitoring.

Although the relationship between postoperative shivering, body temperature, and heat loss is unclear, patients may respond to **warming** their environment and the use of blankets.[1,3,5] Postoperative shivering may sometimes be an appropriate thermoregulatory response to a low body temperature,[3] and it is important before starting therapy to check the patient's temperature and take suitable steps to avoid hypothermia.[1]

Many **drugs** have been tried for the management of postoperative shivering including the central and respiratory stimulant doxapram, the α_2-agonist clonidine, and the opioid analgesic pethidine.[2,4,6,7] Reviews have discussed[1–4,7] other opioids that have been tried including morphine, alfentanil, butorphanol, fentanyl, and sufentanil but studies suggest that not all opioids are effective or that some may only be effective when given epidurally. However, this may be due to the use of insufficient doses rather than a true difference between opioids.[8] Tramadol and nefopam have also been tried.[2,6,7] Neuromuscular blockers have been used after cardiac surgery in order to reduce cardiovascular stress.[9] Vecuronium might be preferable to pancuronium as it does not increase myocardial work and may be associated with fewer complications.[10] However, as profound neuromuscular block is required to inhibit shivering, repeated or higher doses of vecuronium might be required to prevent recurrence. Other drugs that have been investigated include ketanserin,[2] ketamine,[11,12] and magnesium sulfate.[2]

Precautions for General Anaesthetics

Patients with impaired function of the adrenal cortex, for example, those who are being treated, or have recently been treated, with corticosteroids, may develop hypotension with the stress of anaesthesia. Treatment with corticosteroids, pre-operatively and postoperatively, may be necessary. Patients taking other long-term medication such as antiplatelet drugs, oral anticoagulants, potassium-sparing diuretics, ACE inhibitors, angiotensin II receptor antagonists, oestrogens, MAOIs, or lithium may need to change their dosage or therapy, or stop altogether, before major elective surgery.

Patients with chronic diseases such as diabetes or hypertension, or who are taking antivirals for HIV infection, may need adjustment to their therapy before anaesthesia. Anaesthetics should be used with caution in patients with cardiac, respiratory, renal, or hepatic impairment and care may be needed in elderly or obese patients.

Patients should not undertake hazardous tasks such as driving for at least 24 hours after a general anaesthetic; alcohol should also be avoided.

Children. For concerns about the potential effects of general anaesthesia on neurodevelopment in young children, see under Adverse Effects and Treatment, above.

Intraoperative awareness. Intraoperative awareness during general anaesthesia, defined as consciousness and explicit memory of surgical events, has a reported incidence of 0.1 to 0.2% in adults[1,2] and 0.8% in children.[3,4] Risk factors include light anaesthesia and a history of awareness.[1] Neuromuscular blockade-induced paralysis may also contribute by preventing the patient giving signs of awareness.[2] Recommended preventive measures include premedication with sedative or amnestic drugs, induction with sufficient doses of intravenous anaesthetic, the use of effective analgesic techniques during surgery, avoiding or minimising the use of neuromuscular blockers, the use of potent inhalational anaesthetics instead of total intravenous anaesthesia, and ensuring adequate concentrations of inspired anaesthetic gas.[2] The use of brain function monitors to determine depth of anaesthesia is controversial, since none has been proven to be uniformly reliable;[2] some authorities[5,6] advocate against their routine use, and instead recommend the use of clinical techniques (such as checking purposeful or reflex movement) and conventional monitoring systems (such as ECG, blood pressure, heart rate, end-tidal anaesthetic concentration, and capnography).

Interactions of General Anaesthetics

Sensitisation of the myocardium to beta-adrenergic stimulation occurs with some anaesthetics and ventricular fibrillation may occur if *sympathomimetics* such as adrenaline and isoprenaline are also used. Enhanced hypotensive effects may result when anaesthetics are given with *ACE inhibitors*, *tricyclic antidepressants* (which may also increase the risk of arrhythmias), *MAOIs* (see also Anaesthesia, under Precautions for Phenelzine, p. 444.1), *antihypertensives*, *antipsychotics*, or *beta blockers*. The effects of *competitive neuromuscular blockers* may be increased by inhalational anaesthetics. The use of anaesthetics with other *CNS depressant drugs* such as those used for premedication may produce synergistic effects on the CNS and, in some cases, a smaller dose of general anaesthetic should be given.

Alfadolone Acetate *(BANM, rINNM)*

Acetato de alfadolona; Alfadolona, acetato de; Alfadolone, Acétate d'; Alfadoloni Acetas; Alphadolone Acetate; GR-2/1574; Альфадолона Ацетат.

3α,21-Dihydroxy-5α-pregnane-11,20-dione 21-acetate.

$C_{23}H_{34}O_5$=390.5.

CAS — 14107-37-0 (alfadolone); 23930-37-2 (alfadolone acetate).

UNII — 00TN4GS00S.

Pharmacopoeias. In *BP(Vet)*.

BP(Vet) 2014: (Alfadolone Acetate). A white to creamy white powder. Practically insoluble in water and in petroleum spirit; soluble in alcohol; freely soluble in chloroform.

Profile

Alfadolone acetate has been used to enhance the solubility of alfaxalone (below). It possesses some anaesthetic properties and is considered to be about half as potent as alfaxalone.

Alfaxalone *(BAN, rINN)*

Alfaksaloni; Alfaxalon; Alfaxalona; Alfaxalonum; Alphaxalone; GR-2/234; Альфаксалон.

3α-Hydroxy-5α-pregnane-11,20-dione.

$C_{21}H_{32}O_3$=332.5.

CAS — 23930-19-0.

ATC — N01AX05.

ATC Vet — QN01AX05.

UNII — BD07M97B2A.

NOTE. The name Saffan has been used as a trade mark for mixtures of alfadolone acetate with alfaxalone.

Pharmacopoeias. In *BP(Vet)*.

BP(Vet) 2014: (Alfaxalone). A white to creamy white powder. Practically insoluble in water and in petroleum spirit; soluble in alcohol; freely soluble in chloroform.

Profile

Alfaxalone was formerly used with alfadolone acetate (above) 'Althesin', as an intravenous anaesthetic for induction and maintenance of general anaesthesia.

Adverse reactions associated with polyoxyl castor oil (present as a vehicle) led to the general withdrawal of alfaxalone with alfadolone acetate from human use. It is still used in veterinary medicine.

$CHCl_3$=119.4.

CAS — 67-66-3.

ATC — N01AB02.

ATC Vet — QN01AB02.

UNII — 7V31YC746X.

Pharmacopoeias. In *Br.*, *Chin.*, and *Viet.*

BP 2014: (Chloroform). A colourless volatile liquid with a characteristic odour. Not more than 5.0% v/v distils below 60 degrees and the remainder distils at 60 degrees to 62 degrees. It contains 1.0 to 2.0% v/v of ethyl alcohol; amylene 50 micrograms/mL is permitted as an alternative to ethyl alcohol.

Slightly soluble in water; miscible with dehydrated alcohol, with ether, with fixed and volatile oils, and with most other organic solvents. Store in containers with glass stoppers or other suitable closures. Protect from light. The label should state whether it contains ethyl alcohol or amylene.

Stability. The addition of a small percentage of alcohol greatly retards the gradual oxidation that occurs when chloroform is exposed to air and light, and which results in its becoming contaminated with the very poisonous carbonyl chloride (phosgene) and with chlorine; the alcohol also serves to decompose any carbonyl chloride that may have been formed.

From a study[1] of chloroform losses from chloroform water and from 6 typical BPC mixtures under various conditions of storage the following shelf-lives were recommended:

- chloroform solutions and non-sedimented mixtures could be stored in well-closed well-filled containers for 2 months at ambient temperatures
- when stored in partially-filled containers and periodically opened the shelf-life should not exceed 2 weeks
- sedimented mixtures could be stored for 2 months in well-closed well-filled containers, but because loss of chloroform could be expected in containers periodically opened such mixtures should be prepared as required or packed in their final containers
- for chloroform-containing mixtures in the home a shelf-life of 2 weeks was suggested

1. Lynch M, *et al.* Chloroform as a preservative in aqueous systems: losses under "in-use" conditions and antimicrobial effectiveness. *Pharm J* 1977; 219: 507–10.

Storage. It has been recommended[1] that if the period of use would exceed 6 weeks, PVC bottles should not be used for storing or dispensing: Chloroform and Morphine Tincture, or aqueous mixtures containing more than 5% thereof; mixtures or dispersions in which chloroform is present in excess of its aqueous solubility; aqueous mixtures containing chloroform and high concentrations of electrolytes; or of mixtures containing chloroform water.

1. Anonymous. Plastics medicine bottles of rigid PVC. *Pharm J* 1973; 210: 100.

Uses and Administration

Chloroform is a volatile halogenated anaesthetic that was used by inhalation, but safer drugs are now preferred in general anaesthesia.

Chloroform is used as a carminative and as a flavouring agent and preservative. For these purposes it is usually employed as Chloroform Spirit (BP 2014) or Double-strength Chloroform Water (BP 2014) but doubts have been cast on the safety of the long-term use of chloroform in mixtures.

Externally, chloroform has a rubefacient action.

Chloroform is also used as a solvent.

Anaesthesia. An historical review of the use of chloroform in clinical anaesthesia.[1]

1. Payne JP. Chloroform in clinical anaesthesia. *Br J Anaesth* 1981; 53: 115–155.

Adverse Effects and Precautions

Chloroform depresses respiration and produces hypotension. Cardiac output is reduced and arrhythmias may develop. Poisoning can lead to respiratory depression and cardiac arrest. Delayed hepatotoxic and nephrotoxic reactions have occurred 6 to 24 hours after a dose; symptoms may include abdominal pain, vomiting, and, at a later stage, jaundice.

Liquid chloroform is irritant to the skin and mucous membranes and may cause burns if spilt on them. Suitable precautions should be taken to avoid skin contact with chloroform as it can penetrate skin and produce systemic toxicity. Chloroform is not flammable. Care should be taken not to vaporise chloroform in the presence of a flame because of the production of toxic gases.

In the UK medicinal products are limited to a chloroform content of not more than 0.5% (w/w or v/v as appropriate) of chloroform. Exceptions include supply by a doctor or dentist, or in accordance with his prescription, to a particular patient, and supply for anaesthetic purposes.

In the USA the FDA has banned the use of chloroform in medicines and cosmetics, because of reported carcinogenicity in *animals*. It has also been withdrawn from systemic use in other countries.

The sale within or import into England and Wales and Scotland of food containing any added chloroform is prohibited.

See also Adverse Effects and Precautions for General Anaesthetics, p. 1896.3.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving chloroform, and the last available guidance from the American Academy of Pediatrics[1] considered that it was therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 25/05/04)

Poisoning. There has been a report[1] of a 19 year-old man who drank about 75 mL of chloroform in an attempted suicide; he recovered after supportive care and intravenous acetylcysteine therapy. Another report[2] described a 46 year-old woman with chronic alcoholism who developed acute liver failure and rhabdomyolysis after chloroform inhalation and binge drinking; she died despite supportive care.

C_3H_6=42.08

CAS — 75-19-4.

UNII — 99TB643425.

Pharmacopoeias. In *US*.

USP 36: (Cyclopropane). A colourless highly flammable gas with a characteristic odour and pungent taste. Freely soluble in alcohol; soluble in fixed oils. One volume dissolves in about 2.7 volumes of water at 15 degrees.

Stability. CAUTION. Mixtures of cyclopropane with oxygen or air at certain concentrations are explosive. Cyclopropane should not be used in the presence of an open flame or of any electrical apparatus liable to produce a spark. Precautions should be taken against the production of static electrical discharge.

Storage and supply. Cyclopropane is supplied compressed in metal cylinders. National standards are usually in operation for the labelling and marking of such cylinders.

Uses and Administration

Cyclopropane is an anaesthetic that has been given by inhalation for analgesia and induction and maintenance of general anaesthesia. It produces skeletal muscle relaxation, is non-irritant, and induction and recovery are rapid, but it is difficult to use and handle and other anaesthetics are generally preferred. Because of the risk of explosion, it has usually been given by means of a closed circuit. It has a minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) of 9.2%.

Adverse Effects and Precautions

Cyclopropane depresses respiration to a greater extent than many other anaesthetics. Laryngospasm, cardiac arrhythmias, or hepatic injury may occur. Cyclopropane increases the sensitivity of the heart to sympathomimetic amines. Malignant hyperthermia has also been reported. Postoperative nausea, vomiting, and headache are frequent.

Cyclopropane should be used with caution in patients with bronchial asthma and cardiovascular disorders. Premedication with atropine may be advisable to reduce vagal tone.

See also Adverse Effects and Precautions for General Anaesthetics, p. 1896.3.

Abuse. Two of 4 deaths from abuse of volatile anaesthetics in operating rooms were attributed to cyclopropane.[1]

1. Bass M. Abuse of inhalation anesthetics. *JAMA* 1984; 251: 604.

Malignant hyperthermia. Malignant hyperthermia has been associated with cyclopropane.[1]

1. Lipe PJ, *et al.* Malignant hyperthermia triggered by cyclopropane during cesarean section. *Anesthesiology* 1982; 56: 144–6.

Interactions

Care is advised if adrenaline or other sympathomimetics are given during cyclopropane anaesthesia. Potentiation of competitive neuromuscular blockers occurs after use of cyclopropane.

$C_3H_2F_6O$=168.0
CAS — 57041-67-5.
ATC — N01AB07.
ATC Vet — QN01AB07.
UNII — CRS35BZ94Q.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Desflurane). A clear, colourless, mobile, heavy liquid. B.p. about 22 degrees. Practically insoluble in water; miscible with anhydrous alcohol. Store in a glass bottle fitted with a polyethylene-lined cap. Before opening the bottle, cool the contents to below 10 degrees.

USP 36: (Desflurane). Store in airtight containers at a temperature of 20 to 25 degrees, excursions permitted between 15 degrees and 30 degrees. Replace cap securely after each use. Protect from light.

Uses and Administration

Desflurane is a volatile halogenated anaesthetic given by inhalation. It is structurally similar to isoflurane and has anaesthetic actions similar to those of halothane (p. 1902.2). The minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) ranges from about 6% in the elderly to about 11% in infants. It is non-flammable and non-explosive in clinical concentrations but, because of its low boiling-point, it must be delivered by a special vaporiser, preferably within a closed circuit system.

Desflurane is used for induction and maintenance of general anaesthesia (p. 1896.1), but because of its pungency is not recommended for induction in children. Concentrations of 4 to 11% v/v have been used for induction and usually produce surgical anaesthesia in 2 to 4 minutes. Concentrations of 2 to 6% v/v with nitrous oxide or 2.5 to 8.5% v/v in oxygen or oxygen-enriched air may be used to maintain anaesthesia. Higher concentrations of desflurane have been used but it is important to ensure adequate oxygenation; concentrations in excess of 17% v/v are not recommended. For concentrations used in patients with hepatic or renal impairment, see below.

As with other volatile halogenated anaesthetics supplemental neuromuscular blockers may be required. Recovery from anaesthesia is reported to be more rapid than with other halogenated anaesthetics.

Administration in children. Although desflurane is not recommended for induction of anaesthesia in children, it is used for the maintenance of anaesthesia in this group; concentrations given are as for adults (see Uses and Administration, above).

Administration in hepatic or renal impairment. Desflurane concentrations of 1 to 4% v/v in oxygen and nitrous oxide have been used in patients with chronic renal or hepatic impairment and during renal transplantation surgery.

Anaesthesia. The characteristics of desflurane have been reviewed.[1-6] Its advantages are considered to include rapid induction and emergence from anaesthesia, and minimal metabolism makes end-organ toxicity unlikely. Emergence from anaesthesia and recovery of psychomotor and cognitive skills with desflurane is more rapid than after anaesthesia with other halogenated volatile anaesthetics such as isoflurane and possibly than after the intravenous anaesthetic propofol. This is considered to be of particular advantage for outpatient treatment, but studies so far have found no difference in time to discharge with desflurane or other general anaesthetics. Furthermore, the incidence of nausea and vomiting with desflurane is significantly greater than after the use of propofol. Desflurane's pungency may also limit its use for induction especially in children, although it is suitable for maintenance in this group and may be particularly suitable for neonates.[4]

Status epilepticus. For mention of the use of desflurane in the management of refractory status epilepticus, see p. 510.2.

Adverse Effects and Precautions

As with other halogenated anaesthetics, respiratory depression, hypotension, and arrhythmias may occur. Desflurane may rarely precipitate malignant hyperthermia in susceptible individuals; patients with known or suspected susceptibility to malignant hyperthermia should not be anaesthetised with desflurane. It appears to sensitise the myocardium to sympathomimetics to a lesser extent than halothane or enflurane. Nausea and vomiting have been reported in the postoperative period.

Desflurane is irritant to the airways and may provoke breath holding, apnoea, coughing, increased salivation, and laryngospasm. It is therefore not recommended for induction of anaesthesia in paediatric patients.

Desflurane may increase CSF pressure and should therefore be used with caution in patients with, or at risk of, raised intracranial pressure. In children with neuromuscular disease, particularly Duchenne muscular dystrophy, halogenated anaesthetics have been associated with very rare cases of hyperkalaemia resulting in cardiac arrhythmias and death during the postoperative period.

In order to minimise the risk of developing elevated carboxyhaemoglobin levels carbon dioxide absorbents in anaesthetic apparatus should not be allowed to dry out when delivering volatile anaesthetics such as desflurane (see below).

See also Adverse Effects and Precautions of General Anaesthetics, p. 1896.3 and p. 1897.3.

Carbon dioxide absorbents. Significant carboxyhaemoglobinaemia may develop rarely during anaesthesia with volatile anaesthetics given by circle breathing systems containing carbon dioxide absorbents.[1] The effect is only seen when the absorbent has become excessively dried out. The use of barium hydroxide lime (which is not available in the UK) as an absorbent produces more carbon monoxide than soda lime, particularly at low water content. No cases of this complication had been reported to date in the UK.

1. CSM/MCA. Safety issues in anaesthesia: volatile anaesthetic agents and carboxyhaemoglobinaemia. *Current Problems* 1997; 23: 7. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023230&RevisionSelectionMethod=LatestReleased (accessed 16/05/06)

Effects on the cardiovascular system. A review[1] of *animal* and human studies concluded that the cardiorespiratory effects of desflurane were similar to those of isoflurane but that there might be better control of arterial pressure with desflurane during stressful stimuli. A study[2] in patients undergoing coronary artery bypass surgery showed that a state of haemodynamic stability suitable for patients at risk of myocardial ischaemia could be maintained when desflurane was used with the opioid analgesic fentanyl.

2. Parsons RS, *et al.* Comparison of desflurane and fentanyl-based anaesthetic techniques for coronary artery bypass surgery. *Br J Anaesth* 1994; 72: 430–8.

Effects on the liver. Although considered to be less hepatotoxic than some other halogenated anaesthetics (see under Adverse Effects of Halothane, p. 1902.3), delayed hepatotoxicity occurred in a 65-year-old woman after maintenance anaesthesia involving desflurane.[1] She had received halothane on two previous occasions which may have caused sensitisation. A fatal case[2] of acute liver failure associated with desflurane anaesthesia has been reported in a 53-year-old woman. She had significantly raised serum-alanine aminotransferase concentrations on first exposure but this was attributed to antibacterial toxicity; however, on second exposure 10 days later, she developed acute liver failure 96 hours after surgery and died despite supportive treatment. Hepatotoxicity has also been reported[3] after desflurane anaesthesia in a 15-month-old boy who had previously received isoflurane on two occasions, although it has been suggested[4] that this was more likely due to concomitant paracetamol therapy. Investigation of hepatocellular integrity (by measuring glutathione transferase alpha) in 30 women given desflurane indicated a mild subclinical disturbance.[5]

2. Chin MW, *et al.* Desflurane-induced acute liver failure. *Med J Aust* 2008; 189: 293–4.
3. Côté G, Bouchard S. Hepatotoxicity after desflurane anesthesia in a 15-month-old child with Mobius syndrome after previous exposure to isoflurane. *Anesthesiology* 2007; 107: 843–5.
4. Her C. Acetaminophen-induced, not desflurane-induced, hepatotoxicity. *Anesthesiology* 2008; 109: 570–1.
5. Tiainen P, *et al.* Changes in hepatocellular integrity during and after desflurane or isoflurane anaesthesia in patients undergoing breast surgery. *Br J Anaesth* 1998; 80: 87–9.

Effects on the respiratory tract. The irritant effect of desflurane on the lungs limits its role in the induction of anaesthesia, especially in children. Pre-operative use of nebulised lidocaine 4% failed to alleviate the response[1] although pretreatment with intravenous opioids may reduce the irritation.[2]

1. Bunting HB, *et al.* Effect of nebulized lignocaine on airway irritation and haemodynamic changes during induction of anaesthesia with desflurane. *Br J Anaesth* 1995; 75: 631–3.
2. Kong CF, *et al.* Intravenous opioids reduce airway irritation during induction of anaesthesia with desflurane in adults. *Br J Anaesth* 2000; 85: 364–7.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies desflurane as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 04/10/11)

Interactions

The effects of competitive neuromuscular blockers such as atracurium are enhanced by desflurane (see p. 2032.3). Lower doses of desflurane are required in those receiving opioids, benzodiazepines or other sedatives. Care is advised if adrenaline or other sympathomimetics are given to patients during desflurane anaesthesia.

See also Interactions of General Anaesthetics, p. 1897.3.

References.

1. Dale O. Drug interactions in anaesthesia: focus on desflurane and sevoflurane. *Baillieres Clin Anaesthesiol* 1995; 9: 105–17.

Pharmacokinetics

Desflurane has a low blood/gas partition coefficient and on inhalation its absorption, distribution, and elimination are reported to be more rapid than for other halogenated anaesthetics such as isoflurane or halothane. It is excreted mainly unchanged through the lungs. A small amount diffuses through the skin. About 0.02% of inhaled desflurane is metabolised in the liver and trichloroacetic acid has been detected in the serum and urine of patients given desflurane.

Pharmacopoeias. In *Jpn* and *US.*

USP 36: (Enflurane). A clear colourless volatile liquid having a mild sweet odour. Non-flammable. Distilling range 55.5 degrees to 57.5 degrees. Slightly soluble in water; miscible with organic solvents, with fats, and with oils. Store in airtight containers at a temperature not exceeding 40 degrees. Protect from light.

Uses and Administration

Enflurane is a volatile halogenated anaesthetic given by inhalation. It is an isomer of isoflurane. It has anaesthetic actions similar to those of halothane (p. 1902.2). Enflurane has a minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) ranging from 1.7% in middle age to 2.5% in children. Enflurane is given using a calibrated vaporiser for induction and maintenance of general anaesthesia (p. 1896.1); it is also used in

subanaesthetic doses to provide analgesia in obstetrics and other painful procedures (below).

To avoid CNS excitement a short-acting barbiturate or other intravenous induction agent is recommended before the inhalation of enflurane. Anaesthesia may be induced using enflurane alone with oxygen or in nitrous oxide-oxygen mixtures. In general, enflurane concentrations of 2 to 4.5% v/v produce surgical anaesthesia in 7 to 10 minutes. Anaesthesia may be maintained with a concentration of 0.5 to 3% v/v of enflurane; a concentration of 3% v/v should not be exceeded. Although enflurane is reported to possess muscle relaxant properties, neuromuscular blockers may nevertheless be required. Postoperative analgesia may be necessary.

Concentrations of 0.25 to 1% v/v of enflurane are used to provide analgesia for vaginal delivery during childbirth and of 0.5 to 1% v/v to supplement other general anaesthetics during caesarean section.

Pain. Enflurane is used in subanaesthetic doses to provide analgesia in obstetrics and other painful procedures although a study[1] was unable to confirm that it had an analgesic effect at subanaesthetic concentrations.

1. Tomi K, *et al.* Alterations in pain threshold and psychomotor response associated with subanaesthetic concentrations of inhalation anaesthetics in humans. *Br J Anaesth* 1993; 70: 684–6.

Adverse Effects

As with other halogenated anaesthetics, respiratory depression, hypotension, and arrhythmias have been reported although the incidence of arrhythmias is lower with enflurane than with halothane. It sensitises the myocardium to sympathomimetics to a lesser extent than halothane. Compared with halothane, enflurane has a stimulant effect on the CNS and convulsions may occur when concentrations of enflurane are high or hypocapnia is present. Malignant hyperthermia has also been reported. Asthma and bronchospasm may occur. There have been reports of elevated serum-fluoride concentrations although resulting renal damage appears to be rare. There have been changes in measurements of hepatic enzymes and several reports of liver damage. Shivering, nausea, and vomiting have been reported in the postoperative period.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Effects on the blood. The development of carboxyhaemoglobinaemia in patients anaesthetised with volatile anaesthetics is discussed under Precautions, below.

Effects on the kidneys. The nephrotoxicity of volatile anaesthetics has been reviewed.[1] Although enflurane released inorganic fluoride it appeared to be safe in patients with normal renal function. It had also been given to patients with mild to moderate renal impairment without any further deterioration. There was an increase in serum-fluoride concentrations when enflurane was given to a group of patients who had been receiving isoniazid, but there was no change in kidney function. Pretreatment of patients with a single dose of disulfiram before anaesthesia was found to produce a consistent and almost complete inhibition of enflurane metabolism as shown by substantial reductions in plasma-fluoride concentrations and urinary excretion of fluoride.[2]

2. Kharasch ED, *et al.* Clinical enflurane metabolism by cytochrome P450 2E1. *Clin Pharmacol Ther* 1994; 55: 434–40.

Effects on the liver. A review[1] of 58 cases of suspected enflurane hepatitis considered enflurane to be the likely cause of the liver damage in 24. There was biochemical evidence of liver damage in 23 of these cases. Histology reports were available for 15 patients and all showed some degree of hepatocellular necrosis and degeneration.

While the incidence of liver damage from enflurane seemed to be lower than from halothane, the character of the injury was similar.

Another review[2] of the same cases plus an additional 30 (88 in all) came to different conclusions; the main author was a consultant to the manufacturer of enflurane. Of the 88 patients with suspected enflurane hepatitis, 30 were rejected because of insufficient evidence and 43 were considered to have other factors known to produce liver injury. This left 15 possible cases of enflurane hepatitis compared with the 24 identified by the first review. While agreeing that in the rare patient unexplained liver damage follows enflurane anaesthesia, it was considered that the incidence was too small to suggest an association. No consistent histological pattern was identified in this study.

See also under Adverse Effects in Halothane, p. 1902.3.

2. Eger EI, *et al.* Is enflurane hepatotoxic? *Anesth Analg* 1986; 65: 21–30.

Effects on respiration. Overall, enflurane is considered to produce more respiratory depression than halothane or isoflurane.[1,2]

1. Quail AW. Modern inhalation anaesthetic agents: a review of halothane, isoflurane and enflurane. *Med J Aust* 1989; 150: 95–102.
2. Merrett KL, Jones RM. Inhalational anaesthetic agents. *Br J Hosp Med* 1994; 52: 260–3.

Precautions

Enflurane should be used with caution in patients with convulsive disorders. High concentrations of enflurane may cause uterine relaxation. In order to minimise the risk of developing elevated carboxyhaemoglobin levels, carbon dioxide absorbents in anaesthetic apparatus should not be allowed to dry out when delivering volatile anaesthetics such as enflurane (see below).

As with other halogenated anaesthetics, patients with known or suspected susceptibility to malignant hyperthermia should not be anaesthetised with enflurane. In children with neuromuscular disease, particularly Duchenne muscular dystrophy, halogenated anaesthetics have been associated with very rare cases of hyperkalaemia resulting in cardiac arrhythmias and death during the postoperative period.

See also Precautions for General Anaesthetics, p. 1897.3.

Abuse. Report[1] of a fatality in a 29-year-old student nurse anaesthetist who had applied enflurane to the herpes simplex lesions of her lower lip. She was found with an empty 250 mL bottle of enflurane.

1. Lingenfelter RW. Fatal misuse of enflurane. *Anesthesiology* 1981; 55: 603.

Carbon dioxide absorbents. Significant carboxyhaemoglobinaemia may develop rarely during anaesthesia with volatile anaesthetics given by circle breathing systems containing carbon dioxide absorbents.[1] The effect is only seen when the absorbent has become excessively dried out. The use of barium hydroxide lime (which is not available in the UK) as an absorbent produces more carbon monoxide than soda lime, particularly at low water content. No cases of this complication had been reported to date in the UK.

1. CSM/MCA. Safety issues in anaesthesia: volatile anaesthetic agents and carboxyhaemoglobinaemia. *Current Problems* 1997; 23: 7. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023230&RevisionSelectionMethod=LatestReleased (accessed 16/05/06)

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies enflurane as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 04/10/11)

Interactions

Care is advised if adrenaline or other sympathomimetics are given to patients during enflurane anaesthesia. The effects of competitive neuromuscular blockers such as atracurium are enhanced by enflurane (see p. 2032.3).

See also Interactions of General Anaesthetics, p. 1897.3.

Antibacterials. For the effects of *isoniazid* on enflurane defluorination, see Effects on the Kidneys under Adverse Effects, above.

Antidepressants. It appeared likely that the enflurane-induced seizure activity seen in 2 patients could have been enhanced by *amitriptyline*.[1] It may be advisable to avoid the use of enflurane in patients requiring tricyclic antidepressants, especially when the patient has a history of seizures or when hyperventilation or high enflurane concentrations are a desired part of the anaesthetic technique.

1. Sprague DH, Wolf S. Enflurane seizures in patients taking amitriptyline. *Anesth Analg* 1982; 61: 67–8.

Disulfiram. For the effect of disulfiram on the metabolism of enflurane, see Effects on the Kidneys under Adverse Effects, above.

Pharmacokinetics

Enflurane is absorbed on inhalation. The blood/gas partition coefficient is low. It is mostly excreted unchanged through the lungs. Up to 10% of inhaled administered enflurane is metabolised in the liver, mainly to inorganic fluoride.

$(C_2H_5)_2O$=74.12

CAS — 60-29-7.

ATC — N01AA01.

ATC Vet — QN01AA01.

NOTE. Some synonyms applied to anaesthetic ether may also be used for solvent ether (p. 2212.3). Care should be taken to differentiate between the two grades of ether.

Street names. The following terms have been used as 'street names' (see p. vii) or slang names for various forms of anaesthetic ether:

Sweet Vitriol.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 8: (Ether, Anaesthetic). Diethyl ether to which an appropriate quantity of a non-volatile antoxidant may have been added. It contains not more than 2 g/litre of water. A clear, colourless, volatile, highly flammable, and very mobile liquid. Distillation range 34 degrees to 35 degrees.

Soluble 1 in 15 of water; miscible with alcohol and with fatty oils. Store at a temperature of 8 degrees to 15 degrees in airtight containers. Protect from light. Ether remaining in a partly used container may deteriorate rapidly. The label should state the name and concentration of any added non-volatile antoxidant.

USP 36: (Ether). It consists of 96 to 98% of $C_4H_{10}O$, the remainder consisting of alcohol and water. Ether for anaesthetic use contains not more than 0.2% of water. It is a colourless, mobile, highly flammable, highly volatile liquid, having a characteristic sweet, pungent odour. It is slowly oxidised by the action of air and light, with the formation of peroxides. Its vapour, when mixed with air and ignited, may explode. B.p. about 35 degrees.

Soluble 1 in 12 of water; miscible with alcohol, with chloroform, with dichloromethane, with petroleum spirit, with benzene, and with fixed and volatile oils; soluble in hydrochloric acid. Store in partly-filled, airtight containers, remote from fire and at a temperature not exceeding 40 degrees. Protect from light. Ether to be used for anaesthesia must be preserved in airtight containers of not more than 3 kg capacity and is not to be used for anaesthesia if it has been removed from the original container longer than 24 hours.

Labelling. The label should state that it is suitable for use as an anaesthetic.

Stability. Ether is very volatile and flammable and mixtures of its vapour with oxygen, nitrous oxide, or air at certain concentrations are explosive. It should not be used in the presence of an open flame or any electrical apparatus liable to produce a spark. Precautions should be taken against the production of static electrical discharge.

Storage. The Pharmaceutical Society of Great Britain's Department of Pharmaceutical Sciences found that free ether, even in low concentrations, caused softening of PVC bottles and was associated with loss by permeation.[1]

1. Anonymous. Plastics medicine bottles of rigid PVC. *Pharm J* 1973; 210: 100.

Uses and Administration

Ether is an anaesthetic given by inhalation. It has a minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) of 1.92%. Ether is still used in some countries for the induction and maintenance of general anaesthesia although it has been replaced in many other countries by the halogenated anaesthetics. It possesses a respiratory stimulant effect in all but the deepest planes of

anaesthesia. Ether also possesses analgesic and muscle relaxant properties. Premedication with an antimuscarinic such as atropine is necessary to reduce salivary and bronchial secretions.

Solvent ether is described on p. 2212.3.

Adverse Effects

Ether has an irritant action on the mucous membrane of the respiratory tract; it stimulates salivation and increases bronchial secretion. Laryngeal spasm may occur. Ether causes vasodilatation which may lead to a severe fall in blood pressure and it reduces blood flow to the kidneys; it also increases capillary bleeding. The bleeding time is unchanged but the prothrombin time may be prolonged. Ether may cause malignant hyperthermia in certain individuals. Alterations in kidney and liver function have been reported. Convulsions occasionally occur. Hyperglycaemia due to gluconeogenesis has been noted.

Recovery is slow from prolonged ether anaesthesia and postoperative vomiting is common. Acute overdosage of ether is characterised by respiratory failure and cardiac arrest.

Dependence on ether or ether vapour has been reported. Prolonged contact with ether spilt on any tissue produces necrosis.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Precautions

Ether anaesthesia is contra-indicated in patients with diabetes mellitus, impaired kidney function, raised CSF pressure, and severe liver disease. Its use is not advisable in hot and humid conditions in patients with fever, as convulsions are liable to occur, particularly in children and in patients who have been given atropine.

See also Precautions for General Anaesthetics, p. 1897.3.

Interactions

Ether enhances the action of competitive neuromuscular blockers to a greater degree than most other anaesthetics. However, it does not potentiate the arrhythmogenic effect of sympathomimetics, including adrenaline, as much as other inhalational anaesthetics.

See also Interactions of General Anaesthetics, p. 1897.3.

UNII — Z226288598.

NOTE. Do not confuse with edetate; see Inappropriate Administration under Sodium Edetate, p. 1551.2.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii) and *US*.

Ph. Eur. 8: (Etomidate). A white or almost white powder. M.p. about 68 degrees. Very slightly soluble in water; freely soluble in alcohol and in dichloromethane. Protect from light.

USP 36: (Etomidate). A white or almost white powder. Very slightly soluble in water; freely soluble in alcohol and in dichloromethane. Protect from light.

Uses and Administration

Etomidate is an intravenous anaesthetic used for the induction of general anaesthesia (p. 1896.1). Anaesthesia is rapidly induced and may last for 6 to 10 minutes with a single usual dose. Recovery is usually rapid without hangover effect. Etomidate has no analgesic activity.

For the induction of anaesthesia, etomidate is available as a conventional or an emulsion injection formulation. The usual dose is 300 micrograms/kg of etomidate given slowly, preferably into a large vein in the arm, although a lower dose of 150 micrograms/kg of the emulsion formulation may be sufficient. An initial dose of 150 to 200 micrograms/kg is recommended in the elderly, subsequently adjusted according to effects (see also below). Dosage should also be reduced in hepatic cirrhosis. Children may require up to 30% more than the usual adult dose (i.e. up to 400 micrograms/kg). Opioid analgesics or benzodiazepines as premedication reduce myoclonic muscle movements; opioids also reduce injection site pain. A neuromuscular blocker is necessary if intubation is required.

Administration in children. Etomidate is used in children for the induction of anaesthesia; for details of doses, which may be proportionately larger than in adults, see Uses and Administration, above. US licensed product information does not recommend the use of etomidate below 10 years of age. In the UK, etomidate emulsion is licensed for use in those aged over 6 months, although it may be given to younger patients in emergencies, and other formulations do not specify a minimum age; the *BNFC* suggests all etomidate products may be used for induction from 1 month of age.

Administration in the elderly. A study[1] in elderly patients has shown that although reducing the rate of intravenous injection of etomidate reduces the speed of induction, the dosage required is also reduced. Giving etomidate 0.2% solution at a rate of 10 mg/minute induced anaesthesia in a mean of 89.6 seconds and required a mean dose of 110 micrograms/kg. Corresponding values for a rate of 40 mg/minute were 47.7 seconds and 260 micrograms/kg, respectively.

1. Berthoud MC, *et al.* Comparison of infusion rates of three I.v. anaesthetic agents for induction in elderly patients. *Br J Anaesth* 1993; 70: 423–7.

Anaesthesia. Etomidate might be useful for induction if rapid tracheal intubation is required with a competitive neuromuscular blocker as it has been shown to reduce the time to onset of block with vecuronium.[1,2] Indeed, etomidate has been suggested[2,3] by some to be the agent of choice for rapid sequence induction of anaesthesia in emergency settings; advantages include rapid onset and short duration of action, predictable clinical effect, and haemodynamic stability. However, there is considerable controversy about its use in critically-ill patients, see Effects on the Endocrine System, below.

3. Nestor NB, Burton JH. ED use of etomidate for rapid sequence induction. *Am J Emerg Med* 2008; 26: 946–50.

Cushing's syndrome. There have been reports[1–4] of benefit with the use of etomidate for acute control of hypercortisolaemia associated with Cushing's syndrome (p. 2559.1), particularly if the oral route is not available.

3. Dabbagh A, *et al.* Etomidate infusion in the critical care setting for suppressing the acute phase of Cushing's syndrome. *Anesth Analg* 2009; 108: 238–9.
4. Mettauer N, Brierley J. A novel use of etomidate for intentional adrenal suppression to control severe hypercortisolemia in childhood. *Pediatr Crit Care Med* 2009; 10: e37–e40.

Status epilepticus. General anaesthesia may be used to control refractory tonic-clonic status epilepticus (p. 510.2). A short-acting barbiturate such as thiopental is usually used, but other anaesthetics including etomidate have also been tried[1] for intractable convulsive status epilepticus. However, like several other anaesthetics there have been reports of seizures associated with its use in anaesthesia,[2,3] especially in patients with epilepsy.

1. Yeoman P, *et al.* Etomidate infusions for the control of refractory status epilepticus. *Intensive Care Med* 1989; 15: 255–9.
2. Nicoll K, Callender J. Etomidate-induced convulsion prior to electroconvulsive therapy. *Br J Psychiatry* 2000; 177: 373.
3. Sen H, *et al.* Epileptic seizure during anaesthesia induction with etomidate. *Middle East J Anesthesiol* 2010; 20: 723–5.

Adverse Effects and Precautions

Excitatory phenomena (especially involuntary myoclonic muscle movements, which are sometimes severe) are common after injection of etomidate, but may be reduced by giving an opioid analgesic or a short-acting benzodiazepine beforehand. Pain on injection may be reduced by giving etomidate into a large vein in the arm rather than into the hand, or, again, by premedication with an opioid analgesic. Convulsions may occur rarely, as may laryngospasm and cardiac arrhythmias. Hypersensitivity reactions including anaphylaxis have been reported. Etomidate is associated with less hypotension than other drugs commonly used for induction.

Because etomidate inhibits adrenocortical function during maintenance anaesthesia (see below) its use is limited to induction of anaesthesia. Supplementary corticosteroid therapy should be considered in at-risk patients, particularly those with adrenocortical dysfunction.

Etomidate should be used with care in the elderly, who may be more prone to cardiac depression; lower doses may be required. The dose of etomidate should also be reduced in patients with hepatic cirrhosis. Caution may be appropriate in patients with pre-existing epilepsy.

See also Adverse Effects and Precautions for General Anaesthetics, p. 1896.3.

Effects on the endocrine system. Etomidate used for sedation in an intensive care unit was implicated in an increase in mortality.[1] However, there is considerable controversy about the effects of etomidate on mortality in critically-ill patients (such as those with severe trauma or sepsis) when given as a single bolus dose for induction.[2] One systematic review[3] concluded that the use of etomidate for rapid tracheal intubation in critically-ill patients was associated with an increased risk of mortality; however, another review[4] that included patients receiving routine surgical anaesthesia found this effect to be statistically insignificant.

The UK CSM agreed that etomidate could cause a significant fall in circulating plasma-cortisol concentrations, unresponsive to corticotropin stimulation.[5] Other regulators have taken similar views in restricting the use of etomidate, which is now not given by prolonged infusion, essentially limiting its licensed use to induction of anaesthesia. Licensed product information advises that the postoperative rise in serum-cortisol concentration, which has been noted after thiopental induction, is delayed for about 3 to 6 hours when etomidate is used for induction.

A study comparing the effects of etomidate with those of methohexital on the adrenocortical function of neonates borne by mothers who received these agents for induction of anaesthesia before caesarean section indicated that there was no evidence to preclude the use of etomidate in such patients. However, regardless of which anaesthetic agent was used, early feeding was recommended to avoid neonatal hypoglycaemia.[6]

The inhibitory effect of etomidate on adrenocortical function has been used to control episodes of hypercortisolaemia; for details, see Cushing's Syndrome, above.

3. Sold M, Rothhammer A. Lebensbedrohliche anaphylaktoide reaktion nach etomidat. *Anaesthesist* 1985; 34: 208–10.

Interactions

A reduced dose of etomidate may be necessary in patients who have received antipsychotics, sedatives, or opioids. The hypnotic effect of etomidate has been potentiated by other sedative drugs.

See also Interactions of General Anaesthetics, p. 1897.3.

Calcium-channel blockers. Prolonged anaesthesia and Cheyne-Stokes respiration after etomidate injection has been reported in 2 patients also given *verapamil*.[1]

1. Moore CA, *et al.* Potentiation of etomidate anesthesia by verapamil: a report of two cases. *Hosp Pharm* 1989; 24: 24–5.

General anaesthetics. For a report of synergy between *propofol* and etomidate, see p. 1912.2.

Pharmacokinetics

After injection, etomidate is rapidly redistributed from the CNS to other body tissues, and undergoes rapid metabolism in the liver and plasma. Pharmacokinetics are complex and have been described by both 2- and 3-compartment models. Etomidate is about 76% bound to plasma proteins. It is mainly excreted in the urine, but some is excreted in the bile. It may cross the placenta and is distributed into breast milk.

CAS — 258516-89-1 (fospropofol); 258516-87-9 (fospropofol sodium).

UNII — 30868AY0IF.

Profile

Fospropofol is a prodrug of propofol (p. 1909.3) that is given intravenously as the sodium salt for sedation (p. 1032.2) in adult patients undergoing diagnostic or therapeutic procedures. In those aged under 65 years, and who are healthy or have mild systemic disease, an initial bolus injection of 6.5 mg/kg (minimum: 385 mg, maximum: 577.5 mg) may be followed by supplemental doses of 1.6 mg/kg (minimum: 105 mg, maximum: 140 mg) given no more frequently than every 4 minutes. Patients aged 65 years and older, or those with severe systemic disease, should be given 75% of the usual initial (minimum: 297.5 mg, maximum: 437.5 mg) and supplemental (minimum: 70 mg, maximum: 105 mg) doses.

UNII — UQT9G45D1P.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Halothane). A clear, colourless, mobile, dense, non-flammable liquid. Distillation range 49 degrees to 51 degrees. Slightly soluble in water; miscible with dehydrated alcohol and with trichloroethylene. Halothane contains 0.01% w/w of thymol. Store at a temperature not greater than 25 degrees in airtight containers. Protect from light.

USP 36: (Halothane). A colourless, mobile, non-flammable, heavy liquid having a characteristic odour resembling that of chloroform. It contains not less than 0.008% and not more than 0.012% of thymol, by weight, as a stabiliser. It should contain not more than 0.03% of water. Distillation range 49 degrees to 51 degrees.

Slightly soluble in water; miscible with alcohol, with chloroform, with ether, and with fixed oils. Store in airtight containers at a temperature not greater than 40 degrees. Protect from light. Dispense only in the original container.

Incompatibility. In the presence of moisture, halothane reacts with many metals. Rubber and some plastics deteriorate when in contact with halothane vapour or liquid.

Stability. Halothane contains 0.01% w/w of thymol as a stabiliser; some commercial preparations may also contain up to 0.00025% w/w of ammonia. Thymol does not volatilise with halothane and therefore accumulates in the vaporiser. It may give a yellow colour to any remaining liquid; halothane that has discoloured should be discarded.

Uses and Administration

Halothane is a volatile halogenated anaesthetic given by inhalation. It has a minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) ranging from 0.64% in the elderly to 1.08% in infants. It is non-flammable and is not explosive when mixed with oxygen at normal atmospheric pressure. It is not irritant to the skin and mucous membranes and does not produce necrosis when spilt on tissues. It suppresses salivary, bronchial, and gastric secretions and dilates the bronchioles. However, its use has diminished due to the risk of hepatotoxicity; in the UK, it is only available on a named-patient basis and in other countries, such as the USA, it has been withdrawn from the market.

Halothane is used for the induction and maintenance of general anaesthesia (p. 1896.1) and is given using a calibrated vaporiser to provide close control over the concentration of inhaled vapour.

Anaesthesia may be induced initially with 0.5% v/v of halothane in oxygen or mixtures of nitrous oxide and oxygen, and increased gradually, according to response, to a concentration of 2 to 4% v/v. It takes up to about 5 minutes to attain surgical anaesthesia and halothane produces little or no excitement in the induction period. The more usual practice is to induce anaesthesia with an intravenous agent. Anaesthesia is maintained with concentrations of 0.5 to 2% v/v depending on the flow rate used; the lower concentration is usually suitable for the elderly.

Adequate muscle relaxation is only achieved with deep anaesthesia so a neuromuscular blocker is given to increase muscular relaxation if necessary.

Administration in children. Halothane has been used for the induction and maintenance of general anaesthesia in children; however, in the UK, it is now mainly used by specialist anaesthetists to manage difficult airways. Doses are as for adults (see Uses and Administration, above).

Status asthmaticus. Inhalational anaesthetics such as halothane; isoflurane, and sevoflurane, have occasionally been used in the management of life-threatening acute severe asthma (p. 1195.2) unresponsive to standard measures.

Adverse Effects

As with other halogenated anaesthetics, halothane has a depressant action on the cardiovascular system and reduces blood pressure; signs of overdosage are bradycardia and profound hypotension. It is also a respiratory depressant and can cause cardiac arrhythmias; there have been instances of cardiac arrest. The sensitivity of the heart to sympathomimetic amines is increased.

Adverse effects on the liver have limited its use in recent years (see below); these effects range from liver dysfunction to fatal hepatitis and necrosis and are more frequent following repeated use.

Halothane can produce nausea, vomiting, and shivering. Malignant hyperthermia has been reported.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Review.

1. Kharasch ED. Adverse drug reactions with halogenated anesthetics. *Clin Pharmacol Ther* 2008; 84: 158–62.

Effects on the cardiovascular system. The incidence of cardiac arrhythmias is higher with halothane than with enflurane or isoflurane; also the arrhythmogenic threshold with injected adrenaline is lower with halothane than isoflurane or enflurane.

Arrhythmias are considered to be very common in children anaesthetised with halothane and in the UK it is recommended that it should not be used for dental procedures outside hospital in those under 18 years old.

A review[1] of the mechanisms involved suggested that at physiologically relevant concentrations, halogenated anaesthetics interact mainly with the repolarising potassium channels hERG and I_{Ks}, as well as with calcium and sodium channels at slightly higher concentrations. Inhibition of these produces proarrhythmic changes such as slowing of repolarisation and conduction. Other mechanisms, including alteration of catecholamine-induced signal transduction and possibly effects on neuronal pathways may also contribute to arrhythmogenesis.

Effects on the kidneys. Renal failure has been reported after halothane anaesthesia,[1,2] sometimes with concurrent liver failure.[2]

1. Cotton JR, *et al.* Acute renal failure following halothane anesthesia. *Arch Pathol Lab Med* 1976; 100: 628–9.

Effects on the liver. Liver damage has been recognised as an adverse effect of halothane for many years[1-3] and continues to be reported.[4] It may be severe, and associated with a high mortality.

Two types of hepatotoxicity are recognised: in **type I** there is a minor disturbance in liver function shown by increases in liver enzyme values; this may occur in up to 30% of patients given halothane,[5] or more if activity is measured by glutathione-S-transferase rather than serum aminotransferase.[6] Subsequent re-exposure to halothane is not necessarily associated with liver damage.[2,7]

Type II hepatotoxicity, which is rarer, involves massive liver cell necrosis; reported incidences[2] range from 1 in 2500 to 1 in 36 000. Type II liver toxicity is characterised by several clinical features: non-specific gastrointestinal upset, delayed pyrexia, jaundice, eosinophilia, serum autoantibodies, rash, and arthralgia.[1,3] Biochemical tests of liver function show changes typical of hepatocellular damage; histological features are typified by centrilobular necrosis.[3] Several **risk factors** for development of serious toxicity have become apparent;[1-3] they include repeated exposure, previous adverse reactions to halothane (jaundice, pyrexia), female gender, obesity, middle age, genetic predisposition, enzyme induction, and a history of drug allergy.

The **causes** of halothane hepatotoxicity have been debated. Type I reactions may result from toxic products of halothane metabolism, possibly influenced by genetic factors or from an imbalance between hepatic oxygen supply and demand. Changes in cellular calcium homoeostasis may also be involved. Type II reactions are most likely immune-mediated.[2,3] It has been suggested[3] that metabolism of halothane produces a reactive metabolite which binds covalently to proteins in the endoplasmic reticulum of hepatocytes. In susceptible patients it is believed that these metabolite-modified proteins provoke an immune response which is responsible for the liver damage. Findings[8,9] have implicated the cytochrome P450 isoenzyme CYP2E1 as having a major role in the metabolism of halothane and patients with high levels of this isoenzyme may be predisposed to developing immune-medicated liver damage after halothane exposure.

The UK CSM,[10] after receiving 84 further reports of hepatotoxicity between 1978 and 1985, issued the following **guidelines** on **precautions** to be taken before using halothane:

- a careful anaesthetic history should be taken to determine previous exposure and previous reactions to halothane
- repeated exposure to halothane within a period of at least 3 months should be avoided unless there are overriding clinical circumstances. An opinion has been expressed that the 3-month interval between exposures would be unlikely to prevent hepatotoxicity[2]
- a history of unexplained jaundice or pyrexia in a patient following exposure to halothane is an absolute contra-indication to its future use in that patient

These guidelines were reiterated in 1997 after the CSM was notified of a further 15 cases of acute liver failure all requiring transplantation.[11]

The problem of patients sensitised to halothane who require **subsequent anaesthesia** with a volatile anaesthetic has been discussed.[5] Although the incidence of hepatotoxicity produced by *enflurane* appears to be less than with halothane, it is of a similar nature and there have been reports of several patients who apparently had cross-sensitivity to both. Hepatotoxicity with *isoflurane* appears to be rare and it was suggested that for the majority of patients sensitised to halothane, isoflurane would be likely to be free

from hepatotoxic effects. However, there has been a report[12] of a patient who had had two previous exposures to isoflurane and subsequently developed liver function abnormalities after receiving halothane. Hepatotoxicity with *desflurane* (see p. 1899.2) might also be associated with sensitisation to halothane or isoflurane.

Precautions

The risk of halothane hepatitis led the UK CSM to issue guidelines on its use (see Effects on the Liver, under Adverse Effects, p. 1902.3). It is also recommended that patients be informed of any reactions and that this be done in addition to the updating of the patients' medical records.

It is recommended in the UK that halothane should not be used for dental procedures outside hospital in patients under 18 years old.

Halothane reduces uterine muscle tone during pregnancy and generally its use is not recommended in obstetrics because of the increased risk of postpartum haemorrhage.

Premedication with atropine has been recommended to reduce vagal tone and to prevent bradycardia and severe hypotension.

Measures may need to be taken to counteract any increase in CSF pressure or in cerebral blood flow. Halothane should be used with caution in patients with phaeochromocytoma.

As with other halogenated anaesthetics, patients with known or suspected susceptibility to malignant hyperthermia should not be anaesthetised with halothane. In children with neuromuscular disease, particularly Duchenne muscular dystrophy, halogenated anaesthetics have been associated with very rare cases of hyperkalaemia resulting in cardiac arrhythmias and death during the postoperative period.

See also Precautions for General Anaesthetics, p. 1897.3.

Abuse. A brief review[1] of abuse of volatile anaesthetics found that of 14 patients who had ingested or sniffed halothane 10 had died. Another patient who had injected halothane intravenously also died. There has also been another report[2] of fatalities resulting from acute pulmonary oedema after intravenous injection of halothane.

2. Berman P, Tattersall M. Self-poisoning with intravenous halothane. *Lancet* 1982; ii: 340.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving halothane, and the last available guidance from the American Academy of Pediatrics[1] considered that it was therefore usually compatible with breast feeding.

Trace amounts of halothane have been detected in the breast milk of an anaesthetist exposed to environmental halothane in the operating theatre.[2]

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 25/05/04)
2. Coté CJ, *et al.* Trace concentrations of halothane in human breast milk. *Br J Anaesth* 1976; 48: 541–3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies halothane as probably porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be considered in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 04/10/11)

Interactions

Adrenaline and most other sympathomimetics, and theophylline should be avoided during halothane anaesthesia since they can produce cardiac arrhythmias; the risk of arrhythmias is also increased if halothane is used in patients receiving dopaminergics. The effects of competitive neuromuscular blockers such as atracurium, and of ganglion blockers such as trimetaphan are enhanced by halothane and if required they should be given in reduced dosage. Morphine increases the depressant effects of halothane on respiration. Chlorpromazine also enhances the respiratory depressant effect of halothane. The effects of both ergometrine and oxytocin on the parturient uterus are diminished by halothane.

See also Interactions of General Anaesthetics, p. 1897.3.

Antiepileptics. For a case of *phenytoin* intoxication associated with halothane anaesthesia, see p. 542.2.

Benzodiazepines. *Midazolam* has been reported to potentiate the anaesthetic action of halothane.[1]

General anaesthetics. For a report that halothane increases serum concentrations of *propofol*, see p. 1912.2.

Neuromuscular blockers. For the potentiation of the neuromuscular blockade of neuromuscular blockers such as *atracurium* by halothane, see p. 2032.3. For increased toxicity during halothane anaesthesia, see *suxamethonium* p. 2039.3.

Trichloroethane. Evidence of chronic cardiotoxicity was seen in 2 patients after repeated exposure to trichloroethane.[1] In both cases there was circumstantial evidence of a deterioration after routine anaesthetic use of halothane.

1. McLeod AA, *et al.* Chronic cardiac toxicity after inhalation of 1,1,1-trichloroethane. *BMJ* 1987; 294: 727–9.

Xanthines. For references to increased cardiotoxicity when patients taking *theophylline* were anaesthetised with halothane, see p. 1236.2.

Pharmacokinetics

Halothane is absorbed on inhalation. It has a relatively low solubility in blood and is more soluble in the neutral fats of adipose tissue than in the phospholipids of brain cells. Up to 80% of inhaled halothane is excreted unchanged through the lungs. Up to 20% is metabolised by the liver by oxidative and, under hypoxic conditions, reductive pathways. Urinary metabolites include trifluoroacetic acid and bromide and chloride salts (oxidative pathway) and fluoride salts (reductive pathway). Halothane diffuses across the placenta and has been detected in breast milk.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Arg.*: Ineltano; *Austral.*: Fluothane†; *Braz.*: Fluothane; *Cz.*: Narcotan†; *Gr.*: Fluothane; *Hung.*: Narcotan†; *India*: Fluothane; Hypnothane; *Indon.*: Fluothane†; *NZ*: Fluothane; *Pol.*: Narcotan†; *Rus.*: Narcotan (Наркотан); *Turk.*: Fluothane.

Multi-ingredient Preparations. *Braz.*: Tanohalo.

Isoflurane *(BAN, USAN, rINN)*

Compound 469; Isofluraani; Isofluran; Isoflurano; Isoflurum; Izofluran; Izoflurán; Izofluranas; Изофлуран.

1-Chloro-2,2,2-trifluoroethyl difluoromethyl ether; 2-Chloro-2-(difluoromethoxy)-1,1,1-trifluoroethane.

$C_3H_2ClF_5O$=184.5

CAS — 26675-46-7.

ATC — N01AB06.

ATC Vet — QN01AB06.

UNII — CS9AKD70P.

Pharmacopoeias. In *Eur.* (see p. vii), *Jpn*, and *US*.

Ph. Eur. 8: (Isoflurane). A clear, colourless, mobile, heavy liquid. B.p. about 48 degrees. It is non-flammable. Practically insoluble in water; miscible with dehydrated alcohol and with trichloroethylene. Store in airtight containers. Protect from light.

USP 36: (Isoflurane). A clear, colourless, volatile liquid having a slight odour. B.p. about 49 degrees. Insoluble in water; miscible with common organic solvents and with fats and oils. Store in airtight containers at a temperature of 25 degrees, excursions permitted between 15 degrees and 30 degrees.

Uses and Administration

Isoflurane is a volatile halogenated anaesthetic given by inhalation. It is an isomer of enflurane and has anaesthetic actions similar to those of halothane (p. 1902.2). Isoflurane has a minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) ranging from 1.05% in the elderly to 1.87% in infants. It is used in the induction and maintenance of general anaesthesia (p. 1896.1) although induction is more often carried out using an intravenous anaesthetic. Isoflurane is also used in subanaesthetic doses to provide analgesia in obstetrics and other painful procedures.

Isoflurane is given using a calibrated vaporiser. If it is used for induction then it is given with oxygen or oxygen and nitrous oxide mixtures and induction should start with an isoflurane concentration of 0.5% v/v increased to 1.5 to 3% v/v which generally produces surgical anaesthesia within 10 minutes. Its pungency may limit the rate of induction. Anaesthesia may be maintained with a concentration of 1 to 2.5% v/v with oxygen and nitrous oxide mixtures; 1.5 to 3.5% v/v may be required if used only with oxygen. Isoflurane 0.5 to 0.75% v/v with oxygen and nitrous oxide mixtures is suitable to maintain anaesthesia for caesarean section. Although isoflurane is reported to possess muscle relaxant properties, neuromuscular blockers may nevertheless be required. Recovery is rapid.

Administration in children. Isoflurane is used for the induction and maintenance of general anaesthesia in children; doses are as for adults (see Uses and Administration, above).

Anaesthesia. *CAESAREAN SECTION.* Isoflurane 0.8% v/v has been found to be a suitable supplement to nitrous oxide-oxygen anaesthesia for patients undergoing caesarean section.[1] It has been suggested[2] that an overpressure technique might be of use to further reduce awareness in such patients. Giving isoflurane at a concentration of 2% v/v for 5 minutes followed by concentrations of 1.5% v/v for the next 5 minutes and 0.8% v/v thereafter produced higher arterial concentrations of isoflurane in patients undergoing caesarean section than when it was given at a concentration of 1% v/v throughout.[2]

2. McCrirrick A, *et al.* Overpressure isoflurane at Caesarean section: a study of arterial isoflurane concentrations. *Br J Anaesth* 1994; 72: 122–4.

Pain. Isoflurane is used in subanaesthetic doses to provide analgesia in obstetrics and other painful procedures but studies[1,2] have been unable to confirm that it had an analgesic effect at subanaesthetic concentrations. The use of isoflurane 0.2 or 0.25% v/v in a mixture of nitrous oxide 50% v/v and oxygen 50% v/v has been studied.[3,4]

4. Bryden FM, *et al.* Isoflurane for removal of chest drains after cardiac surgery. *Br J Anaesth* 1994; 73: 712P–713P.

Sedation. *INTENSIVE CARE.* The various drugs used to provide sedation in intensive care are discussed on p. 1033.1. Isoflurane is not usually considered for such a purpose but in a comparative 24-hour study[1] in 60 patients requiring mechanical ventilation, isoflurane 0.1 to 0.6% v/v in an air-oxygen mixture produced satisfactory sedation for a greater proportion of time than did the continuous infusion of midazolam 10 to 200 micrograms/kg per hour. Patients given isoflurane also recovered more rapidly. Isoflurane has also been used successfully for sedation over 5 days in a 3-year-old infant who required ventilation for pneumonia, a complication of the child's myasthenia gravis.[2] However, there has been some concern over high plasma fluoride concentrations after prolonged use of isoflurane (see under Metabolism in Pharmacokinetics, p. 1904.3).

Status epilepticus. General anaesthesia may be used to control refractory tonic-clonic status epilepticus (p. 510.2). A short-acting barbiturate such as thiopental is usually used. Despite rare reports of seizures associated with the use of isoflurane in anaesthetic procedures (see Effects on the Nervous System, under Adverse Effects and Precautions, p. 1904.2) it has been used successfully,[1-3] typically

in concentrations of 0.5 to 1% v/v, to control refractory convulsive status epilepticus. Although some[4] consider that isoflurane-induced coma may be more easy to control than barbiturate-induced coma, the use of isoflurane may be limited by the need for special anaesthetic equipment and continuous EEG monitoring. Magnetic resonance imaging (MRI) signal abnormalities have been reported[5] with prolonged (up to 85 days) use of isoflurane in high concentrations (up to 2.5% v/v) for refractory status epilepticus; the authors suggested that these MRI findings may be indicative of neurotoxicity.

Adverse Effects and Precautions

As with other halogenated anaesthetics, respiratory depression, hypotension, arrhythmias, and malignant hyperthermia have been reported; patients with known or suspected susceptibility to malignant hyperthermia should not be anaesthetised with isoflurane. Isoflurane differs from halothane and enflurane in that it produces less cardiac depression than either drug and heart rate may be increased. Also isoflurane sensitises the myocardium to sympathomimetics to a lesser extent than halothane and enflurane. The incidence of cardiac arrhythmias is lower with isoflurane than with halothane. Shivering, nausea, and vomiting have been reported in the postoperative period.

Induction with isoflurane is not as smooth as with halothane and this may be connected with its pungency; breath holding, coughing, and laryngospasm may occur. It has been reported to increase the cerebrospinal pressure and should be used with caution in patients with raised intracranial pressure. In children with neuromuscular disease, particularly Duchenne muscular dystrophy, halogenated anaesthetics have been associated with very rare cases of hyperkalaemia resulting in cardiac arrhythmias and death during the postoperative period. Isoflurane relaxes the uterine muscle; increased blood loss may occur after curettage or termination of pregnancy.

In order to minimise the risk of developing elevated carboxyhaemoglobin levels, carbon dioxide absorbents in anaesthetic apparatus should not be allowed to dry out when delivering volatile anaesthetics such as isoflurane (see below).

See also Adverse Effects and Precautions of General Anaesthetics, p. 1896.3 and p. 1897.3.

A comparison[1] of isoflurane and halothane for outpatient dental anaesthesia in children considered that isoflurane would produce fewer arrhythmias than halothane, but that the ease of induction and the quality of anaesthesia was inferior to that with halothane. Others[2] also found a higher incidence of coughing, salivation, and laryngospasm with isoflurane than halothane, but felt that it could be used as an alternative.

Further information on the adverse effects profile of isoflurane can be obtained from the report of and commentaries on an extensive multicentre study of patients undergoing anaesthesia with this agent.[3,4]

4. Levy WJ. Clinical anaesthesia with isoflurane: a review of the multicentre study. *Br J Anaesth* 1984; 56: 101S–112S.

Carbon dioxide absorbents. Significant carboxyhaemoglobinaemia may develop rarely during anaesthesia with volatile anaesthetics given by circle breathing systems containing carbon dioxide absorbents.[1] The effect is only seen when the absorbent has become excessively dried out. The use of barium hydroxide lime (which is not available in the UK) as an absorbent produces more carbon monoxide than soda lime, particularly at low water content. No cases of this complication had been reported to date in the UK.

1. CSM/MCA. Safety issues in anaesthesia: volatile anesthetic agents and carboxyhaemoglobinaemia. *Current Problems* 1997; 23: 7. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2032306&RevisionSelectionMethod=LatestReleased (accessed 16/05/06)

Effects on the cardiovascular system. Isoflurane is considered to produce less cardiovascular depression than halothane. However, the results of a study[1] suggest that while this may be true for young patients, in elderly patients isoflurane appears to have a cardiac depressant effect similar to that of halothane.

1. McKinney MS, *et al.* Cardiovascular effects of isoflurane and halothane in young and elderly adult patients. *Br J Anaesth* 1993; 71: 696–701.

CEREBRAL BLOOD FLOW. Autoregulation of cerebral blood flow appears to be impaired at higher concentrations of isoflurane. A study[1] in healthy subjects found that increasing isoflurane anaesthesia from a concentration of 1 to 2 minimum alveolar concentration (MAC) increased cerebral blood flow and reduced cerebral oxygen metabolism.

1. Olsen KS, *et al.* Effect of 1 or 2 MAC isoflurane with or without ketanserin on cerebral blood flow autoregulation in man. *Br J Anaesth* 1994; 72: 66–71.

CORONARY CIRCULATION. Halothane, enflurane, and isoflurane decrease coronary perfusion pressure, coronary blood flow, ventricular function, and myocardial oxygen demand. Halothane and enflurane have a variable effect on coronary vascular resistance, but isoflurane dilates coronary vessels.[1] There has been concern over the potential of isoflurane to produce coronary steal and whether this effect is detrimental in patients with ischaemic heart disease.[2] However, despite conflicting results of individual studies[3-6] an early review[7] concluded that isoflurane could be used safely even in high-risk patients with coronary artery disease provided that blood pressure and heart rate were maintained close to baseline concentrations. A subsequent review[8] considered that more recent evidence supported the use of isoflurane as the anaesthetic agent of choice in patients with coronary heart disease.

Effects on the kidneys. See under Metabolism in Pharmacokinetics, below.

Effects on the liver. Of 45 cases of isoflurane-associated hepatotoxicity reported to the FDA between 1981 and 1984 there was some other cause for the liver damage in 29. While isoflurane might have been one of the causes of the damage in the other 16 cases, there was not a reasonable likelihood of an association between isoflurane and postoperative liver impairment.[1] Subsequent rare cases of hepatotoxicity,[2-8] sometimes fatal,[2,5,7,8] have suggested that isoflurane may induce hepatitis, though much less frequently than halothane, and that there may be cross-sensitisation with other halogenated anaesthetics.

Effects on the nervous system. Seizures associated with induction of anaesthesia with isoflurane have been reported in patients without known neurological abnormalities and not undergoing neurosurgery.[1,2] However, data from a retrospective analysis of patients undergoing intracranial surgery indicated that when convulsions occurred postoperatively in these conditions, it was the neurosurgical procedures rather than the anaesthetics that were responsible.[3]

See also Status Epilepticus, under Uses and Administration, p. 1903.3.

3. Christys AR, *et al.* Retrospective study of early postoperative convulsions after intracranial surgery with isoflurane or enflurane anaesthesia. *Br J Anaesth* 1989; 62: 624–7.

Effects on the respiratory tract. A study[1] conducted mainly in adults found that humidification of anaesthetic mixtures containing isoflurane could reduce respiratory complications such as coughing, laryngospasm, and breath holding that were usually associated with the use of isoflurane for induction. However, a similar study[2] in children failed to confirm these findings.

For a report of occupational asthma associated with exposure to isoflurane and sevoflurane, see Occupational Exposure, under Precautions of Sevoflurane, p. 1913.3.

2. Muncaster A, *et al.* Allergic contact dermatitis to isoflurane. *Br J Dermatol* 1999; 141: (suppl 55): 96–7.

Hypersensitivity. For a report of hypersensitivity reactions, including asthma, angioedema, and dermatitis, associated with occupational exposure to isoflurane and sevoflurane, see Occupational Exposure, under Precautions of Sevoflurane, p. 1913.3.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies isoflurane as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 04/10/11)

Interactions

The effects of competitive neuromuscular blockers such as atracurium are enhanced by isoflurane (see p. 2032.3). Care is advised if adrenaline and other sympathomimetics are given during isoflurane anaesthesia.

See also Interactions of General Anaesthetics, p. 1897.3.

Antineoplastics. Prolongation of the QT_c interval to above 440 milliseconds has been seen during anaesthesia with isoflurane 0.5% v/v in women who had received *anthracycline*-based (doxorubicin or epirubicin) chemotherapy for breast cancer.[1]

1. Owczuk R, *et al.* Is prolongation of the QTc interval during isoflurane anaesthesia more prominent in women pretreated with anthracyclines for breast cancer? *Br J Anaesth* 2004; 92: 658–61.

General anaesthetics. For a report that isoflurane increases serum concentrations of *propofol*, see p. 1912.2.

Pharmacokinetics

Isoflurane is absorbed on inhalation. The blood/gas partition coefficient is lower than that of enflurane or halothane. It is mostly excreted unchanged through the lungs. About 0.2% of inhaled isoflurane is metabolised, mainly to inorganic fluoride.

Metabolism. In 26 patients sedated with isoflurane for 24 hours, plasma fluoride ion concentration increased from a mean of 4.03 nanomol/mL to 13.57 nanomol/mL in 12 hours after stopping sedation.[1] These fluoride concentrations were considered to be too low to cause clinical renal dysfunction. In 30 patients sedated with isoflurane for up to 127 hours (mean duration was 36 hours), mean plasma fluoride ion concentration increased[2] to 20.01 nanomol/mL during sedation and continued rising for 16 hours after stopping isoflurane to a maximum mean concentration of 25.34 nanomol/mL; thereafter, levels gradually declined to normal values by the fifth day. Despite the increased plasma fluoride ion concentrations, no biochemical or clinical evidence of deterioration in renal function was found. Giving isoflurane for 34 days to a patient with tetanus who required sedation to facilitate mechanical ventilation resulted[3] in sustained fluoride ion concentrations of 50 nanomol/mL and a peak concentration of 87 nanomol/mL. Although such concentrations are considered to be potentially nephrotoxic no clinical effect on renal function was found.

Ketamine Hydrochloride

(BANM, USAN, rINNM)

CI-581; CL-369; CN-52372-2; Hidrocloruro de ketamina; Ketamiinihydrokloridi; Ketamin Hidroklorür; Ketamina, hidrocloruro de; Kétamine, chlorhydrate de; Ketaminhidroklorid; Ketaminhydrochlorid; Ketamin-hydrochlorid; Ketaminhydroklorid; Ketamini Hydrochloridum; Ketamino hidrochloridas; Ketaminy chlorowodorek; Кетамина Гидрохлорид; Кетамин Хидрохлорид.

(±)-2-(2-Chlorophenyl)-2-methylaminocyclohexanone hydrochloride.

$C_{13}H_{16}ClNO,HCl=274.2$

CAS — 6740-88-1 (ketamine); 1867-66-9 (ketamine hydrochloride).

ATC — N01AX03.

ATC Vet — QN01AX03.

UNII — O18YUO0I83.

Street names. The following terms have been used as 'street names' (see p. vii) or slang names for various forms of ketamine:

Animal trank; Animal tranquilizer; Bump; Cat tranquilizer; Cat valium; Elephant tranquilizer; Green; Honey oil; Horse tranquilizer; Jet; Jet fuel; K; "K"; K wire; Kay Jay; K-blast; Keets; Keezy; Keller; Kellys day; Kenny; Ket; Keta; Ketaset; KFC; Kit kat; Kit-Kat; Kitty; KKK; Klarko K Kat; Klarky Kat; Kustard; Lady K; Naughty horsey; Old Man; Property of Sir John; Purple; Regretamine; Special K; Special "K"; Special la coke; Super acid; Super C; Super K; Tranquilizer; Triple K; Vetamine; Vitamin K; Wonky.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Ketamine Hydrochloride). A white or almost white crystalline powder. Freely soluble in water and in methyl alcohol; soluble in alcohol. A 10% solution in water has a pH of 3.5 to 4.1. Protect from light.

USP 36: (Ketamine Hydrochloride). A white crystalline powder having a slight characteristic odour. Soluble 1 in 4 of water, 1 in 14 of alcohol, 1 in 60 of dehydrated alcohol and of chloroform, and 1 in 6 of methyl alcohol; practically insoluble in ether. pH of a 10% solution in water is between 3.5 and 4.1. Store at a temperature of 25 degrees, excursions permitted between 15 degrees and 30 degrees.

Incompatibility. Ketamine hydrochloride is incompatible with soluble barbiturates. US licensed product information recommends that when use of diazepam and ketamine is required they should be given separately and not mixed in the same giving equipment.

Esketamine Hydrochloride *(BANM, rINNM)*

Esketamiinihydrokloridi; Esketamina, hidrocloruro de; Eskétamine, Chlorhydrate d'; Esketamine, chlorhydrate de; Esketaminhydrochlorid; Esketamin-hydrochlorid; Esketaminhydroklorid; Esketamini hydrochloridum; Esketamino hidrochloridas; Hidrocloruro de esketamina; *S*-Ketamine Hydrochloride; Эскетамина Гидрохлорид.

CAS — 33643-46-8 (esketamine).

ATC — N01AX14.

ATC Vet — QN01AX14.

UNII — LBP1H3SP2Z.

Pharmacopoeias. In *Eur.* (see p. vii).

Ph. Eur. 8: (Esketamine Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water and in methyl alcohol; soluble in alcohol. A 10% solution in water has a pH of 3.5 to 4.5. Protect from light.

Uses and Administration

Ketamine is an anaesthetic given by intravenous injection, intravenous infusion, or intramuscular injection. It produces dissociative anaesthesia characterised by a trance-like state, amnesia, and marked analgesia which may persist into the recovery period. There is often an increase in muscle tone and the patient's eyes may remain open for all or part of the period of anaesthesia. Ketamine is used in general anaesthesia for diagnostic or short surgical operations that do not require skeletal muscle relaxation, for the induction of anaesthesia to be maintained with other drugs, and as a supplementary anaesthetic (see p. 1896.1). It also has good analgesic properties in subanaesthetic doses. It is considered to be of particular value in children requiring frequent repeated anaesthesia. Recovery is relatively slow.

Ketamine is given as the hydrochloride but doses are expressed in terms of the equivalent amount of base; ketamine hydrochloride 1.15 mg is equivalent to about 1 mg of ketamine. The following doses have been used in adults and children:

- For induction, the dose given by *intravenous injection* may range from the equivalent of 1 to 4.5 mg/kg of ketamine; a dose of 2 mg/kg given intravenously over 60 seconds usually produces surgical anaesthesia within 30 seconds of the end of the injection and lasting for 5 to 10 minutes.
- The initial *intramuscular* dose may range from 6.5 to 13 mg/kg; an intramuscular dose of 10 mg/kg usually produces surgical anaesthesia within 3 to 4 minutes lasting for 12 to 25 minutes. For diagnostic or other procedures not involving intense pain an initial intramuscular dose of 4 mg/kg has been used.
- Additional intravenous or intramuscular doses, ranging from half to the full induction dose, may be given for maintenance.
- For induction by *intravenous infusion* a total dose of 0.5 to 2 mg/kg is usually given at an appropriate infusion rate. Maintenance is achieved with 10 to 45 micrograms/kg per minute, the infusion rate being adjusted according to response.

Use should be preceded by atropine or another suitable antimuscarinic. Diazepam or another benzodiazepine may be given before surgery or as an adjunct to ketamine to reduce the incidence of emergence reactions.

The *S*-isomer, esketamine, is also given for similar uses in anaesthesia.

Administration. Although ketamine hydrochloride is usually given intravenously or intramuscularly, oral[1,2] and rectal[3] dosage has been used successfully in children. Intranasal use of ketamine with midazolam in a neonate requiring anaesthesia has also been reported.[4] Unfortunately the onset of sedation with these three routes is too slow for emergency procedures and therefore a jet-injector of ketamine was developed[5] to provide non-traumatic, painless, and rapid anaesthesia in children. Intranasal and transdermal use may be useful in the management of pain (below); oral, rectal, and subcutaneous routes have also been tried.[6]

Administration in children. Ketamine is used in general anaesthesia in children; for details of doses, see Uses and Administration, above.

Nonketotic hyperglycinaemia. Ketamine was tried with strychnine in a neonate with severe nonketotic hyperglycinaemia (p. 2623.2) and resulted in neurological improvement, although motor development remained unsatisfactory.[1] It was thought that ketamine might act by blocking NMDA receptors, which are activated in the CNS by glycine.

1. Tegtmeyer-Metadorf H, *et al.* Ketamine and strychnine treatment of an infant with nonketotic hyperglycinaemia. *Eur J Pediatr* 1995; 154: 649–53.

Pain. For a discussion of pain and its management, see p. 4.1. Ketamine is used for its analgesic action in neuropathic or other pain unresponsive to conventional analgesics. (For mention of its use for outpatient procedures in children, see p. 5.2.) Reviews have found the evidence for such use to be limited,[1–4] and have also differed on its value for postoperative pain.[5–7] Some have suggested[1,3,4] that ketamine is a reasonable third-line option for pain where standard analgesics have failed; however, such use may be limited by its adverse effects. Subcutaneous, intramuscular, intravenous, epidural, intrathecal, intranasal, transdermal, rectal, and oral routes have all been tried.[1,8] Ketamine has also been used topically.[9]

Psychiatric disorders. A small preliminary randomised placebo-controlled study reported[1] rapid reductions in severity of depression after an intravenous infusion of ketamine hydrochloride 500 micrograms/kg was given to patients with treatment-resistant depression (see Depression, p. 398.1); the effect began within 2 hours, and was sustained for up to 1 week after infusion. Single infusions of the same dose have also improved suicidal ideation in those with treatment-resistant depression[2] and reduced severity of depression as an adjunct in those with treatment-resistant bipolar depression (see Bipolar Disorder, p. 397.2).[3] The role of ketamine, an NMDA antagonist, and the glutamatergic system in the treatment of mood disorders has been reviewed.[4,5]

Adverse Effects

Emergence reactions are common during recovery from ketamine anaesthesia and include vivid often unpleasant dreams, confusion, hallucinations, and irrational behaviour. Children and elderly patients appear to be less sensitive. Patients may also develop increased muscle tone, sometimes resembling seizures. Blood pressure and heart rate may be temporarily increased by ketamine; hypotension, arrhythmias, and bradycardia have occurred rarely.

Respiration may be depressed after rapid intravenous injection or with high doses. Apnoea and laryngospasm have occurred. Diplopia and nystagmus may occur. Nausea and vomiting, lachrymation, hypersalivation, and raised intra-ocular and CSF pressure have also been reported. Transient rashes and pain at the site of injection may occur.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Effects on the cardiovascular system. Ketamine has been advocated by some for maintaining or increasing cardiovascular performance in selected patients during induction of anaesthesia as it may increase blood pressure and heart rate.[1] However, there have been reports of reduced cardiac and pulmonary performance in severely ill patients[1] and of arrhythmias.[2]

Some of the cardiovascular effects of ketamine may be attenuated by premedication with diazepam[2] or clonidine.[3]

1. Waxman K, *et al.* Cardiovascular effects of anesthetic induction with ketamine. *Anesth Analg* 1980; 59: 355–8.

2. Cabbabe EB, Behbahani PM. Cardiovascular reactions associated with the use of ketamine and epinephrine in plastic surgery. *Ann Plast Surg* 1985; 15: 50–2.
3. Tanaka M, Nishikawa T. Oral clonidine premedication attenuates the hypertensive response to ketamine. *Br J Anaesth* 1994; 73: 758–62.

Effects on the liver. Changes in liver enzyme values have occurred after ketamine in an initial dose of 1 mg/kg followed by continuous infusion as a 0.1% solution.[1]

1. Dundee JW, *et al.* Changes in serum enzyme levels following ketamine infusions. *Anaesthesia* 1980; 35: 12–16.

Effects on mental state. Mental disturbances after ketamine anaesthesia may vary in incidence from less than 5% to greater than 30%,[1] but a subsequent review[2] assessed the general frequency at 10 to 20%; sedating drugs are effective at preventing and terminating such emergence reactions. Episodes of vomiting are generally associated with emergence from dissociative states. See also Abuse, below.

2. Strayer RJ, Nelson LS. Adverse events associated with ketamine for procedural sedation in adults. *Am J Emerg Med* 2008; 26: 985–1028.

Effects on the skin. Harlequin-like colour skin changes were reported[1] in a 9-month-old boy during anaesthesia with ketamine 15 mg. A transient patchy erythematous rash is seen on the upper torso in about 5 to 20% of adult patients given ketamine;[2] it disappears without treatment within about 20 minutes, and does not recur with further doses of the drug.

2. Strayer RJ, Nelson LS. Adverse events associated with ketamine for procedural sedation in adults. *Am J Emerg Med* 2008; 26: 985–1028.

Malignant hyperthermia. Malignant hyperthermia has been reported in a patient given ketamine.[1]

1. Rasore-Quartino A, *et al.* Forma atipica di ipertermia maligna: osservazione di un caso da ketamina. *Pathologica* 1985; 77: 609–17.

Precautions

Ketamine is contra-indicated in patients in whom elevation of blood pressure would be a serious hazard including those with hypertension, eclampsia or pre-eclampsia, severe coronary or myocardial disease, cerebrovascular accident, or cerebral trauma. Cardiac function should be monitored in patients found to have hypertension or cardiac decompensation. Ketamine should be used with caution in patients with elevated CSF pressure. It can raise intra-ocular pressure and should not be used in the presence of eye injury or increased intra-ocular pressure.

Ketamine does not reliably suppress pharyngeal and laryngeal reflexes and mechanical stimulation of the pharynx should be avoided unless a muscle relaxant is used.

Ketamine should be used with caution in patients with neurotic traits or psychiatric disorders. Verbal, tactile, and visual stimuli should be kept to a minimum during recovery in an attempt to reduce the risk of emergence reactions.

See also Precautions for General Anaesthetics, p. 1897.3.

Abuse. Healthcare workers in the USA were alerted to the dangers associated with the abuse of ketamine as long ago as 1979.[1] Similar concern had also been voiced in the UK[2] over the abuse of ketamine at social gatherings where it has been taken intranasally or orally; it has also been injected intramuscularly.[3] A WHO expert committee[4] considered in 2006 that the available information on ketamine was not sufficient to warrant international control. Studies in *animals* have shown that ketamine can produce dependence, however, reports of dependence in humans are limited (see below). Although tolerance may occur there is no evidence of a withdrawal syndrome (but see below). Ketamine abuse has been reported in several countries.

Ketamine produces a state of psychological dissociation resulting in hallucinations and out of body or near death experiences. It can induce a state of helplessness in which the user loses awareness of the environment and this with severe loss of coordination and pronounced analgesia can put the user at great risk. Furthermore, some users experience a state in which they are unconcerned about whether they live or die. Ketamine has the potential for compulsive repeated use and there have been reports of users self-injecting ketamine several times daily for prolonged periods. Dependency may develop[5,6] and withdrawal symptoms requiring detoxification can occur.[6] Frequent use may produce long-lasting memory impairment.[7,8] Other adverse effects include a report[9] of an acute dystonic reaction in a 20-year old man following self-administration of ketamine intravenously.

In one case series[10] of 20 patients presenting to hospital after ketamine abuse the most common symptoms included anxiety, chest pain, and palpitations. Frequent complications included agitation and rhabdomyolysis. Symptoms were generally short lived with most patients discharged within 5 hours. A more recent retrospective case-note review[11] of 233 patients, also presenting to hospital after ketamine abuse, found the most common presenting symptoms to be impaired consciousness, increased blood pressure, tachycardia, abdominal pain or tenderness, hyperthermia, and dizziness. Symptoms resolved with supportive treatment in most of these patients and none had developed major complications.

Some[2] suggest that patients seeking medical attention are best placed in a quiet darkened room to recover with diazepam being given for unresponsive panic attacks while others advocate that such patients should be admitted to an intensive care unit for close monitoring.[12] The use of intravenous fluids to prevent rhabdomyolysis has also been recommended.[10]

Long-term and frequent abuse of ketamine has been associated with adverse effects on the urinary tract;[13-16] time to onset was reported[17] to range from 1 month to several years. Patients may present with symptoms of dysuria, frequency, urgency, urinary incontinence, suprapubic pain, and haematuria. Examination has shown in some cases a contracted shrunken bladder and ulcerative cystitis. Complications have included hydronephrosis and renal impairment. Dilated common bile duct, presenting as epigastric pain, and abnormal liver function tests have also been reported[18,19] with long-term abuse.

Ketamine is tasteless, odourless, and colourless and has been misused to incapacitate the victim and produce amnesia in sexual assaults and drug-facilitated rape ('date rape').[6]

Neurosurgery. Although the idea that ketamine should not be used in patients at risk from rises in intracranial pressure has limited its use in neurosurgical patients, a review[1] considered that if used with controlled ventilation and a GABA receptor agonist, and without nitrous oxide, it did not appear to have adverse effects in this group; there is evidence suggesting that it may have neuroprotective properties in some circumstances.[1,2]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies ketamine as porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be taken in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 04/10/11)

Interactions

Inhalational anaesthetics, such as ether and halothane, and other cerebral depressants may prolong the effect of ketamine and delay recovery. Prolonged recovery has also occurred when barbiturates and/or opioids have been given with ketamine. It has been recommended that ketamine should not be used with ergometrine.

Xanthines. For a reference to seizures and tachycardia attributed to an interaction between ketamine and *theophylline*, see p. 1236.2.

Pharmacokinetics

After intravenous boluses, ketamine shows a bi- or triexponential pattern of elimination. The alpha phase lasts about 45 minutes with a half-life of 10 to 15 minutes. This first phase, which represents ketamine's anaesthetic action, is terminated by redistribution from the CNS to peripheral tissues and hepatic biotransformation to an active metabolite norketamine. Other metabolic pathways include hydroxylation of the cyclohexone ring and conjugation with glucuronic acid. The beta phase half-life is about 2.5 hours. Ketamine is excreted mainly in the urine as metabolites. It crosses the placenta.

Methohexital *(BAN, rINN)*

Méthohexital; Methohexitalum; Methohexitone; Metoheksitaali; Metohexital; Метогекситал.

(±)-5-Allyl-1-methyl-5-(1-methylpent-2-ynyl)barbituric acid; 1-Methyl-5-(1-methyl-2-pentynyl)-5-(2-propenyl)-2,4,6 (1*H*,3*H*,5*H*)-pyrimidinetrione.

$C_{14}H_{18}N_2O_3$=262.3

CAS — 151-83-7; 18652-93-2.

ATC — N01AF01; N05CA15.

ATC Vet — QN01AF01; QN05CA15.

UNII — E5B8ND5IPE.

Pharmacopoeias. In *US.*

USP 36: (Methohexital). A white to faintly yellowish-white crystalline odourless powder. M.p. 92 degrees to 96 degrees but the range between beginning and end of melting does not exceed 3 degrees. Very slightly soluble in water; slightly soluble in alcohol, in chloroform, and in dilute alkalis.

Methohexital Sodium *(BANM, rINNM)*

Compound 25398; Enallynymalnatrium; Méthohexital Sodique; Methohexitone Sodium; Metohexital sódico; Natrii Methohexitalum; Натрий Метогекситал.

$C_{14}H_{17}N_2NaO_3$=284.3

CAS — 309-36-4; 22151-68-4; 60634-69-7.

ATC — N01AF01; N05CA15.

ATC Vet — QN01AF01; QN05CA15.

UNII — 60200PNZ7Q.

Pharmacopoeias. *US* includes Methohexital Sodium for Injection.

USP 36: (Methohexital Sodium for Injection). A freeze-dried sterile mixture of methohexital sodium and anhydrous sodium carbonate as a buffer, prepared from an aqueous solution of methohexital, sodium hydroxide, and sodium carbonate. It is a white to off-white, essentially odourless, hygroscopic powder. pH of a 5% solution in water is between 10.6 to 11.6.

Incompatibility. Solutions of methohexital sodium are incompatible with acidic substances including some antibacterials, antipsychotics, neuromuscular blockers, antimuscarinics, and analgesics. Compounds commonly listed as incompatible include atropine sulfate, pethidine hydrochloride, metocurine iodide, fentanyl citrate, morphine sulfate, pentazocine lactate, silicones, suxamethonium chloride, tubocurarine chloride, and compound sodium lactate injection. Only preservative-free diluents should be used to reconstitute methohexital sodium; precipitation may occur if a diluent containing a bacteriostatic agent is used.

Stability. Solutions of methohexital sodium in Water for Injections are stable for at least 6 weeks at room temperature; however reconstituted solutions should be stored no longer than 24 hours as they contain no bacteriostatic agent. Solutions in glucose or sodium chloride injections are stable only for about 24 hours.

Uses and Administration

Methohexital is a short-acting barbiturate anaesthetic that has actions similar to those of thiopental (p. 1915.2) but it is about 2 to 3 times more potent. It is given as the sodium salt and has similar uses to thiopental in anaesthesia. Induction of anaesthesia is less smooth than with thiopental and there may be excitatory phenomena. It has a shorter duration of action than thiopental and recovery after an induction dose occurs within 5 to 7 minutes although drowsiness may persist for some time.

As with other barbiturate anaesthetics the dose of methohexital required varies greatly according to the state of the patient and the nature of other drugs also being used (see under Precautions of Thiopental, p. 1916.2, and Interactions of Thiopental, p. 1916.2, for further details). Methohexital sodium is usually given intravenously as a 1% solution. Higher concentrations may markedly increase the incidence of adverse effects. A typical dose for induction of anaesthesia is 50 to 120 mg (usual range 1 to 1.5 mg/kg) given at a rate of about 10 mg (1 mL of a 1% solution) every 5 seconds. For the maintenance of general anaesthesia methohexital sodium may be given by intravenous injection in doses of 20 to 40 mg every 4 to 7 minutes as required or it may be given as a 0.2% solution by continuous intravenous infusion at a rate of 3 mL/minute.

For dosage in children, see below.

Administration in children. Although intravenous use is considered preferable in adults, in the USA methohexital sodium has been licensed for use in children aged over 1 month only by the intramuscular and rectal routes: usual doses for the induction of anaesthesia are 6.6 to 10 mg/kg intramuscularly, as a 5% solution, or 25 mg/kg rectally, as a 1% solution. In some countries methohexital sodium has also been given intravenously to children.

Administration in the elderly. It is usually recommended that the dosage of barbiturate anaesthetics is reduced in the elderly. A study[1] in elderly patients has shown that although reducing the rate of intravenous dosage reduces the speed of induction, the dosage required is also reduced. Giving methohexital sodium 0.5% at a rate of 25 mg/minute induced anaesthesia in a mean of 83.8 seconds and required a mean dose of 560 micrograms/kg. Corresponding values for a rate of 100 mg/minute were 43.6 seconds and 1 mg/kg, respectively.

1. Berthoud MC, *et al.* Comparison of infusion rates of three i.v. anaesthetic agents for induction in elderly patients. *Br J Anaesth* 1993; 70: 423–7.

Dental sedation. Some anaesthetics are used as sedatives in dental procedures (see p. 1032.2). Methohexital has been tried for patient-controlled sedation in oral surgery under local anaesthesia.[1] In a group of 42 patients, results with 2.5 mg of methohexital compared favourably with those obtained in patients receiving 5 mg of propofol on demand, although patients in the methohexital group had a greater degree of postoperative drowsiness.

1. Hamid SK, *et al.* Comparison of patient-controlled sedation with either methohexitone or propofol. *Br J Anaesth* 1996; 77: 727–30.

Adverse Effects and Precautions

As for Thiopental Sodium, p. 1916.1.

Excitatory phenomena are more common and induction less smooth with methohexital than with thiopental. Methohexital should be used with caution, if at all, in patients with a history of epilepsy.

See also Adverse Effects and Precautions for General Anaesthetics, p. 1896.3.

Incidence of adverse effects. In a study of 4379 uses of methohexital in 2722 dental patients the total intravenous dose ranged from 20 mg to 560 mg (with a mean of 151 mg), and the duration of treatment was 8 to 32 minutes.[1] Complications included: restlessness not controlled by diazepam (292 cases), respiratory complications (214), uncontrollable crying during recovery (73), pain along vein (45) with thrombophlebitis (5), jactitations (22), and allergic reactions (10).

1. McDonald D. Methohexitone in dentistry. *Aust Dent J* 1980; 25: 335–42.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving methohexital, and the last available guidance from the American Academy of Pediatrics[1] considered that it was therefore usually compatible with breast feeding.

In a study[2] of 9 breast-feeding women undergoing general anaesthesia, it was estimated that the exposure of a breast-fed infant to methohexital would be less than 1% of the maternal dose after induction with methohexital. Breast feeding was not interrupted during the study and none of the infants appeared drowsy or sedated.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 26/05/04)
2. Borgatta L, *et al.* Clinical significance of methohexital, meperidine, and diazepam in breast milk. *J Clin Pharmacol* 1997; 37: 186–92.

Effects on the nervous system. Two case reports of seizures induced by methohexital in children with seizure disorders.[1] Seizures are considered a rare adverse effect of methohexital. In 48 000 patients given methohexital, only 3 developed clonic-type seizures.[2]

A case of a tonic-clonic seizure possibly due to an interaction between paroxetine and methohexital is discussed below.

1. Rockoff MA, Goudsouzian NG. Seizures induced by methohexital. *Anesthesiology* 1981; 54: 333–5.
2. Metriyakool K. Seizures induced by methohexital. *Anesthesiology* 1981; 55: 718.

Pain on injection. Methohexital is associated with severe pain particularly if veins on the back of the hands are used. The incidence of pain on injection may be reduced by using a forearm vein or by pre-injection with lidocaine.

Porphyria. Licensed product information contra-indicates the use of methohexital in patients with latent or manifest porphyria.

Rebound anaesthesia. Rebound of anaesthesia with abolition of reflexes and depression of respiration occurred in a 6-year-old boy[1] 100 minutes after anorectal induction with 27.6 mg/kg methohexital.

1. Kaiser H, Al-Rafai S. Wie sicher ist die rektale Narkoseeinleitung mit Methohexital in der Kinderanaesthesie? *Anaesthesist* 1985; 34: 359–60.

Interactions

As for Thiopental Sodium, p. 1916.2.

Antidepressants. A 42-year-old woman[1] had a generalised tonic-clonic seizure immediately after being anaesthetised with methohexital for the last in a series of 6 electroconvulsive therapies. She had been receiving *paroxetine* throughout the series. A previous course, without concurrent paroxetine, had been uneventful.

1. Folkerts H. Spontaneous seizure after concurrent use of methohexital anesthesia for electroconvulsive therapy and paroxetine: a case report. *J Nerv Ment Dis* 1995; 183: 115–16.

Pharmacokinetics

Methohexital is less lipid soluble than thiopental but concentrations sufficient to produce anaesthesia are attained in the brain within 30 seconds of an intravenous dose. Methohexital is also absorbed when given rectally, producing an effect within about 5 to 15 minutes. Recovery from anaesthesia occurs quickly as a result of rapid metabolism and redistribution into other body tissues. Methohexital does not appear to concentrate in fatty tissues to the same extent as other barbiturate anaesthetics. Protein binding has been reported to be about 73%. Methohexital is rapidly metabolised in the liver through demethylation and oxidation. The terminal half-life ranges from 1.5 to 6 hours. Methohexital diffuses across the placenta and has been detected in breast milk.

$C_3H_4Cl_2F_2O$=165.0

CAS — 76-38-0.

ATC — N02BG09.

ATC Vet — QN02BG09.

UNII — 30905R8O7B.

Pharmacopoeias. In *US.*

USP 36: (Methoxyflurane). A clear, practically colourless, mobile liquid having a characteristic odour. It may contain a suitable stabiliser. B.p. about 105 degrees. Soluble 1 in 500 of water; miscible with alcohol, with acetone, with chloroform, with ether, and with fixed oils. Store in airtight containers at a temperature not exceeding 40 degrees. Protect from light.

Uses and Administration

Methoxyflurane is a volatile halogenated anaesthetic given by inhalation. It has a minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) of 0.16%, but because of its low vapour pressure, induction of general anaesthesia with methoxyflurane is slow. In recommended concentrations it is non-flammable and not explosive when mixed with oxygen. Methoxyflurane possesses good analgesic properties. It does not produce appreciable skeletal muscle relaxation at the concentrations used. Methoxyflurane does not relax the uterus and has little effect on uterine contractions during labour. It is used in subanaesthetic doses to provide analgesia for painful procedures and trauma. In anaesthetic doses, it has been used mainly for maintenance of general anaesthesia (p. 1896.1), but safer anaesthetics are preferred because of its nephrotoxicity.

Concentrations of about 0.2 to 0.7% v/v are used to provide analgesia to conscious patients. The recommended maximum total dose for intermittent self-administration is 6 mL of liquid daily or 15 mL weekly; use on consecutive days is not recommended.

Adverse Effects

As with other halogenated anaesthetics respiratory depression, hypotension, and malignant hyperthermia have been reported. Methoxyflurane sensitises the myocardium to sympathomimetics to a lesser extent than halothane; arrhythmias appear to be rare.

Methoxyflurane impairs renal function in a dose-related manner that is thought to be due to the effect of the released fluoride on the distal tubule (but see under Pharmacokinetics, p. 1908.1) and may cause polyuric or oliguric renal failure, oxaluria being a prominent feature. Nephrotoxicity is greater with methoxyflurane than with other halogenated anaesthetics because of slower metabolism over several days resulting in prolonged production of fluoride ions, and metabolism to other potentially nephrotoxic substances.

There have also been occasional reports of hepatic dysfunction, jaundice, and fatal hepatic necrosis. Cardiac hypotension, gastrointestinal adverse effects, euphoria, drowsiness, agitation, headache, dizziness, and amnesia have been reported, as have coughing and choking. Blurred vision, diplopia, and nystagmus have been noted.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Precautions

The use of methoxyflurane is limited because of its potential to cause nephrotoxicity and its use as a general anaesthetic is no longer recommended. Methoxyflurane should not be used daily for analgesia and is contra-indicated in the presence of renal impairment.

As with other halogenated anaesthetics it is advisable not to give methoxyflurane to patients who have shown signs of liver damage or fever after previous anaesthesia involving halogenated anaesthetics. Patients with known, or suspected, susceptibility to malignant hyperthermia should not be given methoxyflurane. When used for analgesia, methoxyflurane is also contra-indicated in those with cardiovascular instability, respiratory depression, and head injury or loss of consciousness; it should be used with caution in the elderly.

See also Precautions for General Anaesthetics, p. 1897.3.

Abuse. A 27-year-old nurse suffered from progressive renal disease and painful diffuse and multifocal periostitis, which had developed as a probable consequence of intermittent self-exposure to methoxyflurane possibly over a 9-year period.[1] There has also been a report[2] of hepatitis in a 39-year-old physician who repeatedly self-administered subanaesthetic concentrations of methoxyflurane for insomnia. Inhalation of about 2 mL of methoxyflurane had occurred once or twice almost every day for 6 weeks. A 125-mL bottle of methoxyflurane had been consumed in about 1 month.

1. Klemmer PJ, Hadler NM. Subacute fluorosis: a consequence of abuse of an organofluoride anesthetic. *Ann Intern Med* 1978; 89: 607–11.
2. Okuno T, *et al.* Hepatitis due to repeated inhalation of methoxyflurane in subanaesthetic concentrations. *Can Anaesth Soc J* 1985; 32: 53–5.

Interactions

Care is advised if adrenaline or other sympathomimetics are given to patients also receiving methoxyflurane. The effects of competitive neuromuscular blockers are enhanced by methoxyflurane. The chronic use of hepatic enzyme-inducing drugs, such as barbiturates, may enhance the metabolism of methoxyflurane thereby increasing the risk of nephrotoxicity. Use of nephrotoxic drugs, including certain antibacterials, with methoxyflurane should be avoided; fatal nephrotoxicity has been reported when used with tetracycline.

See also Interactions of General Anaesthetics, p. 1897.3.

Pharmacokinetics

Methoxyflurane is absorbed on inhalation. The blood/gas partition coefficient is high. Methoxyflurane is metabolised to a greater extent than other inhalational anaesthetics. About 50 to 70% of absorbed methoxyflurane undergoes metabolism in the liver to free fluoride, oxalic acid, difluoromethoxyacetic acid, and dichloroacetic acid. Methoxyflurane is very soluble in adipose tissue and excretion may be slow. Peak plasma concentrations of fluoride occur 2 to 4 days after a dose. Methoxyflurane crosses the placenta.

Metabolism. Although fluoride has been thought to be the nephrotoxic metabolite formed during biotransformation of methoxyflurane, studies[1,2] *in vitro* and in *rats* have suggested that dichloroacetic acid, formed with fluoride by *O*-demethylation, may contribute to the nephrotoxic effect.

UNII — K50XQU1029.

Street names. The following terms have been used as 'street names' (see p. vii) or slang names for various forms of nitrous oxide:

Bulb; Buzz bomb; Cartridges; Fall down; Gas; Going to the dentist; Grocery store high; Hippy crack; Hysteria; Laughing gas; Nang; Nie; Nigh; Nitro; Nitrogen; Nitrous; Noss; Pan; Shoot the breeze; Tanks; Whippet; Whippets; Wippets.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 8: (Nitrous Oxide). A colourless gas. One vol. measured at a pressure of 101 kPa dissolves, at 20 degrees, in about 1.5 vol. of water. Store liquefied under pressure in suitable containers complying with the legal regulations.

The BP 2014 directs that Nitrous Oxide should be kept in approved metal cylinders which are painted blue and carry a label stating 'Nitrous Oxide'. In addition, 'Nitrous Oxide' or the symbol 'N_2O' should be stencilled in paint on the shoulder of the cylinder.

USP 36: (Nitrous Oxide). A colourless gas, without appreciable odour or taste. One litre at 0 degrees and at a pressure of 760 mmHg weighs about 1.97 g. One volume dissolves in about 1.4 volumes of water at 20 degrees and at a pressure of 760 mmHg; freely soluble in alcohol; soluble in ether and in oils.

Flammability. Nitrous oxide supports combustion.

Storage and supply. Nitrous oxide is supplied compressed in metal cylinders. National standards are usually in operation for the labelling and marking of such cylinders.

Cylinders containing 50% nitrous oxide and 50% oxygen should be protected from the cold to prevent separation of the gases. Before use, cylinders should be maintained at a temperature above 10 degrees for at least 24 hours to ensure mixing; cylinders containing up to 700 litres of gas may be used immediately if inverted 3 times beforehand.

Uses and Administration

Nitrous oxide is an anaesthetic given by inhalation. It is a weak anaesthetic with a minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) of 110%. It has strong analgesic properties, but produces little muscle relaxation. Nitrous oxide must be given with oxygen, otherwise hypoxia will occur.

Nitrous oxide with oxygen has been used in the induction and maintenance of general anaesthesia (p. 1896.1). However, it is now mainly used as an adjuvant to other inhalational or intravenous anaesthetics, permitting them to be used at significantly lower concentrations. It is also used, with oxygen, in subanaesthetic concentrations for analgesia and sedation in emergency care and obstetric and other painful procedures, including dental procedures (see p. 1032.2).

For maintenance of anaesthesia a mixture containing 50 to 66% nitrous oxide with oxygen is commonly used. Recovery is usually rapid from nitrous oxide anaesthesia.

Nitrous oxide usually 50% v/v with oxygen is used for analgesia; cylinders containing premixed nitrous oxide 50% v/v and oxygen 50% v/v are available in some countries.

Nitrous oxide has also been used occasionally as an insufflating gas for laparoscopy and as a refrigerant in cryosurgery.

Administration in children. Nitrous oxide with oxygen is used in general anaesthesia and for analgesia in children; doses are as for adults (see Uses and Administration, above).

Alcohol withdrawal syndrome. The symptoms of acute alcohol withdrawal (p. 1734.1) are usually managed with benzodiazepines; nitrous oxide has been tried but results have been equivocal.[1,2] More recently, a systematic review[3] found that although nitrous oxide may be a rapidly effective treatment for mild to moderate cases, there was no strong evidence in favour of its use over sedatives due to the small sample sizes of the included studies.

Pain. A mixture of nitrous oxide 50% v/v and oxygen 50% v/v can provide good relief of pain (see Choice of Analgesic, p. 4.2) without loss of consciousness and is suitable for self-administration. It has been widely used for analgesia and sedation during dental procedures. It is also used for short procedures such as dressing changes,[1,2] venepuncture and biopsy,[3] for pain relief during childbirth,[4] in the management of postoperative pain,[1] as an aid to postoperative physiotherapy, and for acute pain in emergency situations such as in ambulances and in the hospital setting.[3,5–7] It has also been tried successfully for colonoscopy,[8] and bronchoscopy.[9,10] Continuous inhalation of nitrous oxide-oxygen has been tried for periods longer than 24 hours in the management of pain in terminal cancer.[11] However, such a practice is not usually otherwise recommended[1] as it may result in megaloblastic bone-marrow changes.

Adverse Effects

The main complications after use of nitrous oxide are those due to varying degrees of hypoxia. Prolonged use has been followed by megaloblastic anaemia and myeloneuropathy. Depression of white cell formation may also occur. There is a risk of increased pressure and volume from the diffusion of nitrous oxide into air-containing cavities; prolonged exposure may lead to bowel distension, middle ear damage, and rupture of the ear drum. Malignant hyperthermia has been reported rarely.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Effects on the blood. Nitrous oxide inactivates vitamin B_{12}, a cofactor for methionine synthase (which converts homocysteine to methionine), thereby increasing plasma-homocysteine concentrations and depleting methionine and tetrahydrofolate. The interference with folate metabolism and DNA synthesis prevents production of both leucocytes and red blood cells by the bone marrow. Megaloblastic changes in bone marrow and impaired granulocyte production are found in patients exposed to anaesthetic concentrations of nitrous oxide for 24 hours. In patients with normal bone marrow, stores of mature granulocytes will normally be adequate to prevent leucopenia during exposure for up to 3 days; in patients exposed to nitrous oxide for longer periods of time, leucopenia will develop and exposure for 4 days or longer can result in agranulocytosis. In general, healthy surgical patients can be given nitrous oxide for up to 24 hours without harm. In situations where nitrous oxide is used for more than 24 hours, folinic acid 30 mg twice daily has been given to protect the haematopoietic system. Repeat exposure to nitrous oxide at intervals of less than 3 days will have a cumulative effect on DNA synthesis and megaloblastic marrow changes have been reported following multiple short-term exposure.[1]

Depletion of methionine has been implicated in the neurological deficit (see Effects on the Nervous System

p. 1909.1) seen mainly after chronic use of nitrous oxide. It may also account for the fetotoxicity seen in *rats*, see Pregnancy, under Precautions, below. For discussion of the effects of hyperhomocysteinaemia, see Effects on the Cardiovascular System, below.

Assessment of vitamin B_{12} levels should be considered before giving nitrous oxide anaesthesia to patients with risk factors for deficiency.[2]

Effects on the cardiovascular system. Nitrous oxide is associated with a dose-dependent increase in plasma-homocysteine concentrations due to the inactivation of vitamin B_{12}, a cofactor for methionine synthase which converts homocysteine to methionine (see also Effects on the Blood and the Nervous System, p. 1908.3 and below, respectively). Acute nitrous oxide-induced hyperhomocysteinaemia has been shown[1] to impair endothelial function in patients with cardiovascular disease undergoing noncardiac surgery. A multicentre randomised controlled study[2] in patients undergoing noncardiac surgery found that the incidence of major postoperative complications, including postoperative fever, wound infection, pneumonia, pulmonary atelectasis, and severe nausea and vomiting, was reduced in the nitrous oxide-free group, but not the length of hospital stay. The authors also noted a possible association between nitrous oxide and postoperative myocardial infarction although this was statistically insignificant. (A substudy[3] on some of the patients identified hyperhomocysteinaemia as an independent risk factor for major postoperative complications, attributed to increased rates of cardiovascular complications.) Follow-up[4] after a median of 3.5 years suggested that nitrous oxide anaesthesia was associated with a marginal increase in the long-term risk of myocardial infarction, but not of death or stroke.

Measures to protect against nitrous oxide-induced hyperhomocysteinaemia have been tried. A randomised study[5] found that oral vitamin B-complex given daily for one week before surgery inhibited the increase in postoperative plasma-homocysteine concentrations; however, differences in clinical outcome were not measured. A later randomised placebo-controlled study[6] concluded that a single pre-operative intravenous infusion of vitamin B_{12} and folate did not prevent nitrous oxide-induced hyperhomocysteinaemia.

Effects on the nervous system. Neurological disorders (mainly myeloneuropathies and neuropathies) have occurred in chronic abusers of nitrous oxide;[1-3] severe myeloneuropathy has been reported after acute use of a high dose.[4] Similar effects have been noted after repeated use of nitrous oxide in hospitalised patients. These neurological effects are considered to be due to nitrous oxide-induced methionine deficiency (see Effects on the Blood and the Cardiovascular System, p. 1908.3 and above, respectively). However, neurological effects can occur without preceding overt haematological changes. Psychosis, responsive to treatment with vitamin B_{12}, has also been reported in a patient abusing nitrous oxide.[5]

In patients with undiagnosed subclinical deficiency of vitamin B_{12} (a cofactor involved in methionine synthesis) neurological manifestations, including those consistent with subacute combined degeneration of the spinal cord, have occurred after a single exposure to nitrous oxide for anaesthesia.[6-8] A literature review[9] of 18 cases found that the onset of symptoms after exposure to nitrous oxide varied from immediately after surgery to about 2 months later; duration of exposure ranged from 60 minutes to 11 hours, at concentrations of 40 to 66%. Acute paralysis, due to degeneration of the spinal cord, has also been reported in a malnourished patient who had been abusing nitrous oxide for 10 days for the self-treatment of a painful sprained ankle.[10]

Precautions

Hypoxic anaesthesia is dangerous and nitrous oxide should always be given with at least 21 to 30% oxygen. Nitrous oxide diffuses into gas-filled body cavities and is contra-indicated in patients with any condition where the expansion of trapped gas may be dangerous, such as head injuries with impairment of consciousness, pneumothorax, air embolism, decompression sickness, severe bullous emphysema, gross abdominal distension, intoxication, maxillofacial injuries, and after air encephalography or recent intra-ocular injection of gas. Nitrous oxide should not be used for more than a total of 24 hours, or more frequently than every 4 days, without close supervision and haematological monitoring. Oxygen should be given during emergence from prolonged anaesthesia with nitrous oxide to prevent diffusion hypoxia where the alveolar oxygen concentration is diminished. See also Precautions for General Anaesthetics, p. 1897.3.

Nitrous oxide has been subject to abuse.

Abuse. 'Recreational' use or abuse of nitrous oxide has been referred to as "nagging" or "nanging". For some of the resulting adverse effects of nitrous oxide abuse, see Effects on the Nervous System, above.

Driving. A slight but quantifiable impairment in driving ability was found up to 30 minutes after 15 minutes' inhalation of nitrous oxide/oxygen mixtures for analgesia and sedation;[1] indeed, licensed product information recommends against driving or operating machinery until at least 30 minutes after administration. Similarly, such activities should be avoided until 12 hours after nitrous oxide anaesthesia.

1. Moyes DG, *et al.* Driving after anaesthetics. *BMJ* 1979; 1: 1425.

Epidural anaesthesia. Nitrous oxide diffuses into gas-filled body cavities and can increase the size of any air bubbles injected into the epidural space to determine placement of the needle in epidural anaesthesia.[1] This could result in uneven spread of the local anaesthetic and produce inadequate analgesia. The volume of air injected should be limited or another technique used to determine placement of the needle if nitrous oxide is to be given subsequently.

1. Stevens R, *et al.* Fate of extradural air bubbles during inhalation of nitrous oxide. *Br J Anaesth* 1994; 72: 482P–483P.

Occupational exposure. A scavenging system and effective ventilation may be necessary to control the nitrous oxide pollution that can occur when this gas is used for analgesia or anaesthesia. Risk areas include, in addition to operating theatres, delivery rooms and dental surgeries.[1-3] Occupational exposure can lead to serious toxicity with bone-marrow and neurological impairment.[1,2] Reduced fertility has been reported in female dental workers exposed to high concentrations of nitrous oxide;[4] such women also appear to have a higher rate of spontaneous abortion.[5] It has been suggested that nitrous oxide can also affect male fertility;[6] in one study a dose-related increase in the incidence of spontaneous abortion was found in the wives of men with occupational exposure to nitrous oxide.[7] A later review[8] concluded that although there is some evidence of a causal link between exposure to nitrous oxide and spontaneous abortion and infertility, this evidence was limited. The author noted that most of the studies were conducted before scavenging was widely used, and none included ambient gas sampling, and that most of the data were obtained by questionnaire.

Vitamin B_{12} deficiency. For reports of neurological dysfunction associated with the use of nitrous oxide in patients with undiagnosed subclinical vitamin B_{12} deficiency, see Effects on the Nervous System, above.

Interactions

Use of nitrous oxide in a high concentration with an inhalational anaesthetic accelerates the uptake of the latter from the lungs. This phenomenon is known as the *second gas effect*. It is due to the disproportionate absorption of nitrous oxide into the blood resulting in an increased alveolar concentration of the second gas.

The use of high doses of opioids such as fentanyl with nitrous oxide may result in a drop in heart rate and cardiac output.

See also Interactions for General Anaesthetics, p. 1897.3.

Methotrexate. Combined use of nitrous oxide and methotrexate may increase some of the adverse effects of methotrexate therapy, see p. 828.2.

Pharmacokinetics

Nitrous oxide is rapidly absorbed on inhalation. The blood/gas partition coefficient is low and most of the inhaled nitrous oxide is rapidly eliminated unchanged through the lungs though small amounts diffuse through the skin.

Preparations

$C_{18}H_{27}NO_5$=337.4

CAS — 1421-14-3.

ATC — N01AX04.

ATC Vet — QN01AX04.

UNII — AO82L471NS.

Profile

Propanidid has been used as an intravenous anaesthetic for rapid induction and for maintenance of general anaesthesia of short duration.

Commercial preparations of propanidid were provided as a liquid in polyoxyl castor oil. Anaphylactoid reactions associated with the vehicle led to the general withdrawal of propanidid from use.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Propofol). A colourless or very light yellow, clear liquid. Very slightly soluble in water; miscible with hexane and with methyl alcohol. Store under an inert gas. Protect from light.

USP 36: (Propofol). A clear, colourless to slightly yellowish liquid. Very slightly soluble in water; very soluble in dehydrated alcohol and in methyl alcohol; slightly soluble in cyclohexane and in isopropyl alcohol. Store under an inert gas in airtight containers. Protect from light.

Uses and Administration

Propofol is a short-acting anaesthetic given intravenously for the induction and maintenance of general anaesthesia (p. 1896.1). It is also used for sedation (p. 1032.2) in adult patients undergoing diagnostic procedures, in those undergoing surgery with local or regional anaesthesia, and in ventilated adult patients under intensive care. When used for anaesthesia, induction is rapid, as is recovery. Propofol has no analgesic activity and supplementary analgesia may be required.

Propofol is available as a 1 or 2% emulsion. The 1% emulsion may be given by intravenous injection or infusion, but the 2% emulsion is for infusion only. Infusions and injections should be prepared using aseptic techniques, see Administration, below.

Induction of **anaesthesia** is generally carried out by giving propofol by injection or infusion at a rate of 40 mg every 10 seconds; a rate of 20 mg every 10 seconds may be used in high-risk patients including elderly, neurosurgical, and debilitated patients. Most adults under 55 years of age can be anaesthetised by a dose of 1.5 to 2.5 mg/kg; high-risk patients usually require a dose of 1 to 1.5 mg/kg.

When used for maintenance propofol is infused at a rate of between 4 to 12 mg/kg per hour (or 3 to 6 mg/kg per hour for elderly and debilitated patients); alternatively intermittent bolus injections of 20 to 50 mg may be given; rapid bolus doses should be avoided in high-risk patients.

For dosage in children, see below.

A novel delivery system is also available for the induction and maintenance of anaesthesia in adults. The Diprifusor target-controlled infusion system allows the speed of induction and depth of anaesthesia to be controlled by specifying target blood concentrations of propofol. Initial target concentrations for induction range from 4 to 8 micrograms/mL for patients under 55 years of age; lower initial target concentrations should be used in older and debilitated patients and should be increased gradually thereafter in steps of 0.5 to 1 microgram/mL at intervals of 1 minute to achieve a gradual induction of anaesthesia. Target concentrations for maintenance are 3 to 6 micrograms/mL.

For **sedation** in diagnostic and surgical procedures in adults an initial infusion of 6 to 9 mg/kg per hour may be given for 3 to 5 minutes; alternatively 0.5 to 1 mg/kg may be injected slowly over 1 to 5 minutes. An infusion of 1.5 to 4.5 mg/kg per hour may be used for maintenance of sedation. High-risk patients usually require a 20% reduction in the maintenance dose.

For the sedation of ventilated adults propofol can be given by intravenous infusion in a dose of 0.3 to 4 mg/kg per hour. If the duration of sedation is in excess of 3 days, lipid concentrations should be monitored.

Administration. Propofol is formulated as an oil-in-water emulsion for injection. Strict aseptic techniques must be maintained when handling propofol as, in some countries, the parenteral product contains no antimicrobial preservatives and the vehicle can support rapid growth of microorganisms. Aseptic techniques must also be applied to formulations, such as those available in the UK and USA, that contain the microbial-retarding agent disodium edetate, as microbial growth is still possible. An emulsion containing 1% of propofol may be diluted with glucose 5% immediately before use but it should not be diluted to a concentration of less than 2 mg/mL. An emulsion containing 2% of propofol should not be diluted. The use of a 5-micrometre filter needle to withdraw propofol emulsion from an ampoule does not cause significant loss of drug.[1] A reduction in concentration of propofol can occur when the diluted emulsion is run through PVC intravenous tubing.[1] Propofol 1 or 2% may be given into a running intravenous infusion through a Y-site close to the injection site and under these circumstances it is compatible with glucose 5%, sodium chloride 0.9%, lactated Ringer's solution, and glucose with sodium chloride or with lactated Ringer's solution.

Because injection of propofol can be painful, it may be mixed with alfentanil or lidocaine before use. UK licensed product information advises mixing lidocaine 0.5 or 1% injection (without preservatives) in a ratio of 1:20 with propofol injection 1% immediately before use; similarly, alfentanil injection 500 micrograms/mL may be mixed in a ratio of 1:20 to 1:50 with propofol 1%. It advises against mixing the 2% emulsion of propofol with other drugs.

Administration in children. In the UK, children aged 1 month and over may be given propofol for the induction and maintenance of anaesthesia. The dose should be adjusted for weight and age, and given slowly until the onset of anaesthesia. Most children aged over 8 years require an induction dose of 2.5 mg/kg; younger children may require a higher dose within the range of 2.5 to 4 mg/kg. Doses of 9 to 15 mg/kg per hour by intravenous infusion or intermittent bolus injections are suitable for maintenance. The 2% emulsion formulation of propofol should only be used in children aged 3 years and over. In the USA, children aged 3 years and over may be given propofol for the induction of anaesthesia; those aged 2 months and over may receive propofol for maintenance of anaesthesia. Doses are similar to those used in the UK.

Propofol is contra-indicated for sedation in children aged 16 years or less. A systematic review[1] found only 1 study of the use of propofol in neonates; although there was some evidence of benefit the numbers were insufficient to establish its role and safety.

1. Shah PS, Shah VS. Propofol for procedural sedation/anaesthesia in neonates. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2011 (accessed 14/04/11).

Nausea and vomiting. It is commonly believed that propofol is associated with less postoperative nausea and vomiting than some other anaesthetics.[1,2] However, a review[3] concluded that any reduction in nausea and vomiting when using propofol anaesthesia may be short term and clinically relevant only for maintenance anaesthesia in procedures with an inherent risk of nausea and vomiting.

There are also reports[4-9] indicating that propofol may have some intrinsic antiemetic action when used in subhypnotic doses although a study[10] of the effect of sedative and non-sedative (sub-hypnotic) doses against apomorphine-induced vomiting has suggested that any antiemetic effect is probably due to sedation.

Pruritus. Propofol is one of many drugs that have been tried in the management of pruritus (p. 1687.3). Sub-hypnotic doses of propofol appear to have an antipruritic action. It has produced conflicting results in the treatment and prophylaxis of pruritus associated with epidural and intrathecal morphine[1-4] although it appears to be able to relieve cholestasis-associated pruritus.[5] It has been suggested that propofol might act by suppression of the spinal transmission of pruritic signals.

Status epilepticus. General anaesthesia may be used to control refractory tonic-clonic status epilepticus (p. 510.2). A short-acting barbiturate such as thiopental is usually used. Propofol is also used[1-7] although good controlled studies of its efficacy are lacking; in addition, it has caused seizures when used in anaesthesia (see CNS Effects, under Precautions, p. 1912.1) and should be given with caution to patients with epilepsy. The risks of respiratory and cerebral depression, lipid overload with prolonged therapy and propofol infusion syndrome should also be borne in mind. It may induce involuntary movements and care is required to distinguish these from seizures. Nonetheless, it has a rapid onset of action and its effects are maintained while the infusion is maintained; recovery is rapid on stopping. Some guidelines[7] recommend giving an initial intravenous bolus of 2 to 3 mg/kg, with further boluses of 1 to 2 mg/kg until seizures are controlled, followed by a continuous infusion of 4 to 10 mg/kg per hour guided by EEG monitoring. A lower initial bolus dose of 1 mg/kg has also been used.[4] The dose should be gradually reduced and the infusion tapered 12 to 24 hours after seizure activity is halted. Lower doses should be used in the elderly. A study[8] comparing propofol with high-dose barbiturates in patients with refractory status epilepticus concluded that recurrent seizures were common when propofol infusions were suddenly stopped but not when the infusions were gradually tapered.

Tetanus. Sedation with propofol has been used in the treatment of tetanus (p. 2029.2) to control spasms and rigidity.

Adverse Effects

Early studies with propofol used a preparation formulated with polyoxyl castor oil. Because of anaphylactoid reactions the preparation was reformulated with a vehicle of soya oil and purified egg phosphatide. Adverse effects with this preparation include pain on injection, especially if the injection is into a small vein. Local pain may be reduced by injection into a large vein or by injection of intravenous lidocaine. Apnoea may be frequent; apnoea lasting longer than 60 seconds has been reported to occur in 12% of patients. There are isolated reports of pulmonary oedema. Cardiovascular effects include a reduction in blood pressure and bradycardia. There have been reports of convulsions (sometimes delayed in onset) and involuntary movements. Fever and pancreatitis have occurred very rarely. Anaphylactoid reactions have been reported. Discoloration of urine has been reported after prolonged use. Nausea, vomiting, and headache may occur during recovery.

Children given propofol for prolonged sedation have suffered severe reactions and there have been fatalities, and a life-threatening infusion syndrome has also been seen in adults, see Incidence of Adverse Effects, below.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Incidence of adverse effects. In May 1989 the UK CSM commented on the 268 reports of adverse reactions to propofol that it had received since propofol was introduced to the UK market, during which period about 2 million patients had been anaesthetised with the drug.[1] These included reports of:

- seizures (37 cases, 13 in known epileptics)
- involuntary movements (16 cases)
- opisthotonus (10 cases)
- anaphylactic reactions (32 cases)
- cardiac arrest (13 cases)
- delayed recovery (8 cases)

In 1992 the CSM pointed to the risk of **delayed convulsions** with propofol and its particular importance

for day-case surgery.[2] While the incidence of convulsions was low (170 reports), 31% of the reports described the convulsions as delayed.

In June 1992 the CSM commented on the dangers of propofol for the **sedation of children** in intensive care,[3] a use for which it is contra-indicated in the UK. (This prohibition does not apply to its use for the sedation of ventilated adults—but see below—or to propofol's use as an *anaesthetic* in children. Sedation in children undergoing surgical and diagnostic procedures is not contra-indicated but is an unlicensed use, and is not recommended.[4])

The CSM reported that there had been 66 reports worldwide of serious adverse effects in children sedated with propofol, and some fatalities had ensued. The children had suffered neurological, cardiac, and renal effects, hyperlipidaemia, hepatomegaly, and metabolic acidosis. Five deaths had been reported to the CSM. These 5 children[5] were aged 4 weeks to 6 years and doses of propofol ranged from 4 to 10.7 mg/kg per hour. They developed metabolic acidosis, bradyarrhythmia, and progressive myocardial failure resistant to treatment. The latter has been reported by others to be significantly associated with the use of long-term, **high-dose** propofol infusions.[6]

Similar adverse effects resulting in fatalities have also been reported in **adult** patients with head injuries who received high doses of propofol infusion (greater than 5 mg/kg per hour) for long-term sedation.[7] The CSM subsequently reminded prescribers that the recommended dose range for sedation (up to 4 mg/kg per hour) should not be exceeded.[8] There has also been a report of death in a patient with a closed head injury who received propofol infusion at an average dose of 4.1 mg/kg per hour for long-term sedation.[9] Other fatalities reported included an adult patient with a spinal injury who was sedated with a maximum dose of 2.6 mg/kg per hour (mean 1.9 mg/kg per hour) for about 85 hours[10] and an adult patient with multiple fractures who received doses of 1.4 to 5.1 mg/kg per hour for 88 hours.[11]

The Australian Adverse Drug Reactions Advisory Committee[12] stated in December 2004 that it had received a report of lactic acidosis and another of torsade de pointes in adult patients receiving lower doses of propofol infusion, 30 and 100 mg/hour, respectively, for about 24 hours.

The term **propofol infusion syndrome** is used to describe the life-threatening adverse reaction that is characterised by metabolic acidosis, rhabdomyolysis, acute renal failure, hepatomegaly, hyperlipidaemia, and cardiac dysfunction.[13-16] A prospective observational study[17] of 1017 adult intensive care patients receiving propofol for at least 24 hours found that propofol infusion syndrome developed in 11 patients after an average of 3 days post infusion. Of these 11 patients, 2 died and 2 had received a dose of more than 4.98 mg/kg per hour of propofol (one of whom died). However, one commentator[18] has questioned the findings of this study, noting that they were at odds with most published literature and that the authors did not establish a dose-dependent association. It has also been suggested that concomitant use of glucocorticoids or vasopressive catecholamines are risk factors for development of the syndrome.[16]

Recent recommendations[19-21] on the safe use of propofol have reiterated that it should only be used by professionals trained in the provision of general anaesthesia and given in medical settings where resuscitation facilities are available.

Effects on the cardiovascular system. The main effect of propofol on the cardiovascular system is a fall in both systolic and diastolic blood pressure of 20 to 30%. The compensatory tachycardia seen after a fall in arterial pressure with other intravenous anaesthetics is not usually seen with propofol. Propofol can also decrease systemic vascular resistance, cardiac output, myocardial blood flow, and myocardial oxygen consumption. Bradycardia can occur even in those premedicated with antimuscarinics, and can occasionally be profound and lead to asystole.[1] Despite these cardiodepressant effects propofol in doses of 1.5 to 2.5 mg/kg does not generally cause unacceptable haemodynamic changes in patients with a healthy cardiovascular system although concern has been expressed about its safety in cardiac surgical patients.[2]

Patients (especially children) given propofol for continuous sedation in intensive care units have suffered adverse cardiac reactions with bradyarrhythmia, progressive myocardial failure, and death—see Incidence of Adverse Effects, p. 1910.3.

2. Ginsberg R, Lippmann M. Haemodynamic effects of propofol. *Br J Anaesth* 1994; **72**: 370–1.

Effects on lipids. Prolonged infusion of propofol may be associated with increases in serum triglycerides. In one patient this was believed to have been the cause of necrotising pancreatitis.[1]

1. Metkus AP, *et al.* A firefighter with pancreatitis. *Lancet* 1996; **348**: 1702.

Effects on mental function. There have been anecdotal reports[1] of disinhibited behaviour or sexually orientated hallucinations associated with the use of propofol, but a study using subanaesthetic doses found no evidence that propofol produced euphoria or other mood changes.[2]

1. Canaday BR. Amorous, disinhibited behaviour associated with propofol. *Clin Pharm* 1993; **12**: 449–51.

Effects on the nervous system. See under Precautions, p. 1912.1.

Effects on respiration. See under Precautions, p. 1912.1.

Hypersensitivity. Anaphylactic reactions associated with polyoxyl castor oil used in propofol preparations had prompted a change to the use of soya oil and egg phosphatide in the formulation. A group of workers have reported a patient who had anaphylactic shock when given the reformulated emulsion.[1] A possible case of anaphylaxis to this formulation has also been reported in a child with allergies to egg and peanut oil.[2] Indeed, licensed product information contra-indicates its use in patients with peanut, soya, or egg allergy. However, some[3] have attributed such reactions to propofol itself, in particular its isopropyl and phenol groups.

1. Laxenaire MC, *et al.* Anaphylactic shock due to propofol. *Lancet* 1988; **ii**: 739–40.
2. Hofer KN, *et al.* Possible anaphylaxis after propofol in a child with food allergy. *Ann Pharmacother* 2003; **37**: 398–401.
3. Bradley AED, *et al.* Use of propofol in patients with food allergies. *Anaesthesia* 2008; **63**: 439.

Infection. Between June 1990 and February 1993, 62 cases of postsurgical infections identified in 7 hospitals in the USA were attributed to improper handling of propofol.[1] The infusion was not prepared aseptically and the syringes used in the infusion pumps were reused for several patients. Propofol is formulated as a soybean fat emulsion and the injection contains no antimicrobial preservative although, in the UK and USA, the formulation now contains the microbial-retarding agent, disodium edetate (see Administration, p. 1910.1). However, either formulation still has the potential to support microbial growth. Licensed product information now warns of the importance of aseptic technique in the preparation and use of propofol. Microbial multiplication did not appear to be clinically significant when propofol infusions were prepared and given using conventional aseptic techniques.[2]

1. Bennett SN, *et al.* Postoperative infections traced to contamination of an intravenous anesthetic, propofol. *N Engl J Med* 1995; **333**: 147–54.
2. Farrington M, *et al.* Do infusions of midazolam and propofol pose an infection risk to critically ill patients? *Br J Anaesth* 1994; **72**: 415–17.

Malignant hyperthermia. From an *in-vitro* study it was concluded that propofol does not trigger malignant hyperthermia.[1] There is a report of the safe use of propofol in 19 patients considered susceptible to malignant hyperthermia.[2]

1. Denborough M, Hopkinson KC. Propofol and malignant hyperpyrexia. *Lancet* 1988; **i**: 191.
2. Harrison GG. Propofol in malignant hyperthermia. *Lancet* 1991; **337**: 503.

Pain on injection. Product information suggests the use of lidocaine or alfentanil to reduce the pain associated with injection of conventional formulations of propofol (see Administration, p. 1910.1); alternatively, the larger veins in the forearm and antecubital fossa can be used. Studies indicate that metoclopramide[1] might also be effective. The pain is thought to be caused by the proportion of the propofol dose that is present in the aqueous rather than the oily phase of the emulsion. It has been suggested[2] that the analgesic effect of lidocaine, and possibly metoclopramide, is due to a pH-lowering effect, causing more propofol to be present in the oily phase, but a study showing that lidocaine given by iontophoresis also reduces pain[3] suggests this is not the only mechanism. In another attempt to reduce pain by decreasing the amount of aqueous propofol, a formulation containing a mixture of medium-chain and long-chain triglycerides (*Propofol-Lipuro*), assumed to improve distribution into the lipid phase, has been introduced in some countries. However, studies in adults[4] and children[5] suggest that the reduction in pain with the newer formulation is not as great as that achieved by mixing lidocaine with the conventional long-chain formulation. Licensed product information for this formulation makes similar recommendations for reducing injection pain to those of the conventional formulation. Although some studies in adults[6] and children[7] have suggested that mixing lidocaine with *Propofol-Lipuro* resulted in less injection pain than mixing lidocaine with the conventional formulation, another study in children[8] had found the incidence and intensity of the pain to be similar with both methods. A systematic review and meta-analysis[9] of 177 randomised controlled studies found that about 60% of patients develop pain on injection of propofol alone, and that using an antecubital vein, or pretreating the hand vein with lidocaine along with venous occlusion, were most effective in reducing injection pain. The authors also recommended routine use of a small dose of opioids before induction unless contra-indicated.

Precautions

Propofol should not be given to patients known to be allergic to it, or who have peanut, soya, or egg allergy (see Hypersensitivity, p. 1911.2). Propofol should be used with caution in patients with hypovolaemia, epilepsy, or lipid metabolism disorders, and in the elderly. Since there have been reports of delayed convulsions associated with the use of propofol it is recommended that special care should be taken when propofol is used for day-case surgery. When used in patients with increased intracranial pressure it should be given slowly to avoid a substantial decrease in mean arterial pressure and a resultant decrease in cerebral perfusion pressure. It is also recommended that propofol should not be used with ECT. Premedication with an antimuscarinic may be advisable since propofol does not cause vagal inhibition.

Propofol is used to provide continuous sedation for ventilated adult patients under intensive care. Account should be taken of increasing the patient's lipid load. If the duration of sedation is in excess of 3 days, lipid concentrations should be monitored. Children aged 16 years or less should not be sedated in this manner with propofol (see Incidence of Adverse Effects, p. 1910.3). Propofol is not recommended for use in obstetrics including caesarean section.

See also Precautions for General Anaesthetics, p. 1897.3.

For the need for aseptic handling of propofol see Administration, p. 1910.1 and Infection, p. 1911.2.

Breast feeding. A patient reported that the first breast milk expressed 8 hours after surgery, performed under an anaesthetic regimen that included propofol, had a bluish-green colour that changed to green on standing. The exact compound responsible for the discoloration could not be identified and any potential risk to a breast-fed infant was unknown.

1. Birkholz T, *et al.* Green breast milk after propofol administration. *Anesthesiology* 2009; 111: 1168–9.

CNS effects. Epileptic activity was seen[1] on the EEGs of 3 patients given propofol and it was suggested that it might be useful in ECT, but others[2,3] found that the duration of seizures was less with propofol anaesthesia than with methohexital anaesthesia. It has been suggested[4] that propofol should not be used with ECT and this is the advice in UK licensed product information.

Some consider that abnormal movements induced by propofol are not associated with cortical seizure activity.[5,6] These appear to be more frequent with low doses of propofol[6] and can be abolished in children by increasing the induction dose of propofol from 3 to 5 mg/kg.

Impaired respiration. The manufacturer has stated[1] that some patients who have received propofol for sedation in regional anaesthesia have had bradypnoea or hypoxaemia, or both. A reduction in oxygen saturation has also been noted in other patients sedated for endoscopy.[2] Licensed product information therefore recommends that oxygen saturation should be monitored and that oxygen supplementation should be readily available.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies propofol as not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

Interactions

The use of propofol with other CNS depressants, including those used in premedication, may increase the sedative, anaesthetic, and cardiorespiratory depressant effects of propofol. It is recommended that propofol is given after opioids so that the dose of propofol can be carefully titrated against the response. The dosage of propofol should be reduced if used with nitrous oxide or halogenated anaesthetics. Although propofol does not potentiate the effects of neuromuscular blockers, bradycardia and asystole have occurred after use of propofol with atracurium or suxamethonium (but see under Adverse Effects, p. 1911.2 for the effects of propofol itself on the cardiovascular system).

See also Interactions of General Anaesthetics, p. 1897.3.

Benzodiazepines. Propofol and *midazolam* have been reported to act synergistically.[1-3]

3. Teh J, *et al.* Pharmacokinetic interactions between midazolam and propofol: an infusion study. *Br J Anaesth* 1994; 72: 62–5.

Catecholamines. For the suggestion that use of catecholamines increases the risk of developing the propofol infusion syndrome see Incidence of Adverse Effects, p. 1910.3.

Clonidine. Premedication with clonidine has been reported[1] to reduce intraoperative requirements of propofol.

1. Guglielminotti J, *et al.* Effects of premedication on dose requirements for propofol: comparison of clonidine and hydroxyzine. *Br J Anaesth* 1998; 80: 733–6.

Corticosteroids. For the suggestion that use of *glucocorticoids* increases the risk of developing the propofol infusion syndrome see Incidence of Adverse Effects, p. 1910.3.

Gastrointestinal drugs. The dose of propofol required for induction is reduced in patients given *metoclopramide*.[1]

1. Page VJ, Chhipa JH. Metoclopramide reduces the induction dose of propofol. *Acta Anaesthesiol Scand* 1997; 41: 256–9.

General anaesthetics. Use with *halothane* or *isoflurane* has been reported to increase serum concentrations of propofol.[1] Synergy has been reported between propofol and *etomidate*.[2]

1. Grundmann U, *et al.* Propofol and volatile anaesthetics. *Br J Anaesth* 1994; 72 (suppl 1): 88.
2. Drummond GB, Cairns DT. Do propofol and etomidate interact kinetically during induction of anaesthesia? *Br J Anaesth* 1994; 73: 272P.

Local anaesthetics. A reduction in the amount of propofol required to provide adequate hypnosis[1] or sedation[2] has been reported after *bupivacaine*[1] or *lidocaine*.[1,2] However, lidocaine is often added to propofol emulsions to reduce the pain of injection, see Administration, p. 1910.1.

1. Ben-Shlomo I, *et al.* Hypnotic effect of iv propofol is enhanced by im administration of either lignocaine or bupivacaine. *Br J Anaesth* 1997; 78: 375–7.
2. Mallick A, *et al.* Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation. *Br J Anaesth* 1996; 77: 731–4.

Opioids. In a study mean blood concentrations of propofol were higher in patients pretreated with *fentanyl* compared with patients maintained only on nitrous oxide.[1] However, others[2] were unable to confirm this interaction.

1. Cockshott ID, *et al.* Pharmacokinetics of propofol in female patients. *Br J Anaesth* 1987; 59: 1103–10.
2. Dixon J, *et al.* Study of the possible interaction between fentanyl and propofol using a computer-controlled infusion of propofol. *Br J Anaesth* 1990; 64: 142–7.

Pharmacokinetics

The pharmacokinetics of propofol are best described by a 3-compartment model. After a single bolus dose, two distribution phases are seen. The first phase has a half-life of 2 to 4 minutes. This is followed by a second phase with a half-life of 30 to 60 minutes during which significant metabolism of propofol occurs, and then by a slower redistributive phase. The terminal half-life ranges from 3 to 12 hours; with prolonged use, the terminal half-life may be longer. The termination of anaesthetic effect after a single intravenous bolus or maintenance infusion is due to extensive redistribution from the brain to other tissues and to metabolic clearance.

Propofol is over 95% bound to plasma proteins. It undergoes extensive hepatic metabolism to conjugates which are eliminated in the urine. The pharmacokinetics of propofol do not appear to be altered by gender, chronic hepatic cirrhosis, or chronic renal impairment. Propofol crosses the placental barrier and is distributed into breast milk.

Pharmacopoeias. In *Eur.* (see p. vii) and *US.*

Ph. Eur. 8: (Sevoflurane). A clear, colourless, volatile non-flammable liquid. Slightly soluble in water; miscible with alcohol. Store in airtight, stainless-steel containers Protect from light.

USP 36: (Sevoflurane). A clear, colourless, volatile non-flammable liquid. Slightly soluble in water; miscible

with alcohol, with chloroform, and with ether. Store in airtight containers at a temperature of 20 degrees to 25 degrees, excursions permitted between 15 degrees and 30 degrees. Protect from light.

Uses and Administration

Sevoflurane is a volatile halogenated anaesthetic given by inhalation. It has a minimum alveolar concentration (MAC) value (see Uses of General Anaesthetics, p. 1896.1) ranging from 1.4% in the elderly to 3.3% in neonates. It is used for the induction and maintenance of general anaesthesia (p. 1896.1). It is non-flammable. Sevoflurane has a nonpungent odour and does not cause respiratory irritation. It also has muscle relaxant properties which may be sufficient for some surgical procedures to be performed without a neuromuscular blocker. However, it has been reported to possess no analgesic properties (but see Pain, below).

Sevoflurane is given using a calibrated vaporiser. A short-acting barbiturate or other intravenous induction agent may be given before inhaling sevoflurane. For induction in premedicated patients, sevoflurane is given in concentrations of up to 5% v/v in adults, with oxygen or a mixture of oxygen and nitrous oxide; concentrations of up to 7% v/v may be used in children. For induction in unpremedicated patients, concentrations of up to 8% v/v may be used. Induction with sevoflurane is rapid (surgical anaesthesia in less than 2 minutes) and smooth because of its nonpungent odour. Maintenance of anaesthesia is achieved with a concentration of 0.5 to 3% v/v with or without nitrous oxide.

Reviews.

Administration in children. Sevoflurane is used for the induction and maintenance of general anaesthesia in children; for details of doses, see Uses and Administration, above.

Pain. Two small, open-label studies[1,2] found self-administered sevoflurane 0.8% v/v in oxygen to be effective for pain relief during childbirth although an earlier study[3] was unable to confirm that it had an analgesic effect at subanaesthetic concentrations.

Adverse Effects

As with other halogenated anaesthetics sevoflurane may cause cardiorespiratory depression, hypotension, and malignant hyperthermia. However, the effects of sevoflurane on heart rate have only been seen at higher concentrations and it appears to have little effect on heart rhythm in comparison to other halogenated anaesthetics. Sevoflurane appears to sensitise the myocardium to sympathomimetics to a lesser extent than halothane or enflurane. Other effects seen with sevoflurane include agitation, especially in children, laryngospasm, and increased cough and salivation. Urinary retention and acute renal failure have also been noted, as have changes in liver enzyme values and reports of liver damage. Seizures have occurred in children and young adults, as well as older adults, with and without predisposing risk factors; dystonic movements have also been seen in children. Shivering, nausea, and vomiting have been reported in the postoperative period.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Effects on the cardiovascular system. The cardiovascular effects of sevoflurane are similar to those of isoflurane (see p. 1904.1) but it does not produce coronary steal. Also sevoflurane produces less tachycardia than isoflurane suggesting that it may be preferable in those predisposed to myocardial ischaemia.

Effects on the kidneys. Investigations[1] of the nephrotoxic potential of sevoflurane have found no evidence of renal function impairment despite peak plasma-fluoride ion concentrations greater than 50 nanomol/mL (a level considered to be nephrotoxic) being recorded in some patients at the end of sevoflurane anaesthesia,[2] and clinical experience would tend to support this.[3] The lack of renal toxicity with sevoflurane may be due to low concentrations of intrarenally generated fluoride ions;[4] in comparison, methoxyflurane defluorination in the kidney is much greater, and other metabolites may contribute to its known nephrotoxicity (see p. 1908.1).

Compound A, formed by the degradation of sevoflurane by carbon dioxide absorbents (see under Precautions, below), is nephrotoxic in *rats*.[1] However, studies in humans undergoing sevoflurane anaesthesia have detected no renal impairment postoperatively even when compound A was detected in the anaesthetic circuits.

Effects on the liver. There have been signs of hepatotoxicity in *animal* studies but in studies in humans, markers for hepatocellular dysfunction were no greater after sevoflurane anaesthesia than those after isoflurane.[1] The metabolism of sevoflurane differs from other halogenated anaesthetics in such a way that metabolites implicated in liver toxicity are not formed (see Pharmacokinetics, p. 1914.1). Nevertheless, licensed product information states that there have been postmarketing reports of hepatitis, and fatal cases of hepatic failure[2] and necrosis[3] have been reported. The production of compound A (see Carbon Dioxide Absorbents, under Precautions, below), increased cytosolic free calcium, and activation of free radical metabolising enzymes have been proposed as possible mechanisms of sevoflurane hepatotoxicity.[4]

Effects on the nervous system. Sevoflurane has been shown to have a dose-related epileptogenic effect although the mechanism is unknown.[1] Tonic-clonic seizure-like movements associated with induction of anaesthesia using sevoflurane have been reported particularly in children[1-3] with or without a personal and/or family history of epilepsy or seizures, including an infant[4] with a history of tonic-clonic seizures. To minimise the risk, some have suggested[1] using a maximum of 1.5 times the minimum alveolar concentration (MAC) sevoflurane for maintenance of anaesthesia, and avoiding hypocapnia and monitoring cortical activity during the procedure.

Hypersensitivity. For a report of hypersensitivity reactions, including asthma, associated with occupational exposure to isoflurane and sevoflurane, see under Precautions, below.

Precautions

As with other halogenated anaesthetics, patients with known or suspected susceptibility to malignant hyperthermia should not be anaesthetised with sevoflurane. It should also not be used in those with a history of moderate or severe hepatic impairment associated with halogenated anaesthetics and should be used with caution in those with underlying liver disease. Sevoflurane reduces uterine muscle tone during pregnancy and should be used with caution in obstetrics because of the increased risk of uterine bleeding. Although the effects of sevoflurane on cerebral pressure are minimal in normal patients, safety in those with raised intracranial pressure has not been established and therefore sevoflurane should be used with caution together with techniques to lower intracranial pressure. As emergence and recovery are particularly rapid with sevoflurane patients may require early postoperative pain relief. In children with neuromuscular disease, particularly Duchenne muscular dystrophy, halogenated anaesthetics have been associated with very rare cases of hyperkalaemia resulting in cardiac arrhythmias and death during the postoperative period.

See also Precautions for General Anaesthetics, p. 1897.3.

Abuse. Fatalities have been reported[1-3] with the abuse of sevoflurane. Autopsy revealed pulmonary oedema and frothing in the lung of one victim, suggesting death by asphyxia,[1] and cardiac arrhythmias were considered the cause of death in another 2 victims.[2,3]

Carbon dioxide absorbents. During anaesthesia given by circle breathing systems, the degradation of sevoflurane by carbon dioxide absorbents (such as soda lime) results in the formation of pentafluoroisopropenyl fluoromethyl ether (PIFE; compound A), and trace amounts of pentafluoromethoxy isopropyl fluoromethyl ether (PMFE; Compound B). The degree of degradation, absorption, and solubility of volatile anaesthetics is affected by the water content of carbon dioxide absorbents. In the case of sevoflurane, patients may inhale significant amounts of degradation products when the soda lime dries out. Compound A has been shown to be nephrotoxic in *rats* (see under Effects on the Kidneys, above). Even during short exposure times, as required for induction of anaesthesia, use of moist soda lime is important to minimise sevoflurane degradation, which is also aggravated by a high potassium hydroxide content of the soda lime.[1] Licensed product information states that the problem of compound A formation may be greater if barium hydroxide lime is used as a carbon dioxide absorbent rather than soda lime. Newer carbon dioxide absorbents that contain no, or reduced amounts of, potassium and/or sodium hydroxide have been developed and subsequently shown[2-4] to reduce the degradation of sevoflurane.

The use of desiccated carbon dioxide absorbents with sevoflurane has also been associated with rare cases of extreme heat and smoke or fire developing in the anaesthetic apparatus.[5]

5. Abbott Laboratories, Canada. Important safety information regarding the use of Sevorane AF (sevoflurane) in conjunction with anesthesia machines (issued 17th November, 2003). Available at: http://www.hc-sc.gc.ca/dhp-mps/alt_formats/hpfb-dgpsa/pdf/medeff/sevorane_hpc-cps-eng.pdf (accessed 08/08/08)

Occupational exposure. Hypersensitivity reactions, manifesting as asthma, angioedema, or dermatitis, associated with occupational exposure to isoflurane and sevoflurane have been reported[1] in 3 healthcare workers. Of these, one worker with positive response on bronchial provocation testing subsequently had an anaphylactic reaction to sevoflurane during general anaesthesia; indirect exposure to sevoflurane resulted in a late asthmatic reaction in another, and exposure to isoflurane resulted in a rash in the third.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sevoflurane as possibly porphyrinogenic; it should be used only when no safer alternative is available and precautions should be considered in vulnerable patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 04/10/11)

Interactions

Care is advised if adrenaline or other sympathomimetics are given during sevoflurane anaesthesia. The effects of competitive neuromuscular blockers such as atracurium are enhanced by sevoflurane (see p. 2032.3). The metabolism, and hence toxicity, of sevoflurane may be increased by drugs or compounds that induce cytochrome P450 isoenzyme CYP2E1 including isoniazid and alcohol.

See also Interactions of General Anaesthetics, p. 1897.3.

References.

Pharmacokinetics

Sevoflurane is absorbed on inhalation. The blood/gas partition coefficient is low. Up to 5% of the absorbed dose of sevoflurane is metabolised in the liver by the cytochrome P450 isoenzyme CYP2E1 and defluorinated to its major metabolites hexafluoroisopropanol (HFIP), inorganic fluoride, and carbon dioxide. HFIP is rapidly conjugated with glucuronic acid and eliminated in the urine. Sevoflurane crosses the placenta.

Sodium Oxybate (USAN)

JZP-6; NSC-84223; Ossibato di Sodio; Oxibato sódico; Sodium Gamma-hydroxybutyrate; Wy-3478; Натрия Оксибат; Натрия Оксибутират.

Sodium 4-hydroxybutyrate.

$C_4H_7NaO_3$=126.1.

CAS — 502-85-2.

UNII — 7G33012534.

NOTE. The name Rekinla has been used as a trade mark for sodium oxybate.

Street names. The following terms have been used as 'street names' (see p. vii) or slang names for various forms of sodium oxybate or gamma-hydroxybutyrate:

Blue nitro; Blue verve; Caps; Cherry Meth; Date rape drug; Drogue Du Cambriolage Sexuel Parfait; Easy lay; Everclear; EZLay; Fantasy; G; Gamma Oh; Gamma-OH; GBH; Georgia home boy; GHB; Goop; Great hormones at bedtime; Grievous bodily harm; G-riffic Jib; Liquid E; Liquid ecstacy; Liquid ecstasy; Liquid G; Liquid X; Organic quaalude; Salty water; Scoop; Sleep; Sleep-500; Soap; Somatomax; Somatomax PM; Vita-G; Water.

Pharmacopoeias. In *Chin.*

Uses and Administration

Sodium oxybate has hypnotic properties and, in its endogenous form, gamma-hydroxybutyrate (a catabolite of gamma-aminobutyric acid), increases dopamine concentrations in the brain. It is given intravenously usually with an opioid analgesic and a neuroleptic to produce general anaesthesia (p. 1896.1). Skeletal muscle relaxants may also be necessary. Sodium oxybate given orally is used in the treatment of cataplexy in patients with narcolepsy (below); in the USA it is also indicated for the excessive daytime sleepiness associated with narcolepsy.

In general anaesthesia a solution of sodium oxybate equivalent to 20% of the acid is given slowly by intravenous injection, usually in a dose of 60 mg/kg; in children 100 mg/kg may be used. For maintenance, a further dose that is half of the initial dose may be given.

For the management of narcolepsy in adults, sodium oxybate is given in initial oral doses of 4.5 g daily, as two equally-divided doses. The first dose should be taken at bedtime while in bed and at least 2 to 3 hours after food; the second dose should be taken 2.5 to 4 hours later also while sitting in bed. Both doses should be prepared before going to bed; each dose should be diluted with 60 mL of water. The initial dose may be increased in steps of 1.5 g (0.75 g per dose) every 1 to 2 weeks to a maximum dose of 9 g daily. If therapy has been stopped for more than 14 consecutive days, titration should be restarted at the lowest dose. Reduced doses are recommended in patients with hepatic impairment (see below).

Administration in children. Sodium oxybate is used in general anaesthesia in children; for details of doses, see Uses and Administration, above.

Administration in hepatic impairment. The recommended initial oral dose of sodium oxybate (see Uses and Administration, above) should be halved in patients with hepatic impairment. Subsequent increases should be monitored against effect.

Alcohol withdrawal syndrome. A systematic review[1] of 13 randomised controlled studies involving 648 patients concluded that oral sodium oxybate 50 mg/kg daily is effective, when compared with placebo, in reducing symptoms of alcohol withdrawal (p. 1734.1) and in helping to prevent relapse for up to 3 months thereafter. It also appeared to be as effective as the benzodiazepines and clomethiazole in the treatment of alcohol withdrawal syndrome, and as effective as naltrexone and disulfiram in the maintenance of abstinence. The most commonly reported adverse effects were dizziness and vertigo. However, the risk of addiction, misuse, and/or abuse of the drug is of concern with this patient group.

Adverse Effects

When used in general anaesthesia adverse effects with sodium oxybate include abnormal muscle movements during the induction period and nausea and vomiting. Occasional emergence delirium has been reported. Bradycardia frequently occurs. Respiration may be slowed and hypokalaemia has been reported.

The most common adverse reactions seen in patients taking sodium oxybate orally for the management of narcolepsy are dizziness, headache, and, particularly in women, nausea. Other common reactions include anorexia, vomiting, diarrhoea, peripheral oedema, abnormal dreams and nightmares, sleepwalking, confusion, depression, anxiety, insomnia, paraesthesia, somnolence, tremor, amnesia, blurred vision, sweating, muscle cramps, nocturnal enuresis, urinary incontinence, asthenia, and fatigue. Blood pressure may also be increased. Psychosis, convulsions, hallucinations, agitation, hypersensitivity, and faecal incontinence are less common; rarely, respiratory depression has been reported.

See also Adverse Effects of General Anaesthetics, p. 1896.3.

Effects on electrolyte balance. A report of severe metabolic disorders occurring during therapy with sodium oxybate and tetracosactide in 4 patients with severe head injuries.[1] The disorders consisted of hypernatraemia, hypokalaemia, and metabolic acidosis.

Precautions

In general anaesthesia, sodium oxybate should not be given to patients with severe hypertension, bradycardia, conditions associated with defects of cardiac conduction, epilepsy, eclampsia, renal impairment, or alcohol abuse.

Treatment with oral sodium oxybate is contra-indicated in patients with succinic semialdehyde dehydrogenase deficiency, an enzyme involved in its metabolism to succinic acid. Its use is also contra-indicated in patients with epilepsy as safety and efficacy have not been established; convulsions have been reported with sodium oxybate use.

Patients with a history of depression or suicide attempt should be carefully monitored for depressive symptoms while taking sodium oxybate. The high sodium content of sodium oxybate (0.75 g of sodium in a 4.5 g daily dose) should be considered in patients with heart failure, hypertension, or impaired renal function.

Rebound symptoms with an increased frequency of cataplexy may be seen when sodium oxybate is stopped. There have also been rare reports of withdrawal symptoms such as insomnia, headache, dizziness, anxiety, hallucinations, and psychotic disorders following the illicit use of sodium oxybate (see Abuse, below).

See also Precautions for General Anaesthetics, p. 1897.3.

Abuse. Reports[1] of acute poisoning with oral sodium oxybate after illicit use led the FDA to issue warnings[2] about its potential for abuse. It is usually supplied illicitly as the sodium salt under a variety of names (see Street Names, above) and has been promoted for body building, weight loss, as a psychedelic substance, and as a sleep aid. Sodium oxybate has also been abused at social gatherings.[3,4] Adverse effects include vomiting, drowsiness, amnesia, hypotonia, vertigo, respiratory depression, and involuntary movements. Seizure-like activity, bradycardia, hypotension, and respiratory arrest have also been reported. Resolution of symptoms occurs spontaneously over 2 to 96 hours. However, some patients have required hospitalisation and respiratory support; deaths have been reported in several countries.[5-9] Severity of symptoms depends on the dose of sodium oxybate and the presence of other drugs such as alcohol, benzodiazepines, cannabis, or amfetamines; however, fatalities associated with the ingestion of sodium oxybate alone have been reported.[9] Prolonged use of large doses may lead to a withdrawal syndrome on stopping.[3,4,10-12]

Sodium oxybate is available in tasteless and odourless forms, and has occasionally been misused to incapacitate the victim and produce amnesia in sexual assaults and drug-facilitated rape ('date rape').[3,4,13]

Its precursors gamma-butyrolactone (GBL) and 1,4-butanediol are abused similarly.[3,4,7,13] Withdrawal symptoms have also been associated with stopping these 2 substances in abusers.[12]

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies sodium oxybate as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/10/11)

Interactions

In anaesthesia, sodium oxybate enhances the effects of opioid analgesics, barbiturates, and competitive neuromuscular blockers. The CNS depressant effects of sodium oxybate may be potentiated by alcohol, sedative-hypnotics, and other CNS depressants. The risk of respiratory depression may also be increased by benzodiazepines.

See also Interactions of General Anaesthetics, p. 1897.3.

Pharmacokinetics

After oral doses sodium oxybate is rapidly but incompletely absorbed from the gastrointestinal tract; absolute bioavailability is about 25%. Peak concentrations are reached within 0.5 to 2 hours. Absorption may be delayed and decreased following a high fat meal. Protein binding is less than 1%. Sodium oxybate is metabolised in the liver via GHB dehydrogenase to succinic semialdehyde, which is then converted to succinic acid via another enzyme, succinic semialdehyde dehydrogenase. Succinic acid enters the Krebs cycle and is metabolised to carbon dioxide, which is expired, and water. Less than 5% of unchanged drug appears in the urine; faecal excretion is also negligible.

Thiamylal Sodium

Tiamilal sódico.

Sodium 5-allyl-5-(1-methylbutyl)-2-thiobarbiturate.

$C_{12}H_{17}N_2NaO_2S$=276.3

CAS — 77-27-0 (thiamylal); 337-47-3 (thiamylal sodium).

UNII — T4L2P3KH7K.

Pharmacopoeias. In *Jpn.*

Profile

Thiamylal sodium is a short-acting intravenous barbiturate anaesthetic. It is possibly slightly more potent than thiopental sodium (below) and has similar actions and uses. It has been used for the production of complete anaesthesia of short duration, for the induction of general anaesthesia, or for inducing a hypnotic state.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. ***Jpn:*** Citosol; Isozol.

$C_{11}H_{17}N_2NaO_2S$=264.3

CAS — 76-75-5 (thiopental); 71-73-8 (thiopental sodium).

ATC — N01AF03; N05CA19.

ATC Vet — QN01AF03; QN05CA19.

UNII — 49Y44QZL70.

NOTE. The name thiobarbital has been applied to thiopental and has also been used to describe a barbiturate of different composition.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), *Int.*, *Jpn*, *US*, and *Viet.* Some include thiopental sodium with, some without, anhydrous sodium carbonate; some only include a sterile mixture for injection.

Ph. Eur. 8: (Thiopental Sodium and Sodium Carbonate; Thiopental Sodium BP 2014). A yellowish-white hygroscopic powder. It contains 84 to 87% thiopental and 10.2 to 11.2% sodium. Freely soluble in water; partly soluble in dehydrated alcohol. Store in airtight containers. Protect from light.

USP 36: (Thiopental Sodium). A white to off-white crystalline powder, or yellowish-white to pale greenish-yellow hygroscopic powder. May have a disagreeable odour. Its solutions are alkaline to litmus, decompose on standing, and on boiling, precipitation occurs. Soluble in water and in alcohol; insoluble in ether, in petroleum spirit, and in benzene. Store in airtight containers.

Incompatibility. Solutions of thiopental sodium are incompatible with acidic and oxidising substances including some antibacterials, neuromuscular blockers and analgesics. Compounds commonly listed as incompatible include amikacin sulfate, benzylpenicillin salts, cefapirin sodium, codeine phosphate, ephedrine sulfate, fentanyl citrate, glycopyrronium bromide, morphine sulfate, pentazocine lactate, prochlorperazine edisilate, suxamethonium salts, and tubocurarine chloride. Solutions decompose on standing and precipitation occurs on boiling.

Stability. Loss of thiopental in PVC and cellulose propionate delivery systems has been reported,[1,2] but in another study,[3] no loss of potency was noted. Adsorption has been reported[4] not to occur in polyolefin infusion bags.

4. Trissel LA, *et al.* Drug compatibility with new polyolefin infusion solution containers. *Am J Health-Syst Pharm* 2006; 63: 2379–82.

Uses and Administration

Thiopental is a short-acting barbiturate anaesthetic. It is given intravenously, usually for the induction of general anaesthesia (p. 1896.1), but may be used as the sole anaesthetic to maintain anaesthesia for short procedures with minimal painful stimuli. It is also used in anaesthesia as a supplement to other anaesthetics and as a hypnotic in balanced anaesthesia. Thiopental sodium may also be used intravenously in the control of refractory tonic-clonic status epilepticus and in neurosurgical patients to reduce increased intracranial pressure. It has also been given rectally for basal anaesthesia or basal narcosis.

Thiopental does not usually produce excitation and induction of anaesthesia is usually smooth. It has poor muscle relaxant properties and a muscle relaxant must be given before intubation is attempted. Thiopental also has poor analgesic properties and small doses may even lower the pain threshold. Recovery from moderate doses usually occurs within 10 to 30 minutes, but the patient may remain sleepy or confused for several hours. Large doses, repeated smaller doses, or continuous use may markedly delay recovery.

In **anaesthesia**, the dosage of thiopental varies greatly according to the state of the patient and the nature of other drugs being used concurrently (see under Precautions p. 1916.2 and Interactions p. 1916.2 for further details). Thiopental is usually given intravenously as the sodium salt as a 2.5% solution but a 5% solution is occasionally used. UK licensed product information states that a typical dose for inducing anaesthesia is 100 to 150 mg injected over 10 to 15 seconds, repeated after 30 to 60 seconds according to response. It also recommends that the total dosage used should not exceed 500 mg; in pregnant patients the total maximum dose is 250 mg. In some other countries, it has been recommended that induction begin with a test dose of 25 to 75 mg; thereafter, a dose of 50 to 75 mg may be given at intervals of 20 to 40 seconds according to response. Once anaesthesia has been established, additional doses of 25 to 50 mg may be given as necessary. When thiopental is used as the sole anaesthetic, anaesthesia can be maintained by repeat doses as needed or by continuous intravenous infusion of a 0.2 or 0.4% solution.

To **reduce elevations of intracranial pressure** in neurological patients, thiopental sodium is licensed for use as intermittent bolus injections of 1.5 to 3 mg/kg if adequate ventilation is provided (but see also Cerebrovascular Disorders, below). Higher doses have been tried.

For suggested doses in refractory tonic-clonic **status epilepticus**, see Status Epilepticus, p. 1916.1.

For dosage in *children* and the *elderly*, see also below.

References.

1. Russo H, Bressolle F. Pharmacodynamics and pharmacokinetics of thiopental. *Clin Pharmacokinet* 1998; 35: 95–134.

Administration in children. For the *induction of anaesthesia* in children, UK licensed product information recommends that thiopental sodium is given by slow intravenous injection (over 10 to 15 seconds) in a dose of 2 to 7 mg/kg; the dose may be repeated after 1 minute. Intravenous injections are normally given as a 2.5% solution.

In the treatment of prolonged *status epilepticus* (see p. 1916.1), the *BNFC* recommends an initial dose of up to 2 mg/kg in neonates or up to 4 mg/kg in children aged 1 month to 18 years, given as a slow intravenous injection; for all patients, this should then be followed by a continuous intravenous infusion of up to 8 mg/kg per hour, adjusted according to response.

Administration in the elderly. It is usually recommended that the dosage of barbiturate anaesthetics is reduced in the elderly. A study[1] in elderly patients showed that although reducing the rate of intravenous injection reduced the speed of induction, the dosage required was also reduced. Giving thiopental sodium 2.5% solution at a rate of 125 mg/minute induced anaesthesia in a mean of 90.8 seconds and required a mean dose of 2.8 mg/kg. Corresponding values for a rate of 500 mg/minute were 40.8 seconds and 5 mg/kg, respectively.

1. Berthoud MC, *et al.* Comparison of infusion rates of three i.v. anaesthetic agents for induction in elderly patients. *Br J Anaesth* 1993; 70: 423–7.

Anaesthesia. Some of the adverse effects of the neuromuscular blocker suxamethonium may be reduced when thiopental is used as part of the anaesthetic regimen. For a suggestion that thiopental may help to counteract the rise in intra-ocular pressure associated with the use of suxamethonium for intubation, see under Anaesthesia, p. 2028.1.

Cerebrovascular disorders. Barbiturates have been considered as suitable anaesthetics for use in patients with or at risk of raised intracranial pressure. Barbiturate-induced coma (commonly with pentobarbital or thiopental) has been used, both therapeutically and prophylactically, to protect the brain from ischaemia resulting from neurological insults including head injury, stroke, Reye's syndrome, and hepatic encephalopathy.[1-3] Rationale includes the ability of barbiturates to reduce intracranial pressure and to reduce metabolic demands of cerebral tissues. Although thiopental protected patients against the neuropsychiatric complications of cardiopulmonary bypass,[4] the Brain Resuscitation Clinical Trial I Study Group[5] found no cerebral benefit from thiopental in comatose survivors of cardiac arrest. Nor did others[6] observe any benefit from thiopental-induced coma in infants with severe birth asphyxia. A review in 1989 considered that there was no convincing evidence of improvement in neurological outcome to justify the risks of the procedure in conditions causing global ischaemia, although use of barbiturates without necessarily inducing coma might have a limited role in reduction of raised intracranial pressure refractory to other therapy. Use of barbiturates in the setting of regional cerebral ischaemia, including use during cardiopulmonary bypass to prevent focal neurological complications, remained controversial.[1] A systematic review[7] came to similar conclusions, pointing out that although the barbiturates may reduce intracranial pressure their hypotensive effects are likely to offset any beneficial action on cerebral perfusion, perhaps accounting for the lack of evidence for any clinical benefit. In addition, there have been individual case reports of effects on blood-potassium associated with thiopental-induced coma (see Effects on Electrolytes, under Adverse Effects and Treatment, p. 1916.1).

For a discussion of the treatment of raised intracranial pressure, including a mention of the use of barbiturates, see p. 1271.3.

Status epilepticus. General anaesthesia may be used to control refractory tonic-clonic status epilepticus (p. 510.2). A short-acting barbiturate such as thiopental is usually used.

Doses of thiopental sodium in the treatment of status epilepticus appear to vary widely and may be defined by local clinical protocols. Licensed product information and the *BNF* recommend a dose of 75 to 125 mg intravenously as a 2.5% solution. Other regimens advocate an initial loading dose followed by further intermittent doses or a continuous infusion. European guidelines for the management of status epilepticus in adults suggest thiopental is started with a bolus of 3 to 5 mg/kg, then further boluses of 1 to 2 mg/kg every 2 to 3 minutes until seizures are controlled, followed by continuous intravenous infusion at a rate of 3 to 7 mg/kg per hour, titrated against EEG burst suppression, which should be maintained for at least 24 hours.[1] Recovery may be prolonged.[2]

For the dose of thiopental in children, see Administration in Children, p. 1915.3.

Adverse Effects and Treatment

As for Phenobarbital, p. 536.3.

Excitatory phenomena such as coughing, hiccuping, sneezing, and muscle twitching or jerking may occur with any of the barbiturate anaesthetics, particularly during induction, but they occur more frequently with methohexital than with thiopental. Symptoms of laryngeal spasm or bronchospasm including cough and sneezing may also occur during induction. The intravenous injection of concentrated solutions of thiopental sodium such as 5% may result in thrombophlebitis. Extravasation of barbiturate anaesthetics may cause tissue necrosis. Intra-arterial injection causes severe arterial spasm with burning pain and may cause prolonged blanching of the forearm and hand and gangrene of digits. Hypersensitivity reactions have been rarely reported. Barbiturate anaesthetics can cause respiratory depression. They depress cardiac output and often cause an initial fall in blood pressure, and overdosage may result in circulatory failure. Arrhythmias may occur. Excessive doses are associated with hypothermia and profound cerebral impairment. Postoperative vomiting is infrequent but shivering may occur and there may be persistent drowsiness, confusion, and amnesia. Other relatively common postoperative effects include anorexia, malaise, fatigue, and dizziness; delirium has been seen in elderly patients. Headache has also been reported.

See also under Adverse Effects of General Anaesthetics, p. 1896.3.

Effects on electrolytes. Although barbiturate-induced coma with intravenous thiopental is used in the management of raised intracranial pressure, it has been associated with reports of hypokalaemia and severe rebound hyperkalaemia.[1-3] Frequent monitoring of serum-potassium concentrations during the first 24 hours after stopping thiopental infusion,[1] and tapering the dose,[2] have been recommended by some.

1. Bouchard PM, *et al.* Thiopental-associated dyskalemia in severe head trauma. *J Trauma* 2008; 64: 838–42.
2. Neil MJE, Dale MC. Hypokalaemia with severe rebound hyperkalaemia after therapeutic barbiturate coma. *Anesth Analg* 2009; 108: 1867–8.
3. Jung JY, *et al.* Sequential occurrence of life-threatening hypokalemia and rebound hyperkalemia associated with barbiturate coma therapy. *Clin Nephrol* 2009; 71: 333–7.

Hypersensitivity. Anaphylactic reactions to thiopental have been reported[1,2] although such reactions are rare. There has also been a report of haemolytic anaemia and renal failure with the development of an anti-thiopental antibody in a patient who had undergone general anaesthesia induced by thiopental.[3]

1. Westacott P, *et al.* Anaphylactic reaction to thiopentone: a case report. *Can Anaesth Soc J* 1984; 31: 434–8.
2. Moneret-Vautrin DA, *et al.* Simultaneous anaphylaxis to thiopentone and a neuromuscular blocker: a study of two cases. *Br J Anaesth* 1990; 64: 743–5.
3. Habibi B, *et al.* Thiopental-related immune hemolytic anemia and renal failure: specific involvement of red-cell antigen I. *N Engl J Med* 1985; 312: 353–5. Correction. *ibid.*; 1136.

Intra-arterial injection. Accidental intra-arterial injection of thiopental sodium produces severe arterial spasm with intense burning pain. Anaesthesia, paresis, paralysis, and gangrene may occur. Therapy has concentrated on dilution of injected thiopental, prevention and treatment of arterial spasm, prophylaxis of thrombosis, thrombectomy and other measures to sustain good blood flow. There has been a report[1] of the successful use of urokinase intra-arterially in the management of one patient accidentally given thiopental intra-arterially.

1. Vangerven M, *et al.* A new therapeutic approach to accidental intra-arterial injection of thiopentone. *Br J Anaesth* 1989; 62: 98–100.

Precautions

Barbiturate anaesthetics are contra-indicated in severe shock, dystrophia myotonica, and when there is dyspnoea or respiratory obstruction such as in acute severe asthma or when maintenance of an airway cannot be guaranteed.

Barbiturate anaesthetics should be used with caution in patients with dehydration, hypovolaemia, severe haemorrhage, burns, severe anaemia, hyperkalaemia, toxaemia, myasthenia gravis, myxoedema and other metabolic disorders, or severe renal disease. Caution is also required in those with cardiovascular disease, adrenocortical insufficiency, cachexia, or increased intracranial pressure or blood urea. Reduced doses are required in the elderly and in severe hepatic disease.

See also Precautions for General Anaesthetics, p. 1897.3.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers received thiopental, and the last available guidance from the American Academy of Pediatrics[1] considered that it was therefore usually compatible with breast feeding.

In two groups of 8 women undergoing induction with thiopental, the milk-to-plasma ratio was less than 1 in both groups and it was considered that the effects of thiopental on breast-fed infants would be negligible.[2]

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; 108: 776–89. [Retired May 2010] Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 26/05/04)
2. Andersen LW, *et al.* Concentrations of thiopentone in mature breast milk and colostrum following an induction dose. *Acta Anaesthesiol Scand* 1987; 31: 30–2.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies thiopental as porphyrinogenic; it should be prescribed only for compelling reasons and precautions should be taken in all patients.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 05/10/11)

Interactions

Producing anaesthesia with the usual dose of barbiturate anaesthetics in patients accustomed to taking alcohol or other CNS depressants may be difficult; additional anaesthetics may be necessary. Patients being treated with phenothiazine antipsychotics may develop increased hypotension. Some phenothiazines, especially promethazine, may also increase the incidence of excitatory phenomena produced by barbiturate anaesthetics; cyclizine may possibly have a similar effect. Opioid analgesics can potentiate the respiratory depressant effect of barbiturate anaesthetics and the dose of the anaesthetic may need to be reduced. Use with nitrous oxide greatly reduces the dose of barbiturate anaesthetics required for anaesthesia. Reduced doses of thiopental may be required in patients receiving sulfafurazole.

See also Interactions of General Anaesthetics, p. 1897.3.

Antidepressants. Potentiation of barbiturate anaesthesia may be expected in patients receiving *tricyclic antidepressants* or *MAOIs* (see Anaesthesia under Precautions of Amitriptyline, p. 404.3 and for Phenelzine, p. 444.1, respectively).

Antipsychotics. For mention of the effect of *droperidol* on thiopental see Gastrointestinal Drugs, below.

Aspirin. Pretreatment with aspirin, a highly protein-bound drug, has been shown to potentiate thiopental anaesthesia.[1]

1. Dundee JW, *et al.* Aspirin and probenecid pretreatment influences the potency of thiopentone and the onset of action of midazolam. *Eur J Anaesthesiol* 1986; 3: 247–51.

Gastrointestinal drugs. *Metoclopramide* profoundly reduced the dose of thiopental required to produce hypnosis in female patients; *droperidol* had a similar effect.[1]

1. Mehta D, *et al.* Metoclopramide decreases thiopental hypnotic requirement. *Anesth Analg* 1993; 77: 784–7.

Probenecid. Pretreatment with probenecid, a highly protein-bound drug, potentiates thiopental anaesthesia.[1]

1. Dundee JW, *et al.* Aspirin and probenecid pretreatment influences the potency of thiopentone and the onset of action of midazolam. *Eur J Anaesthesiol* 1986; 3: 247–51.

Pharmacokinetics

Thiopental is highly lipid soluble and when it is given intravenously as the sodium salt, concentrations sufficient to produce unconsciousness occur in the brain within 30 seconds. Onset of action occurs within 8 to 10 minutes when thiopental sodium is given rectally but absorption may be unpredictable if a suspension rather than a solution is used. Recovery from anaesthesia is also rapid due to redistribution to other tissues, particularly fat. About 80% of thiopental may be bound to plasma proteins, although reports show a wide range of figures. Thiopental is metabolised almost entirely in the liver, but as it is only released slowly from lipid stores this occurs at a very slow rate.

It is mostly metabolised to inactive metabolites but a small amount is desulfurated to pentobarbital. Repeated or continuous use can lead to accumulation of thiopental in fatty tissue and this can result in prolonged anaesthesia and respiratory and cardiovascular depression. Elimination of thiopental after bolus injection can be described by a triexponential curve. The terminal elimination half-life has been reported to be 10 to 12 hours in adults and about 6 hours in children. However, values of 26 to 28 hours have been reported in obese patients and pregnant patients at term. Thiopental readily diffuses across the placenta and is distributed into breast milk.

Pharmacopoeial Preparations
BP 2014: Thiopental Injection;
USP 36: Thiopental Sodium for Injection.

Tiletamine Hydrochloride *(BANM, USAN, rINNM)*

CI-634; CL-399; CN-54521-2; Hidrocloruro de tiletamina; Tiletamina, hidrocloruro de; Tilétamine, Chlorhydrate de; Tiletamini Hydrochloridum; Тилетамина Гидрохлорид.

2-Ethylamino-2-(2-thienyl)cyclohexanone hydrochloride.

$C_{12}H_{17}NOS,HCl$=259.8

CAS — 14176-49-9 (tiletamine); 14176-50-2 (tiletamine hydrochloride).

UNII — 99TAQ2QWJI.

Pharmacopoeias. In *US* (for veterinary use only.

USP 36: (Tiletamine Hydrochloride). A white to off-white crystalline powder. Freely soluble in water; slightly soluble in chloroform; practically insoluble in ether; soluble in methyl alcohol; freely soluble in 0.1N hydrochloric acid. pH of a 10% solution in water is between 3.0 and 5.0. Store in airtight containers.

Profile

Tiletamine has similar properties to ketamine (p. 1905.1). It is used as the hydrochloride with zolazepam (p. 1116.2) for general anaesthesia in veterinary medicine.

$CHCl:CCl_2$=131.4

CAS — 79-01-6.

ATC — N01AB05.

ATC Vet — QN01AB05.

UNII — 290YE8AR51.

Street names. The following terms have been used as 'street names' (see p. vii) or slang names for various forms of trichloroethylene:

Trichlo.

Stability. NOTE. Trichloroethylene used for anaesthetic purposes contains thymol 0.01% w/v as a stabiliser and is coloured blue for identification. It is non-flammable.

Uses and Administration

Trichloroethylene is a volatile halogenated anaesthetic given by inhalation. It has been used in some countries for the maintenance of light anaesthesia (p. 1896.1) but it has weak anaesthetic properties compared with other halogenated anaesthetics and poor muscle relaxant activity, and safer anaesthetics are generally preferred. It has also been used to supplement anaesthesia with nitrous oxide-oxygen or halothane. Trichloroethylene is a potent analgesic and has been used in subanaesthetic concentrations to provide analgesia for obstetrics, emergency management of trauma, and other acutely painful procedures.

Trichloroethylene is used in industry as a solvent for oils and fats, for degreasing metals, and for dry cleaning. It has also been used in type correction fluids but is no longer included in most brands.

Adverse Effects and Precautions

Trichloroethylene increases the rate and decreases the depth of respiration and may be followed by apnoea. The sensitivity of the heart to beta-adrenergic activity may increase, possibly with ventricular arrhythmias.

Acute exposure to trichloroethylene may be followed by dizziness, lightheadedness, lethargy, nausea, and vomiting; hepatic and renal dysfunction may follow. Fatalities have occurred, although temporary unconsciousness is a more common manifestation.

Chronic poisoning may result in visual disturbances, intolerance to alcohol as manifested by transient redness of the face and neck (degreasers' or trichloroethylene flush), impairment of performance, hearing defects, neuralgia, and mild liver dysfunction. Prolonged contact with trichloroethylene can cause dermatitis, eczema, burns, and conjunctivitis.

Dependence has been reported in medical personnel and factory workers who regularly inhale trichloroethylene vapour.

If trichloroethylene is used as an anaesthetic it should not be used in closed-circuit apparatus since there is a reaction with soda lime to produce a toxic end product that may cause cranial nerve paralysis and possibly death.

See also Adverse Effects and Precautions for General Anaesthetics, p. 1896.3.

Reviews[1-4] of the toxicity of trichloroethylene.

3. Davidson IWF, Bellies RP. Consideration of the target organ toxicity of trichloroethylene in terms of metabolite toxicity and pharmacokinetics. *Drug Metab Rev* 1991; 23: 493–599.
4. Tabrez S, Ahmad M. Toxicity, biomarkers, genotoxicity, and carcinogenicity of trichloroethylene and its metabolites: a review. *J Environ Sci Health C Environ Carcinog Ecotoxicol Rev* 2009; 27: 178–96.

Abuse. Toxicity associated with inhalation of volatile substances including trichloroethylene has been reviewed.[1,2] Trichloroethylene can damage the kidney, liver, heart, and lung. However, in young healthy subjects, organ toxicity becomes apparent only with intensive and protracted abuse of volatile substances and fatalities have been reported.[3,4]

1. Marjot R, McLeod AA. Chronic non-neurological toxicity from volatile substance abuse. *Hum Toxicol* 1989; 8: 301–6.
2. Anonymous. Solvent abuse: little progress after 20 years. *BMJ* 1990; 300: 135–6.
3. Jones GR, Singer PP. An unusual trichloroethanol fatality attributed to sniffing trichloroethylene. *J Anal Toxicol* 2008; 32: 183–6.
4. Takaki A, *et al.* A 27-year-old man who died of acute liver failure probably due to trichloroethylene abuse. *J Gastroenterol* 2008; 43: 239–42.

Carcinogenicity. The use of trichloroethylene in foods, drugs, and cosmetics was banned by the FDA after studies found that hepatocellular carcinomas could be induced in *mice* by chronic exposure to very high doses. However, similar effects have not been found in *rats* and larger species and several epidemiologic studies have failed to show an increased incidence of liver tumours, total mortality, or mortality due to cancer in workers exposed to trichloroethylene. Suggestions that the carcinogenicity of trichloroethylene is due to one of its intermediate metabolites, cloral hydrate, have raised concern over the continuing use of cloral hydrate as a medicine. For further details, see p. 1056.1.

Effects on the liver. References[1,2] to hepatotoxicity after occupational exposure to trichloroethylene. See also Carcinogenicity, above, and Effects on the Skin, below.

1. McCunney RJ. Diverse manifestations of trichloroethylene. *Br J Ind Med* 1988; 45: 122–6.
2. Schattner A, Malnick SDH. Anicteric hepatitis and uveitis in a worker exposed to trichloroethylene. *Postgrad Med J* 1990; 66: 730–1.

Effects on the skin. A hypersensitivity syndrome comprising rashes, fever, hepatitis, and lymphadenopathy has been associated with occupational exposure to trichloroethylene, as have severe skin reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis.[1-3] Carriers of the HLA allele HLA-B*1301, which occurs almost exclusively in persons of Asian ancestry, have been suggested to be at increased risk for developing such reactions.[4]

Scleroderma has been reported[5] in 3 patients occupationally exposed to trichloroethylene and, in 2 cases, also to trichloroethane.

1. Kamijima M, *et al.* Occupational trichloroethylene exposure as a cause of idiosyncratic generalized skin disorders and accompanying hepatitis similar to drug hypersensitivities. *Int Arch Occup Environ Health* 2007; 80: 357–70.

5. Flindt-Hansen H, Isager H. Scleroderma after occupational exposure to trichloroethylene and trichlorethane. *Acta Derm Venereol (Stockh)* 1987; 67: 263–4.

Poisoning. There has been a report[1] of a fatal self-poisoning in a 47-year-old woman with severe anorexia nervosa who ingested 500 mL of trichloroethylene and an unknown quantity of benzodiazepines. Coma developed shortly after ingestion, followed by abdominal distension, perforation, and necrosis, and multiple organ failure.

1. Llotier J, *et al.* A rare cause of abdominal compartment syndrome: acute trichlorethylene overdose. *Clin Toxicol* 2008; 46: 905–7.

Interactions

The arrhythmogenic effects of trichloroethylene may be potentiated by sympathomimetics such as adrenaline. Alcohol consumption after chronic exposure to trichloroethylene may result in a reddening of the skin (see Adverse Effects and Precautions, above).

See also Interactions of General Anaesthetics, p. 1897.3.

Pharmacokinetics

Trichloroethylene is rapidly absorbed by inhalation and ingestion. Percutaneous absorption can occur. Some of the inhaled trichloroethylene is slowly eliminated through the lungs; trichloroethylene is metabolised mainly in the liver, cloral hydrate (see p. 1055.2) being the first stable major metabolite formed; most is then metabolised to trichloroethanol and trichloroacetic acid which are excreted in the urine. The latter may be used as an indicator of industrial exposure. Trichloroethylene diffuses across the placenta.

Xenon

Ksenon; Ksenonas; Ksenons; Ksenon; Senon; Xeanón; Xenó; Xeno; Xenón; Xénon; Xenônio; Xénonum; Ксенон.

Xe=131.293

Growth Hormone and its Modulators

Human growth is under a complex system of hormonal controls. Growth hormone is produced by specialised cells (somatotropes) in the anterior pituitary; production and secretion are under a system of double regulation by a release-inhibiting hormone, somatostatin, and a growth hormone-releasing hormone, somatorelin, both produced in the hypothalamus. These in turn are modulated by various stimuli: dopamine, serotonin, hypoglycaemia, stress or emotional excitement, and ingestion of protein-rich meals all stimulate growth hormone release, whereas glucose, free fatty acids, insulin-like growth factor and growth hormone itself all suppress it.

The effects of growth hormone in the body rely on its interaction with a distinct growth hormone receptor; some effects, such as stimulation of lipolysis and gluconeogenesis, are direct but others, including its anabolic and growth-promoting effects, are mediated by induction of insulin-like growth factors (somatomedins).

Included in this chapter are growth hormone itself, now generally given as *recombinant somatropin* (p. 1919.3) or its synthetic methionyl analogue somatrem (p. 1919.3), and somatomedins such as mecasermin (p. 1929.2). Also included are the hypothalamic releasing hormone, somatorelin (p. 1930.1), and its analogue sermorelin (p. 1930.1); the hypothalamic inhibiting hormone, somatostatin (p. 1930.3), and its analogues such as lanreotide (p. 1923.2) and octreotide (p. 1924.1); the growth hormone release stimulant pralmorelin (p. 1929.1); and the growth hormone-receptor antagonist pegvisomant (p. 1928.2). Their use in acromegaly and growth retardation is discussed in more detail below.

Acromegaly and gigantism

Acromegaly and gigantism are syndromes of excess growth hormone secretion, usually associated with a secretory pituitary adenoma (somatropinoma).

Excessive growth hormone secretion in childhood, while the epiphyses of the long bones are open, results in ***gigantism***,[1,2] with a proportional growth spurt and skeletal enlargement. Other common features include obesity, coarse facial features, and disproportionately large hands and feet with thick fingers and toes. Puberty, with the increase in sex hormone secretion that leads to epiphyseal fusion, may be delayed by concomitant hypogonadism, leading to attainment of an even greater ultimate height. If growth hormone excess persists into adulthood, features of acromegaly may be superimposed on gigantism.[1] Treatment is similar to that used in acromegaly, as described below, although radiotherapy is used less often in gigantism because of the potential long-term consequences, such as hypopituitarism, for relatively young patients.[2] There is also more urgency to control the condition and avoid potentially irreversible musculoskeletal deformities and excessively tall stature.

When excess growth hormone secretion develops first in adulthood the condition is known as ***acromegaly***. Signs and symptoms tend to develop slowly and may be missed, sometimes for years. Growth hormone concentrations, and hence those of insulin-like growth factor I (IGF-I), which is produced in the liver in response to growth hormone, are elevated, sometimes markedly. The facial features become coarser, the jaw enlarges (prognathism), and hands and feet become enlarged. Peripheral neuropathy and carpal tunnel syndrome due to nerve entrapment, arthropathy, osteoarthritis, and muscle weakness, abnormal glucose tolerance, hypertension and left ventricular hypertrophy are all common, as is nodular goitre. Daytime somnolence may occur due to sleep apnoea. Acromegalics have an increased mortality if left untreated, largely due to cardiovascular disease.

Diagnosis and monitoring. The biochemical goal of treatment is to normalise growth hormone and IGF-I concentrations in order to reduce some of the signs and symptoms of acromegaly and to reverse the increased risk of mortality.[2,3] Growth hormone may be measured after an oral glucose tolerance test (OGTT); this suppresses growth hormone concentrations in healthy subjects, but not in patients with acromegaly. A growth hormone concentration below 400 nanograms/litre after an OGTT may be used to exclude acromegaly at the initial diagnosis, and in the assessment of surgical efficacy. Growth hormone concentrations taken as random samples may be used during the long-term monitoring of medical therapy for acromegaly; in such circumstances a target concentration below 1 microgram/litre is often used.[2,3] However, the target concentrations that have been suggested have changed over time with the development of more sensitive assays, and results must be interpreted in the context of the method used.[2-4] Random IGF-I concentrations should fall to normal for age and sex.[2,3]

Treatment. As for most pituitary tumours, **surgery** is the mainstay of treatment.[2,5] The success rate depends on surgical expertise and the size and extension of the mass, with success rates higher for microadenomas (75 to 95%) than macroadenomas (40 to 68%) depending on criteria.[5]

Drug therapy for acromegaly is indicated for patients who refuse surgery, have a low probability of a surgical cure, are at increased risk from surgery, have active disease after surgery, or are awaiting the effects of radiotherapy (see below).[2,5]

The *somatostatin analogues*, octreotide and lanreotide, reduce growth hormone secretion in most patients, but not all will have persistent suppression and normalisation of growth hormone levels.[6,7] Reported response rates vary, but effective growth hormone suppression occurs in about 50 to 55% of patients, and IGF-I is normalised in about 50 to 65%. Somatostatin analogues also produce tumour shrinkage, reducing tumour size by more than 20% in about 75% of patients,[5] and improve signs and symptoms of acromegaly, including improvements in cardiac structure and function.[8] Octreotide and lanreotide appear to have similar efficacy in the control of growth hormone and IGF-I concentrations based on limited data, but comparative studies of tumour shrinkage are lacking.[7,9]

There has been increasing interest in the use of somatostatin analogues for primary therapy, but when there is visual or neurological compromise then surgery is preferred because drug therapy may not provide enough tumour shrinkage to relieve pressure on the optic chiasm.[6,10] Guidelines[2,5] consider somatostatin analogues only suitable as first-line treatment for patients with a low likelihood of surgical cure or at high surgical risk. There are some data that suggest pre-operative use of somatostatin analogues could improve cardiovascular, respiratory, and metabolic functions and hence reduce morbidity associated with surgery, but further study is needed.[2,5,7,11] Pre-operative use might also improve surgical remission rates, particularly in patients with macroadenomas, but again further study is needed.[2,7,11]

Dopaminergics can produce a paradoxical reduction in growth hormone secretion in some patients with acromegaly, providing symptomatic relief. Cabergoline may be more effective than bromocriptine, but they are both less effective than somatostatin analogues. They are generally added to somatostatin analogue therapy, but may be considered alone for medical therapy in patients with modest IGF-I elevations when oral therapy is preferred.[2,5]

Pegvisomant is a growth hormone-receptor antagonist that may be used when other therapies have failed or are inappropriate.[2,5,7,12] It is reported[13,14] to lower IGF-I concentrations, improve signs and symptoms of acromegaly, and be well tolerated. Pegvisomant does not reduce growth hormone concentrations so these patients must be monitored by IGF-I measurement.[2,4] The addition of pegvisomant has also been reported to normalise IGF-I concentrations in patients with persistently elevated levels during somatostatin analogue therapy.[2,15]

Tumour regression induced by **radiotherapy** is a possible alternative, usually when surgical and/or medical therapy have failed.[2,5] Although it reduces growth hormone concentrations in most patients, its effects are slow and it often produces hypopituitarism. Since it may take several years for growth hormone concentrations to fall, drug therapy is also given until the effects of radiation therapy are satisfactory.

Growth retardation

Stature follows a normal (bell-shaped) distribution within the population. Short stature has been defined as a height more than 2 standard deviations below the population mean, but there may be some difficulty in deciding at what point short stature becomes abnormal and to some extent this is determined by cultural as well as physiological norms.

Certain disorders are associated with well-defined deficiencies of growth which may be severe enough to warrant the description ***dwarfism***. Some forms are associated with disorders of bone or cartilage growth (skeletal dysplasias), and many of these result additionally in disproportionate growth, as in the short-limbs and large head characteristic of achondroplasia. Other genetic conditions that feature short stature include Noonan syndrome and SHOX (short stature homeobox-containing gene) deficiency. Other important causes of dwarfism include inadequate production of growth hormone (idiopathic growth hormone deficiency), either alone (isolated growth hormone deficiency) or combined with other pituitary hormone deficiencies as part of hypopituitarism; resistance to circulating growth hormone, as in Laron-type dwarfism, where there is a mutation of the growth hormone receptor; or defects in somatomedin synthesis.

Some other endocrine causes of short stature include hypothyroidism, Cushing's syndrome, and Turner's syndrome. Severe chronic disease in childhood such as asthma, chronic renal failure, or liver disorders can result in some growth retardation as can inadequate nutrition due to malabsorption syndromes such as coeliac disease.

Endocrine causes of growth retardation are significant because they may be treatable by appropriate replacement therapy. Isolated growth hormone deficiency, or growth hormone and gonadotrophin deficiencies, are the commonest congenital forms of hypopituitarism. Since most children with short stature will not have growth hormone deficiency and deficiency is rarely complete, care is required in its **diagnosis**. Although provocative growth hormone tests, which use non-physiological means to stimulate growth hormone secretion, have long been considered the gold standard for diagnosis of growth hormone deficiency they have limitations and some consider measurement of circulating somatomedins (insulin-like growth factors; IGFs) or their binding proteins to be more useful.[1] Different assays may give different results, and it has been advised that therapeutic decisions should be based on a combination of comprehensive clinical and height assessments, biochemical tests, and radiological evaluation.[2,3]

In children with confirmed **growth hormone deficiency** replacement therapy is appropriate, and is given by subcutaneous injections of synthetic human *growth hormone* (somatropin) or its methionyl analogue (somatrem). Treatment improves bone density[4,5] and growth velocity;[6,7] final adult height is also increased but the extent of the benefit is unclear.

A cohort study of French children registered to receive growth hormone between 1973 and 1993 suggested that the eventual outcome was not as good as expected, and treated individuals remained short.[8] However, a large American cohort that included more than 11 000 growth-hormone deficient patients found that although treated patients remained below target heights, many did achieve heights within the normal range for chronological age.[9] Maximum growth rates occurred in the first year of treatment and fell progressively thereafter, with no significant difference between growth rates after 4 years compared with pretreatment rates. A further cohort study[10] from the same French register for 1987 to 1996 found that adult heights were similar whether patients completed treatment or stopped before reaching adult height, and that patients

with severe growth hormone deficiency may respond better than those with less severe deficiency.

Growth hormone treatment regimens have changed over the years, and it appears that with optimal treatment it may be possible for some growth-hormone deficient children to achieve their genetic height potential.[7] An important prognostic factor is age, and for optimum results treatment should be started as early as possible in an attempt to maximise height before the onset of puberty.[2,7]

In patients with multiple pituitary hormone deficiencies, genetic defects in growth hormone synthesis, or severe organic growth hormone deficiency, growth hormone therapy should be continued into adulthood. In other patients, growth hormone deficiency may or may not persist into adult life, and retesting should be done after the patient reaches adult height and after 1 to 3 months without therapy.[2,11-13] In those patients who need continued treatment, the dose of growth hormone should be gradually reduced in order to maintain IGF-I concentrations within the normal range.[11,12]

Somatorelin (*growth hormone-releasing hormone*) or its analogue sermorelin have also been tried to boost growth hormone secretion in patients with growth hormone deficiency. Although there have been reports of improved growth rates, there are limited data directly comparing these with growth hormone. One large study[14] of sermorelin found that, compared with results generally reported for growth hormone therapy, fewer patients responded over a 12-month period and growth responses were poorer.

In patients with Laron dwarfism (**growth hormone resistance or insensitivity**), conventional growth hormone therapy is ineffective because of defects in the growth hormone receptors. However, replacement therapy with *mecasermin*, the recombinant form of insulin-like growth factor-I, may be of substantial benefit in the treatment of this disorder.[15]

The use of growth hormone in **short stature** other than that due to indisputable growth hormone deficiency is controversial. Benefit has been reported from growth hormone therapy in children with chronic renal failure,[16-18] juvenile idiopathic arthritis[19] (p. 12.1), cystic fibrosis (see also p. 1921.1)[20,21] in girls with Turner's syndrome (but see p. 2254.3), in young children (6 months to 3 years of age) with Down's syndrome,[22,23] and in Prader-Willi syndrome[24,25] (p. 2315.2), all of which are associated with marked growth retardation. However, many commentators see such interventions as essentially cosmetic. The treatment of idiopathic short stature in particular, for which no underlying disorder can be identified, poses problems as the risks and also the benefits in terms of final height are uncertain.[26-28] Children who are born small for gestational age usually experience catch-up growth by 2 years of age. In those who do not achieve this, growth hormone therapy can induce catch-up growth and improve childhood height scores; data on adult height are limited, however.[29,30] Guidelines suggest that therapy is justifiable in chronic renal insufficiency,[3,6,31] Turner's syndrome,[3,6,31] Prader-Willi syndrome,[3,31] and for children born small for gestational age.[3,31,32] However, sufficient evidence of benefit is lacking for other disorders including non-growth hormone deficient short stature and growth retardation associated with Down's syndrome, and some[6] consider that growth hormone should not be given to children with constitutional delay of growth.

More recently, growth hormone therapy has improved growth rate and height in children with SHOX deficiency.[31,33] Mutations and deletions of the SHOX gene, a gene involved in bone and cartilage formation, are associated with various short stature conditions such as Léri-Weill dyschondrosteosis, and are now understood to play a role in the short stature of Turner's syndrome and in some cases of idiopathic short stature. Growth hormone therapy can also improve height in children with Noonan syndrome.[34,35] As in other forms of growth retardation, starting treatment early before the onset of puberty might produce better results.

Although *sex hormones* have effects on growth they may also cause premature closure of the epiphyses when given to prepubertal or pubertal children, and this has limited their use. Nonetheless, anabolic drugs such as testosterone and oxandrolone have been used in boys, and oestrogen in girls, who have constitutional delay of growth associated with delayed puberty (see p. 2252.1). Oestrogens are not generally used for growth promotion in girls with Turner's syndrome, but as replacement therapy to promote puberty (see p. 2254.3).

Several *other drugs* have been investigated in growth retardation. Clonidine, which can promote growth hormone-releasing hormone release, has been given to children with growth hormone deficiency as well as to short children without proven deficiency, but results have been contradictory and largely unsatisfactory.[36-38] Gonadorelin analogues have also been given with growth hormone to short girls with or without growth hormone deficiency, in an attempt to slow bone maturation and delay puberty, thereby improving adult height.[39,40] However, a decrease in bone mineral density may outweigh any modest increase in height.[41] Where growth retardation is associated with zinc deficiency, zinc supplementation may be useful (see p. 2127.2).

ATC Vet — QH01AC01.

UNII — NQX9KB6PCL.

Description. Somatropin is synthetic human growth hormone having the normal structure of the major (22K) component of natural human pituitary growth hormone. It consists of a single polypeptide chain of 191 amino acids with disulfide linkages between positions 53 and 165 and between 182 and 189. For labelling purposes, the name may carry in parentheses an approved code in lower case letters indicative of the method of production: (epr) indicates production by enzymatic conversion of a precursor produced by a bacterium genetically modified by recombinant DNA technology; (rbe) indicates production from bacteria genetically modified by recombinant DNA technology; (rmc) indicates production from genetically engineered and transformed mammalian (mouse) cells.

Somidobove (*BAN*) is synthetic bovine growth hormone.

Pharmacopoeias. In *Chin.*, *Eur.* (see p. vii), and *US*.

Ph. Eur. 8: (Somatropin). A protein having the structure (191 amino acid residues) of the major component of growth hormone produced by the human pituitary. A white or almost white powder, containing not less than 2.5 units/mg. Store at 2 degrees to 8 degrees in airtight containers.

Ph. Eur. 8: (Somatropin Concentrated Solution). A clear or slightly turbid, colourless solution. It may contain buffer

salts and other auxiliary substances. Store at -20 degrees in airtight containers. Avoid repeated freezing and thawing.

USP 36: (Somatropin). A protein hormone consisting of 191 amino acid residues, and its structure corresponds to the major component of the growth hormone extracted from human pituitary glands. It is produced as a lyophilised powder or bulk solution by methods based on recombinant DNA technology. The lyophilised powder contains not less than 910 micrograms of somatropin per mg, calculated on the anhydrous basis. The bulk solution contains not less than 910 micrograms of somatropin per mg of total protein.

Store at -25 degrees to -10 degrees in airtight containers.

Units

4.4 units of human growth hormone (somatropin) are contained in 1.75 mg of freeze-dried purified human growth hormone, with 20 mg of glycine, 2 mg of mannitol, 2 mg of lactose, and 2 mg of sodium bicarbonate, in one ampoule of the first International Standard (1987).

The second International Standard for Somatropin (2000), rDNA-derived human growth hormone, has a defined content of 1.95 mg of protein per ampoule, with a specific activity of 3.0 units/mg. One mg of anhydrous Somatropin USP is equivalent to 3.0 USP Somatropin Units. Commercial preparations vary somewhat in the number of units/mg.

Uses and Administration

Growth hormone is an anabolic hormone secreted by the anterior lobe of the pituitary, varying in size and amino-acid sequence between animal species. It promotes growth of skeletal, muscular, and other tissues, stimulates protein anabolism, and affects fat and mineral metabolism. The hormone has a diabetogenic action on carbohydrate metabolism. Secretion is pulsatile and dependent on neural and hormonal influences including a hypothalamic release-inhibiting hormone (see Somatostatin, p. 1930.3), and a hypothalamic releasing hormone (see Somatorelin, p. 1930.1). Sleep, hypoglycaemia, and physical or emotional stress result in increased secretion of growth hormone. The effects of growth hormone on skeletal growth are mediated by the somatomedins (see p. 1929.1). Somatropin is synthetic human growth hormone and somatrem its methionyl analogue.

Somatropin is given to children with open epiphyses for the treatment of short stature due to growth hormone deficiency (pituitary dwarfism) following assessment of pituitary function. Somatrem has been used similarly but is no longer generally available. Somatropin is also used in children with some other forms of growth retardation, such as that associated with Turner's syndrome, Noonan syndrome, SHOX (short stature homeobox-containing gene) deficiency, or chronic renal insufficiency, in short children born small for gestational age, and in idiopathic short stature. In Prader-Willi syndrome, somatropin is given to improve growth and body composition (but see also under Adverse Effects and Precautions, p. 1922.3). In adults, somatropin is given for confirmed growth hormone deficiency. It is also used in the management of wasting or cachexia associated with AIDS. In short bowel syndrome, somatropin is used to increase intestinal absorption of water, electrolytes, and nutrients from specialised nutritional support.

Doses in **growth retardation** should be individualised for each patient. Manufacturers vary somewhat in their estimates of the number of units/mg for somatropin and although some countries specify labelling in mg, others require labelling in units or both.

- In *children with growth hormone deficiency*, the usual daily dose in the UK is 25 to 35 micrograms/kg (0.07 to 0.1 units/kg), or 0.7 to 1 mg/m^2 (2 to 3 units/m^2). Doses are usually given by subcutaneous injection although some preparations are also licensed for intramuscular use; needle-free delivery systems are also available. Some licensed product information also suggests that doses should be given in the evening. Similar doses are used in other countries, where the total weekly dose may be divided into 3, 6, or 7 doses.
  When children with growth hormone deficiency reach their final height they should be re-assessed for the need to continue therapy, usually after at least 4 weeks without treatment. During *transition into adulthood* a subcutaneous dose of 200 to 500 micrograms daily may be used, and adjusted as required to maintain IGF-I concentrations in the normal range.
- In *Turner's syndrome* (gonadal dysgenesis), a subcutaneous daily dose of 45 to 50 micrograms/kg (0.14 units/kg), or 1.4 mg/m^2 (4.3 units/m^2), is generally used, although higher doses of up to 67 micrograms/kg daily may be needed.
- Doses of up to 66 micrograms/kg daily have been used for growth retardation related to *Noonan syndrome*.
- Daily doses of 45 to 50 micrograms/kg may be used in children with growth retardation due to *chronic renal insufficiency* or *SHOX deficiency*.
- In children with growth retardation who were *born small for gestational age*, the licensed daily dose in the UK is 35 micrograms/kg by subcutaneous injection (0.1 units/kg), or 1 mg/m^2 (3 units/m^2). In the USA, the licensed dose is somewhat higher, at 480 micrograms/kg weekly, divided into 6 or 7 doses.
- In children with *idiopathic short stature* somatropin is given subcutaneously in a weekly dose of up to 300 to 470 micrograms/kg divided into 6 or 7 doses.
- In children with *Prader-Willi syndrome*, a daily dose of about 35 micrograms/kg, or 1 mg/m^2, is given subcutaneously; daily doses should not exceed 2.7 mg.

In patients with **adult-onset growth hormone deficiency** lower doses are recommended. The initial dose is not more than 6 micrograms/kg (0.018 units/kg) subcutaneously daily. The dose can then be gradually increased according to patient response, to a usual maximum of 12.5 micrograms/kg daily. Alternatively, an initial dose in the range of 100 to 300 micrograms daily (0.3 to 0.9 units) in the evening is increased gradually at monthly intervals, based on clinical response, to a maintenance dose that is usually no more than 1 mg daily. Dosage requirements may decline with increasing age. In the UK, it has been recommended that treatment should be re-assessed 9 months after starting therapy.

In the treatment of **HIV-associated wasting or cachexia** somatropin is given in doses of 100 micrograms/kg daily by subcutaneous injection at bedtime, to a maximum of 6 mg daily. A starting dose of 100 micrograms/kg on alternate days may be considered for patients who are at increased risk of adverse effects.

In **short bowel syndrome** somatropin is given subcutaneously in a dose of about 100 micrograms/kg daily (to a maximum of 8 mg daily) for 4 weeks.

Sustained-release injections and inhalation formulations of growth hormone are also under investigation.

Administration in children. For details of somatropin doses in children with growth retardation, see Uses and Administration, above. See also below for doses that have been tried in those with severe burns.

Administration in adults. Growth hormone continues to be secreted in adult life, although secretion and activity gradually decline with increasing age, and it appears to play a role in maintaining skeletal and lean body-mass amongst other things. In adults with growth hormone deficiency (usually secondary to pituitary adenoma or its treatment) replacement therapy with growth hormone is reported to decrease body fat and abdominal adiposity, increase lean body-mass, and improve lipid profiles.[1-5] It may also increase bone density,[1,3] but many studies have been uncontrolled and of short duration, and any beneficial effect on bone density appears to be small.[6] Strength[7] and exercise capacity[8] can also be improved, although prolonged growth hormone therapy and physical training may be required to increase muscle performance.[3] Cardiac structure and function can be adversely affected by growth hormone deficiency, and replacement therapy in adults can have a positive effect on some cardiac parameters.[9] There are also some reports of improvements in quality of life;[3] although a study[10] using general standardised psychometric tests found no benefit, another[11] using a questionnaire developed for adults with hypopituitarism reported long-term benefits. Long-term data are not yet available to determine whether growth hormone therapy reduces the mortality rate in this group of patients, but it may provide some protection against myocardial infarction.[12] Guidelines on the use of growth hormone in adults with growth hormone deficiency have been issued.[13-16]

Less well established is the use of growth hormone in otherwise healthy elderly patients. Considerable controversy has attended suggestions that growth hormone therapy may retard or reverse some of the metabolic effects of ageing, and there is some concern that these patients may be at increased risk of adverse effects.[17] Studies[18] have shown that growth hormone can increase lean body-mass and decrease body fat, but functional ability does not necessarily improve and common adverse effects include peripheral oedema, carpal tunnel syndrome, arthralgias, and gynaecomastia.

Other uses for growth hormone in adult patients are discussed below. For mention of managing the transition to adulthood of children with growth hormone deficiency, see above and under Growth Retardation, p. 1918.3.

Burns. Growth hormone has been studied as a possible treatment to increase the rate of wound healing after severe burns. In a small study[1] of children with severe burns requiring skin grafts, subcutaneous somatropin 100 micrograms/kg daily, given from the first autograft until donor-site healing, was ineffective. However, a higher dose of somatropin 200 micrograms/kg daily by intramuscular injection, given throughout hospitalisation, reduced donor-site healing times and the length of hospital stay. There has been some concern that growth hormone therapy might increase hypertrophic scar formation, but studies[2,3] of subcutaneous somatropin given daily from hospital discharge until 1 year after burning have not found this. Somatropin treatment given during hospitalisation has also been reported to ameliorate burn-induced growth delays in such children; those injured during non-growth-spurt years may benefit most.[4,5] Long-term therapy given for 1 year after wound healing may also improve weight, linear growth, lean body-mass, and bone mineral content.[3,6] However, the manufacturers have recommended that somatropin should not be used to treat acute catabolic states in critically ill and burn patients, as there is some evidence in adults that mortality may be increased.[7] The management of burns is described on p. 1683.1.

Cachexia and lipodystrophy. Treatment with subcutaneous growth hormone has been reported to reverse weight loss and improve body wasting in subjects with HIV disease (p. 959.1).[1,2] It can have beneficial effects on

physical function, body-weight, lean body-mass, and measures of health-related quality of life.

Some benefit has been reported[3] with growth hormone therapy in HIV-associated lipodystrophy. However, the optimal dose of growth hormone for these patients has yet to be found. Studies using subcutaneous doses of 6 mg daily, although very effective in reducing visceral adipose fat, led to supraphysiological levels of IGF-I and treatment-limiting adverse effects in particular decreased insulin sensitivity. The use of lower doses such as 4 mg on alternate days had a more favourable adverse effect profile and produced acceptable decreases in visceral fat; physiological doses of growth hormone (about 1 mg daily) did not adversely affect insulin sensitivity but had modest effects on body composition. Furthermore, the effect of growth hormone on visceral fat is not sustained once treatment is withdrawn.

Growth hormone therapy has also been reported to improve metabolic indicators of malnutrition in some[4] but not other[5] studies of patients undergoing haemodialysis.

Cardiovascular disorders. A few small uncontrolled studies have reported improvements in heart failure (p. 1262.3) with the use of growth hormone.[1] A meta-analysis[2] of 12 studies using growth hormone in adults with chronic heart failure, including 8 placebo-controlled studies, also found evidence for improvement in several cardiovascular measures; however, individual results have been mixed and further study of long-term high-dose therapy is needed. A small underpowered study[3] of 6 months of treatment in children with dilated cardiomyopathy found only a trend towards improved cardiac function. Retrospective analysis[4] of a group of childhood cancer survivors found that growth hormone used to treat deficiency had some beneficial effects on anthracycline-induced left ventricular dysfunction, but that these diminished when growth hormone therapy was stopped.

Cystic fibrosis. The use of growth hormone has been investigated in several small studies in patients with cystic fibrosis (p. 177.2). A review[1] of studies in children, adolescents, and young adults found improvements in measures of pulmonary function, height, and weight in those treated with growth hormone, usually without a comparator. However, further study is needed to determine whether there are significant effects on pulmonary exacerbations or infections, bone fractures, or death. The typical dose used was 300 micrograms/kg per week [subcutaneously], and treatment was generally given for 6 months to 1 year.

Infertility. Growth hormone appears to sensitise the ovary to stimulation by gonadotrophins and it has been suggested that somatropin may have a role in the management of female infertility. However, studies of somatropin added to gonadotrophin regimens have generally been small, used different treatment protocols and outcome measures, and studied mixed groups of women in terms of the cause of infertility. Studies in women with poor response to ovarian stimulation have shown mixed results, and response may depend on the cause of infertility. Mixed results have also been reported in women with polycystic ovary syndrome. Benefits may be most likely in women with hypogonadotrophic hypogonadism,[1] or those considered to be poor responders,[2] but there is no additional benefit for women who have a normal ovarian response to gonadotrophins.[1,2] UK guidelines[3] for the treatment of infertility do not recommend its use. Growth hormone has also been tried similarly to enhance spermatogenesis in infertile men unresponsive to conventional therapy, but studies have been small, and despite some encouraging reports[4] others have found no benefit.[5,6]

For a discussion of infertility and the more usual drugs used in its management, see p. 2253.1.

Osteogenesis imperfecta. For reference to possible benefit from growth hormone therapy in patients with osteogenesis imperfecta, see p. 1167.3.

Osteomalacia. As mentioned on p. 1168.1, there has been some interest in the use of growth hormone in children with hypophosphataemic rickets.

Prader-Willi syndrome. Growth hormone treatment may be of benefit in the management of children with Prader-Willi syndrome (p. 2315.2). It increases growth velocity and improves body composition, by reducing fat mass and increasing muscle mass. However, there is limited information about long-term efficacy, and the effect on growth velocity is reported to wane after 1 to 3 years of therapy. There are also specific contra-indications and precautions relating to the use of growth hormone in these patients (see under Adverse Effects and Precautions, p. 1922.3). Growth hormone treatment may also improve body composition in adults with Prader-Willi syndrome.

Short bowel syndrome. A combination of growth hormone, glutamine, and dietary modification may improve intestinal absorption of fluid, electrolytes, and other nutrients, and thus reduce parenteral nutrition requirements in patients with short bowel syndrome.[1] However, studies have produced conflicting results, and benefit may depend on several factors including the type and length of remaining bowel, the presence or absence of mucosal disease, and the doses of somatropin and glutamine.[2] Additionally the beneficial effects may be short-lived, returning to baseline if therapy is stopped.[3]

Veterinary and agricultural use. Bovine growth hormone or bovine somatotrophin (bovine somatotropin; BST) can increase milk yield in dairy cows. There has been considerable debate about both animal welfare and human food safety, and although it is approved in the USA[1] its use is banned in the EU.

Adverse Effects and Precautions

Antibodies to growth hormone have been formed in some patients but these rarely seem to affect growth. There may be redness, itching, lumps, or lipoatrophy at the site of injection. Transient dose-related fluid retention with peripheral oedema and carpal tunnel syndrome has occurred; headache, muscle and joint pain, paraesthesia, and cases of benign intracranial hypertension have been reported. Although growth hormone has diabetogenic effects, high acute dosage has been associated with hypoglycaemia followed by hyperglycaemia. Growth hormone therapy may further increase the risk of ear disorders and otitis media in patients with Turner's syndrome, who are already at increased risk of ear and hearing disorders.

Growth hormone therapy is contra-indicated in patients with active neoplasms or intracranial lesions and should be stopped if evidence of tumour growth develops. Growth hormones should not be used for growth promotion in patients with closed epiphyses. Patients with scoliosis should be monitored during growth hormone therapy because of the risk of progression of scoliosis that can occur with rapid growth. Because of the diabetogenic effect of growth hormone it should be given with care to patients with diabetes mellitus; adjustment of antidiabetic therapy may be necessary. Somatropin is contra-indicated in patients with proliferative or preproliferative diabetic retinopathy. Hypothyroidism may develop during treatment, and may result in suboptimal response. Secondary hypoadrenalism may be unmasked by somatropin treatment, requiring glucocorticoid replacement therapy (see also Interactions, p. 1923.1). Growth hormone should not be used in patients with Prader-Willi syndrome who are severely obese or have severe respiratory impairment (see also p. 1922.3). For the suggestion that growth hormone should not be used to treat acute catabolic states, as in patients with severe burns or who are otherwise critically ill, see Burns, under Uses and Administration, p. 1920.3.

Abuse. Growth hormone has been subject to abuse in sport for its anabolic effects.[1,2] Limited study data suggest that it may increase lean body-mass,[3,4] however, it has minimal effect on strength and athletic performance, and may worsen exercise capacity.[3]

Benign intracranial hypertension. Benign intracranial hypertension (pseudotumor cerebri) has been described[1,2] in patients given growth hormone treatment. In an analysis[3] of a postmarketing surveillance database (1985 to 2000) of almost 40 000 children and adolescents who had been treated with growth hormone for various conditions, benign intracranial hypertension was more common than in the general paediatric population. The incidence in new patients starting growth hormone therapy was estimated to be about 30 in 100 000, and it had occurred more frequently in patients with renal failure or Turner's syndrome. Headache and papilloedema were the most common symptom and sign, but these did not occur in all patients, and most cases had an onset of a few months. The condition was effectively managed by stopping growth hormone. A small number of patients were rechallenged after the benign intracranial hypertension had resolved, and most could be treated with doses that were 25 to 50% of the original dose. Another surveillance database[4] of nearly 58 000 children and adolescents found an overall incidence of 27.7 per 100 000 treatment years; the incidence was highest in patients with chronic renal impairment, and lowest in those with idiopathic growth hormone deficiency. The median onset of benign intracranial hypertension also varied between diagnostic groups, ranging from about 4 days to 1.3 years. Headache alone is a commonly reported adverse effect of growth hormone treatment, and this study found an incidence of 793.5 per 100 000 treatment years. It has been pointed out that diagnosis of benign intracranial hypertension may be complicated by the occurrence of headaches, which usually resolve spontaneously.[5]

Carcinogenicity. Despite fears to the contrary, studies in children given growth hormone after cranial irradiation for brain tumours or CNS leukaemia have found no evidence that therapy with growth hormone increased the *relapse* rate.[1-3]

Cases of acute *leukaemia* have been reported among patients treated with growth hormones. An international workshop convened in 1988 to review known leukaemia cases in patients treated with growth hormones in Europe, North America, Japan, and Australia since 1959 found the incidence of leukaemia in growth hormone-treated patients represented a twofold increase over the expected rate.[4] It was concluded that there may be a small increase in leukaemia incidence associated with growth hormone treatment of growth hormone-deficient patients, but that it was not clear that this was actually attributable to growth hormone. A later study involving 6284 patients treated with growth hormone between 1963 and 1985 in the USA confirmed an increase of about 2.5-fold in the incidence of leukaemia in this population, but noted that many of the patients had other risk factors for leukaemia.[5] It has been suggested that growth hormone deficiency is itself a risk factor for leukaemia and that perhaps this, rather than growth hormone treatment, is related to the increased incidence of leukaemia in these patients.[6] If there is any risk it is relatively small, and in view of the essential nature of growth hormone therapy in growth hormone-deficient children it was considered inappropriate and unwise to withhold it.[4] Further large cohort studies of survivors of childhood cancers[3] or patients treated for idiopathic growth hormone deficiency[7] have found that the use of growth hormone was not associated with an increased risk of leukaemia.

There is some evidence to suggest that growth hormone may increase the risk of *solid tumours*. The risk of secondary solid tumours was increased in a cohort of childhood cancer survivors, but the authors considered that the risk was probably quite small compared with the benefits of growth hormone therapy in these patients.[3] Extended follow-up of this group also suggested that the elevation of risk diminished with time.[8] Another cohort of patients who had been treated for idiopathic growth hormone deficiency showed increased risks in the incidence and mortality of colorectal cancer.[7]

Further reports of malignancies associated with growth hormone therapy include two children with Bloom's syndrome (a rare chromosomal disorder affecting DNA replication), one of whom developed B-cell non-Hodgkin's lymphoma and the other stem-cell leukaemia.[9]

Continued surveillance of patients who have received growth hormone therapy has been encouraged.[10,11]

Creutzfeldt-Jakob disease. Reports in 1985 of a small number of deaths from Creutzfeldt-Jakob disease in patients under 40 years of age who had received growth hormone extracted from human pituitary glands resulted in the suspension of the distribution of pituitary-derived growth hormone by the licensing authorities in a number of countries, including Australia, Canada, the Netherlands, the UK, and the USA. Preparations of non-pituitary-derived growth hormone are now available that are free from contamination with Creutzfeldt-Jakob agent. However, because of the long incubation period of the disease, cases have been reported in patients who had received pituitary-derived growth hormone years previously.[1-5]

Effects on carbohydrate metabolism. A retrospective analysis[1] of data from a pharmacoepidemiological survey of children treated with growth hormone found a higher incidence of type 2 diabetes, compared with that found in untreated children. The researchers speculated that growth hormone treatment might precipitate the onset of type 2 diabetes in predisposed patients, and proposed that patients with risk factors for diabetes, including Turner's syndrome, Prader-Willi syndrome, or intra-uterine growth retardation, be monitored. Studies of growth hormone have reported rises in serum concentrations of insulin, fasting and postprandial blood-glucose, and glycosylated haemoglobin, although these changes were generally small.[2] It has been noted that these effects appear to regress during treatment, but not always, and in some patients glucose intolerance or diabetes mellitus are not reversible after withdrawal of growth hormone.

Nonketotic hyperglycaemia developed within weeks of beginning growth hormone therapy in a 22-month-old child, leading to convulsions and metabolic acidosis; the patient died despite correction of the hyperglycaemia.[3]

Effects on immune function. Growth hormone is generally considered to interact with the immune system although there is a lack of evidence that this is clinically significant.[1-4] There has been a report of acute renal transplant rejection in 2 children receiving treatment for growth retardation with somatropin.[5] In both children renal function of the transplant was stable for several years before somatropin was started, and growth hormone therapy had continued for some months before rejection occurred. It was suggested that during the first months of growth hormone therapy in transplant recipients, immunosuppressive therapy should be increased and transplant function carefully monitored. However, in subsequent studies[6,7] the use of growth hormone did not affect the incidence of rejection.

Effects on mortality. The EMEA[1] and FDA[2] are conducting safety reviews of growth hormone after a long-term French epidemiological study of patients who had received treatment during childhood for short stature showed an increased mortality risk for patients given growth hormone compared with the general population. Until the reviews have been completed somatropin should be used according to licensed indications and doses, and the EMEA has issued a reminder that the recommended daily dose of 50 micrograms/kg should not be exceeded.[1]

Iron deficiency. The view has been expressed[1] that given the increased production of haemoglobin and the prevalence of iron deficiency in patients treated with growth hormone, supplementation with iron should be considered in patients receiving growth hormone treatment.

1. Vihervuori H, *et al.* Increases in hemoglobin concentration and iron needs in response to growth hormone treatment. *J Pediatr* 1994; 125: 242–5.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies somatropin as probably not porphyrinogenic: it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 24/10/11)

Prader-Willi syndrome. Somatropin is used in children diagnosed with Prader-Willi syndrome to improve growth and body composition (see Uses and Administration, p. 1920.1). One US manufacturer of somatropin (*Pharmacia*) has stated that as of April 2003 it was aware of 7 reports of death in children with Prader-Willi syndrome treated with growth hormone.[1] The patients shared one or more of the following risk factors: severe obesity, a history of respiratory impairment or sleep apnoea, or unidentified respiratory infection. It was recommended that patients with Prader-Willi syndrome should be evaluated for upper airway obstruction, before beginning treatment, and if signs of such obstruction, for example snoring, developed during treatment therapy should be suspended. Somatropin was considered contra-indicated in these patients if

they were severely obese or had severe respiratory impairment; licensed product information had been amended accordingly. Early diagnosis and aggressive treatment of respiratory infections was also recommended. A few cases have been described in the literature.[2-4]

Children with Prader-Willi syndrome appear to have a higher incidence of respiratory problems such as sleep apnoea, hypoventilation, and infections than healthy children.[5] A prospective study[6] of 25 patients reported that sleep-disordered breathing had actually improved in most of them after 6 weeks of growth hormone therapy. However, there was a subgroup of 6 patients in which obstructive sleep apnoea and hypopnoea worsened; 4 of them had developed upper respiratory-tract infections and enlarged tonsils, and 2 had high serum concentrations of insulin-like growth factor I (IGF-I) and enlarged tonsils.

Interactions

High doses of corticosteroids may inhibit the growth promoting effects of growth hormone. For the effects of growth hormone on corticosteroids, see p. 1620.2. Doses of growth hormone may need to be increased in women receiving oral oestrogen replacement therapy, and may require adjustment if the route of oestrogen administration is changed.

Pharmacokinetics

Somatropin is well absorbed after subcutaneous or intramuscular injection with a bioavailability varying from about 60 to 80%; peak serum concentrations may not be achieved for several hours. After intravenous injection it has a half-life of about 20 to 30 minutes but after subcutaneous or intramuscular doses serum concentrations decline with a half-life of 3 to 5 hours, due to more prolonged release from the injection site. It is metabolised in the liver and kidneys and excreted in bile.

Absorption. Studies of the pharmacokinetics of somatropin after transdermal jet injection from 2 devices in healthy subjects suggested that absorption was more rapid and peak serum concentration higher than after conventional subcutaneous injection of the same dose.[1,2] However, this did not seem to result in any difference in the total amount absorbed, nor in the biological effect. Other needle-free devices[3,4] provided have similar concentration-time profiles for somatropin compared with conventional injection in healthy subjects. When studied in children with growth hormone deficiency, however, one device[3] was considered to cause more bleeding, pain, soreness, and bruising at the injection site than a needle-injection pen device.

ATC — H01CB03.
ATC Vet — QH01CB03.
UNII — IEU56G3J9C.

Uses and Administration

Lanreotide is a somatostatin analogue with similar properties to those of octreotide (p. 1924.1). It is given, as a long-acting depot injection, in the treatment of acromegaly (p. 1918.1) and thyrotrophic adenoma, as well as in the symptomatic management of neuroendocrine tumours, particularly carcinoid syndrome (p. 716.3).

Lanreotide is given as the acetate, but doses are usually expressed in terms of the base. The usual starting dose of one **intramuscular** depot injection (*Somatuline LA; Ipsen, UK*) is equivalent to lanreotide 30 mg every 14 days. In acromegaly and symptomatic neuroendocrine tumours, this may be increased if necessary to 30 mg every 7 to 10 days; in thyrotrophic adenoma it may be increased to 30 mg every 10 days.

An alternative preparation (*Somatuline Autogel; Ipsen, UK*) for acromegaly and symptomatic neuroendocrine tumours may be given by deep **subcutaneous** injection.

In acromegaly, an initial dose of 60 mg once every 28 days may be used in treatment-naive patients. For patients already receiving the intramuscular formulation, the same total dose of lanreotide that would have been given over 28 or 30 days may be replaced by a single dose of the subcutaneous preparation once every 28 days. In patients who respond to treatment, lanreotide may be gradually reduced to subcutaneous maintenance doses of 120 mg given at intervals of up to 56 days. In those who are not adequately controlled, a maximum dose of 120 mg once every 28 days may be used. Doses are adjusted according to symptoms and concentrations of growth hormone and IGF-I.

In patients with neuroendocrine tumours, the preparation for deep subcutaneous injection may be given in doses of 60 to 120 mg once every 28 days, and adjusted according to symptomatic relief.

In the USA, a preparation for deep subcutaneous injection (*Somatuline Depot; Tercica, USA*) may be given for acromegaly in initial doses of 90 mg once every 28 days for 3 months, then adjusted to between 60 and 120 mg every 28 days as necessary. Alternatively, for maintenance therapy a dose of 120 mg every 42 or 56 days may be appropriate.

For doses in hepatic and renal impairment, see below.

Lanreotide has been tried for the prevention of restenosis in coronary blood vessels following angioplasty (see Reperfusion and Revascularisation Procedures, p. 1259.2).

Administration in hepatic and renal impairment. The clearance of lanreotide, given by intravenous bolus, was significantly reduced in patients with severe chronic renal impairment requiring haemodialysis.[1] However, the authors of this study suggested that considering the wide therapeutic window of lanreotide, depot formulations may be given at the usual initial dose, with further doses adjusted according to response. Clearance of lanreotide was only slightly reduced in patients with moderate to severe hepatic impairment (Child-Pugh category B and C).[2]

The UK licensed product information for one depot **subcutaneous** formulation (*Somatuline Autogel; Ipsen, UK*) given every 28 days recommends that dose adjustment is not necessary in renal or hepatic impairment. Product information for a similar US preparation (*Somatuline Depot; Tercica, USA*) advises that in moderate and severe renal or hepatic impairment, an initial dose of 60 mg instead of 90 mg should be given by deep subcutaneous injection once every 28 days for 3 months, then adjusted as needed. Product information for another preparation (*Somatuline LA; Ipsen, UK*) usually given **intramuscularly** every 14 days suggests that it is not necessary to adjust the starting dose in hepatic or renal impairment.

Adverse Effects and Precautions

As for Octreotide Acetate, p. 1927.1.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies lanreotide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 24/10/11)

Interactions

As for Octreotide Acetate, p. 1927.3.

Pharmacokinetics

After intravenous injection lanreotide has a terminal half-life of about 2.5 hours. Lanreotide is available as injectable depot preparations, and after subcutaneous or intramuscular use of these an initial rapid liberation of the drug is followed by more prolonged release with an apparent half-

life of about 5 to 30 days. The absolute bioavailability is stated to range from about 55 to 80%, depending on the product.

Incompatibility. Apparent loss of insulin has been reported from a total parenteral nutrient solution containing octreotide; there may be an incompatibility.[1] Also the manufacturers had suggested that octreotide might be adsorbed onto plastics. However, a solution containing octreotide 200 micrograms/mL as the acetate was reported to be stable at 5 degrees or -20 degrees for up to 60 days when stored in polypropylene syringes.[2]

Uses and Administration

Octreotide is an octapeptide analogue of somatostatin (p. 1930.3) with similar properties but a longer duration of action.

It is used as the acetate in the symptomatic management of neuroendocrine tumours such as carcinoid tumours, VIPomas, and glucagonomas. Octreotide acetate is also used in the treatment of acromegaly and the prevention of complications after pancreatic surgery, and may be used in the treatment of other disorders including variceal haemorrhage and HIV-associated diarrhoea. It has also been investigated in a variety of other disorders.

In the management of **secretory neoplasms** octreotide acetate is given subcutaneously in an initial dose equivalent to 50 micrograms of octreotide once or twice daily gradually increased, according to response, to up to 600 micrograms daily in 2 to 4 divided doses. Higher doses have been used. If there is no benefit within a week of starting treatment for carcinoid tumour, continued therapy is not recommended.

Where a rapid response is required, the initial dose may be given by the intravenous route. In the UK, licensed product information states that it should be diluted not less than 1 in 1 or not more than 1 in 9 in sodium chloride 0.9%, but in the USA, product information permits the use of the undiluted solution as an intravenous bolus in emergencies; alternatively, the dose may be given by intermittent infusion over 15 to 30 minutes, diluted in 50 to 200 mL of sodium chloride 0.9% or glucose 5%.

Once control has been established maintenance therapy with a depot preparation may be possible; initially 20 mg by intramuscular injection every 4 weeks is suggested. Subcutaneous injection with a rapid-acting preparation should be continued for 2 weeks after the first depot injection to provide symptomatic cover, and may be added to therapy when necessary thereafter. Maintenance doses of the depot preparation may be adjusted after 2 or 3 months to between 10 and 30 mg every 4 weeks, as necessary.

In **acromegaly**, the usual dose is the equivalent of 100 to 200 micrograms of octreotide three times daily by subcutaneous injection. In the USA it is suggested that dosage begin with 50 micrograms three times daily in order to minimise gastrointestinal disturbance. If there is no relevant reduction in growth hormone concentrations and no improvement in clinical symptoms within 3 months of starting treatment, octreotide should be stopped. Once control has been established maintenance therapy with a depot preparation is possible; an initial dose equivalent to 20 mg of octreotide given intramuscularly once every 4 weeks has been recommended for patients with acromegaly, adjusted after 3 months to between 10 and 30 mg every 4 weeks. For patients who are not adequately controlled on 30 mg, the dose may be further increased to 40 mg every 4 weeks. The depot preparation may also be used for short-term treatment before pituitary surgery, but the last dose should be given at least 3 to 4 weeks before surgery to ensure successful endocrine testing for tumour removal 5 to 6 weeks after surgery.

For the prevention of complications after **pancreatic surgery** the equivalent of 100 micrograms of octreotide may be given three times daily by subcutaneous injection of a rapid-acting preparation; treatment is given for 7 consecutive days, beginning at least 1 hour before laparotomy on the day of operation.

In the management of **variceal haemorrhage** in patients with cirrhosis, octreotide is given as a continuous intravenous infusion at a dose equivalent to octreotide 25 micrograms/hour for 48 hours. Doses up to 50 micrograms/hour have been used. Patients at high risk of rebleeding may continue treatment for up to 5 days. For octreotide doses in oesophageal or gastric variceal bleeding in children, see below.

HIV-associated diarrhoea may be treated with an initial dose of octreotide 100 micrograms three times daily, given subcutaneously. If the diarrhoea is not controlled after a week, the dose may be increased to 250 micrograms three times daily, but if this is not effective after one further week then octreotide therapy should be stopped.

For doses in hepatic and renal impairment, see below.

General reviews of octreotide.

1. Anthony L, Preda PU. From somatostatin to octreotide LAR: evolution of a somatostatin analogue. *Curr Med Res Opin* 2009; 25: 2989–99.

Administration in children. Although octreotide is not licensed in the UK for oesophageal or gastric variceal bleeding in children, the *BNFC* includes a dose of 1 microgram/kg per hour by continuous intravenous infusion for children aged from 1 month to 18 years. Higher doses may be needed initially, to a maximum dose of 50 micrograms/hour. The dose should be reduced gradually over 24 hours once there is no active bleeding.

For other uses of octreotide in children see Chylous Effusion, below, Hyperinsulinism, p. 1926.1, and Obesity, p. 1926.3.

Administration in hepatic and renal impairment. The clearance of octreotide may be reduced in patients with hepatic or renal impairment. US licensed product information suggests that intramuscular depot therapy should be started at a dose of octreotide 10 mg once every 4 weeks in patients with established liver cirrhosis or renal failure requiring dialysis. Patients with lesser degrees of renal impairment may be given normal doses (see above).

Acromegaly. Although surgery remains the most important method of treatment, octreotide has a useful role in the management of acromegaly (p. 1918.1), particularly as adjuvant therapy when there is still active disease after surgery, as primary therapy when surgery is not possible, or while awaiting the full effects of radiotherapy. Octreotide can reduce growth hormone concentrations, normalise IGF-I concentrations, reduce tumour size, and improve signs and symptoms.[1] There is also some evidence that it may improve cardiac function, which is usually compromised in these patients.[1,2] Octreotide can be given subcutaneously and this route is generally used initially to determine patient response and tolerance, but it must be given three times daily making it unattractive for long-term use. Intramuscular sustained-release octreotide is effective for maintenance therapy. There is also increasing interest in the role of octreotide for primary therapy of acromegaly, instead of surgery[3-5] and a meta-analysis[6] suggested that tumour shrinkage was greatest when somatostatin analogues were given as primary rather than secondary therapy. Additionally, pre-operative treatment with octreotide might improve surgical cure rates in patients with macroadenomas.[7]

Cardiovascular disorders. There have been reports of benefit from octreotide in patients with postprandial hypotension and orthostatic hypotension (p. 1634.3) associated with autonomic neuropathy.[1-6] Octreotide has also produced cardiac improvement in patients with acromegaly (see above). Promising results have been reported in patients with primary hypertrophic cardiomyopathy.[7,8] Benefit has also been reported in a few patients with dilated cardiomyopathy.[9] For the usual management of cardiomyopathies, see p. 1261.3.

Chylous effusion. Chylous effusion results in accumulation of a milky lymphatic fluid containing raised concentrations of white blood cells, triglycerides, and cholesterol. Chylothorax, when the effusion affects the pleural cavity, is generally a complication of malignancy or chest surgery or may be idiopathic. Treatment usually involves catheter drainage and dietary modification; surgery is used when these measures fail. Octreotide has been used successfully in several cases to treat chylothorax,[1-5] although there are also reports of it being ineffective.[6] Doses have generally been 50 to 100 micrograms subcutaneously 3 times daily. Octreotide has also been used for treating chylothorax in paediatric patients, particularly after cardiothoracic surgery. Doses noted in reviews[7-9] have ranged from 7 to 240 micrograms/kg daily by intravenous infusion, or around 4 to 40 micrograms/kg daily by subcutaneous injection. Octreotide has also been used in chyloperitoneum[10-15] and for cervical chylous fistula.[16]

Cushing's syndrome. Cushing's syndrome (p. 2559.1) can be caused by excessive secretion from an ectopic ACTH secreting tumour. Many of these ectopic tumours express somatostatin receptors and it has been suggested that octreotide may be useful in the diagnosis, and possibly the treatment, of selected patients.[1] However, there are

types of somatostatin receptor,[2,3] and responses to octreotide have been variable,[4] even in the same patient.[3,5]

Diabetes mellitus. Although octreotide has been reported to impair glucose tolerance, and even precipitate frank diabetes (see Effects on Carbohydrate Metabolism, under Adverse Effects, p. 1927.2), its variable effects on blood glucose and insulin have led to investigations[1,2] of its ability to induce beta cell rest in patients with diabetes mellitus (p. 458.2) who still have residual insulin secretion. There is also some suggestion that it may be of benefit in the treatment or prevention of diabetic nephropathy[3,4] and retinopathy.[5–7] Benefit has been reported from the use of octreotide in patients with diabetic diarrhoea—see Diarrhoea, under Gastrointestinal Disorders, below.

Diagnosis and testing. Radiolabelled octreotide or other somatostatin analogues such as pentetreotide and depreotide may be used to visualise various malignant neoplasms which express somatostatin receptors.[1–5]

Octreotide may also have a role in the diagnosis of Cushing's syndrome, see p. 1924.3.

Eye disorders. There are reports of response to octreotide in patients with cystoid macular oedema, a refractory form of retinal oedema.[1–4] The problem recurred when octreotide was withdrawn[1,3,4] but responded to resumption of octreotide therapy.[1]

Gastrointestinal disorders. Somatostatin inhibits gastric and intestinal secretion and the production of various active substances in the gastrointestinal tract. It also reduces splanchnic arterial blood flow and portal and gastric mucosal blood flow. These properties are made use of, usually in the form of octreotide, in the management of several gastrointestinal disorders including bleeding, refractory diarrhoea, fistulae, dumping syndrome, and nausea and vomiting secondary to bowel obstruction (see below).

Octreotide is used particularly in the treatment of carcinoid syndrome arising from endocrine tumours (see Neuroendocrine Tumours, p. 716.3).

BLEEDING. There have been mixed results with octreotide in the treatment of **nonvariceal** upper gastrointestinal bleeding. Although a large multicentre study[1] showed that octreotide had no benefit compared with placebo in the management of bleeding upper gastrointestinal ulcers, a meta-analysis that included somatostatin and octreotide suggested there might be some benefit.[2] Nevertheless, a later study[3] found that octreotide, given as an adjunct to endoscopic haemostasis using noradrenaline, did not seem to provide any additional benefit, and it is not recommended in the management of nonvariceal bleeding associated with peptic ulcer (p. 1813.2). A review suggested that octreotide was useful in patients with acquired gastrointestinal angiodysplasia with refractory bleeding, and might be considered for use particularly in those with inaccessible lesions or at high risk from other interventions.[4]

Octreotide may be used in the management of **variceal haemorrhage** (see under Monoethanolamine, p. 2563.1). There is some evidence that octreotide is as effective as sclerotherapy in the control of acute bleeding.[5] A meta-analysis[6] of studies comparing octreotide with other therapies (including vasopressin, terlipressin, sclerotherapy, or balloon tamponade) for the control of acute variceal bleeding found that octreotide had a similar effect to sclerotherapy in the prevention of rebleeding and was more effective and associated with fewer major complications than vasopressin or terlipressin. However, there was no evidence of mortality benefit associated with octreotide use. A systematic review[7] of studies comparing somatostatin or its analogues with either placebo or no drug treatment also found that although there was a small benefit in controlling bleeding, it was doubtful whether this benefit was worthwhile, and that deaths were not reduced. A third systematic review[8] found that sclerotherapy was associated with more frequent and severe adverse effects than drug therapy, including octreotide.

Controlled studies have suggested that *combination* of octreotide infusion for 5 days with endoscopic ligation[9] or sclerotherapy[10,11] reduces the risk of rebleeding. In another study,[12] sclerotherapy with 48 hours of octreotide infusion was more effective at controlling bleeding than sclerotherapy alone, and octreotide was as effective as sclerotherapy in those with evidence of recent bleeding. However, another study[13] found that octreotide given subcutaneously for up to 29 days after sclerotherapy did not affect the rate of early rebleeding. Octreotide has also produced some benefit (combined with regular sclerotherapy), in the long-term management of patients with cirrhotic portal hypertension.[14]

DIARRHOEA. Octreotide has been tried for its effects on gastrointestinal secretion and intestinal transit time in the management of severe refractory diarrhoea associated with a variety of conditions. A review[1] found that studies were generally small, and that although there appeared to be an overall benefit associated with the use of octreotide, response was influenced by the cause of diarrhoea. There are reports of octreotide controlling diarrhoea associated with amyloidosis,[2–4] diabetes mellitus,[5–11] and bone marrow transplantation.[12,13] Although octreotide was reported to be useful in a case of microvillous atrophy,[14] others have not found it to be effective.[15] There have been reports of benefit in refractory AIDS-associated diarrhoea,[16] and it has been licensed for this use in some countries, but a double-blind, controlled study found octreotide to be no more beneficial than placebo.[17] Octreotide has also been used successfully for symptomatic treatment of chronic diarrhoea associated with cytomegalovirus colitis.[18] In patients with the short bowel syndrome and jejunostomies or ileostomies, octreotide may be useful in decreasing faecal mass[19] or jejunal efflux,[20] and increasing small bowel transit time.[21] Octreotide has also been used with some benefit in refractory diarrhoea associated with chemotherapy, particularly with regimens that include fluorouracil[22,23] and irinotecan.[24] In a small series of patients[25] the use of depot octreotide controlled most episodes of diarrhoea, and allowed the continuation of chemotherapy in some cases.

FISTULAE. Octreotide has been used in the management of postoperative small-bowel fistulae. There have been mixed reports, but some have found reduced fistula output,[1,2] with the time to spontaneous fistula closure either reduced[1] or unchanged.[2] Octreotide has also been reported to accelerate healing of pancreatic cutaneous fistulae of various causes,[3] but others[4] have found no benefit from octreotide in preventing pancreatic fistula formation after pancreaticoduodenectomy. A systematic review[5] of controlled studies commented on the variation in study methods and conflicting results, but concluded that there is probably benefit in giving octreotide pre-operatively to prevent complications of pancreatic surgery, and that in established postoperative fistulae it may have a limited role in reducing fistula output and reducing the time to fistula closure. In a series of 5 patients[6] with Crohn's disease who were treated for 8 weeks with high-dose octreotide, enterocutaneous fistulae closed in 4 cases.

OTHER GASTROINTESTINAL DISORDERS. Further gastrointestinal disorders in which octreotide might be useful include

dumping syndrome[1-3] (p. 1806.2). One report[4] suggested that preprandial subcutaneous doses produce higher peak serum concentrations and might therefore be more effective than a long-acting intramuscular formulation. Other disorders include reactive (or postprandial) hypoglycaemia,[5] and protein-losing enteropathy associated with intestinal lymphangiectasia.[6,7] Nausea and vomiting secondary to bowel obstruction in patients terminally ill with cancer may also be relieved by octreotide.[8,9] The *BNF* states that in palliative care a dose of 250 to 500 micrograms (sometimes up to 750 micrograms or occasionally higher) may be given by subcutaneous infusion over 24 hours to reduce intestinal secretions and to reduce vomiting due to bowel obstruction.

Hypercalcaemia. There have been individual reports of hypercalcaemia associated with raised plasma concentrations of parathyroid hormone-related protein (hypercalcaemia of malignancy—p. 1167.2) being successfully controlled with octreotide in patients with malignant pancreatic endocrine tumours[1-3] and adrenal phaeochromocytoma.[4] Octreotide also resolved hypercalcaemia occurring in a patient with VIPoma and vasoactive intestinal peptide concentrations declined.[5] In 2 patients with a parathyroid hormone-related protein secreting carcinoid tumour, octreotide reduced protein concentrations in both patients[6,7] but controlled hypercalcaemia in only one.[7] Octreotide also normalised calcium concentrations in a patient with hypercalcaemia related to B cell lymphoma.[8] In many of these cases, hypercalcaemia had previously been resistant to treatment with bisphosphonates.

Hyperinsulinism. As well as reactive hypoglycaemia (see under Other Gastrointestinal Disorders, p. 1925.3), octreotide has been used to control inappropriate insulin secretion, both in the short-term and long-term, in children with hypoglycaemia of infancy,[1-4] or nesidioblastosis.[5-7] Although not licensed in the UK for children, the *BNFC* includes a dose of octreotide for persistent hyperinsulinaemic hypoglycaemia (p. 1554.3) unresponsive to diazoxide and glucose. For neonates an initial dose of 2 to 5 micrograms/kg may be given every 6 to 8 hours subcutaneously and adjusted according to response. For children aged from 1 month to 18 years, an initial dose of 1 to 2 micrograms/kg every 4 to 6 hours may be used. Doses up to 7 micrograms/kg every 4 hours may be required in rare cases.

Octreotide has also been used to treat a patient with hyperinsulinaemia induced by quinine.[8,9] For mention of investigations of octreotide for the reverse effect, see Diabetes Mellitus, p. 1925.1.

Malignant neoplasms. See also Neuroendocrine Tumours, below. For mention of the use of octreotide to treat nausea and vomiting associated with malignant gastrointestinal obstruction see under Other Gastrointestinal Disorders, p. 1925.3. Octreotide has also proved of benefit in some patients with cancer pain (see Pain, below). An unconventional regimen using octreotide or somatostatin with melatonin, bromocriptine, and a solution of retinoids (the Di Bella regimen) was investigated in patients with a variety of advanced malignancies and found to be ineffective.[1,2]

HEPATOCELLULAR CARCINOMA. In a study in 58 patients with advanced hepatocellular carcinoma (p. 709.3) treatment with octreotide was associated with prolongation of survival compared with no treatment.[1] In a further case report[2] cancer regression occurred in a patient given octreotide, and a study[3] found better survival in patients treated with octreotide and tamoxifen compared with fluorouracil and mitomycin. However, other studies of octreotide in patients with advanced hepatocellular carcinoma failed to show any benefit.[4-7] A systematic review of randomised studies[8] concluded that octreotide did not improve survival.

MENINGIOMA. Octreotide has been reported to suppress headaches and visual disturbances associated with meningioma in a small number of patients.[1-3] Doses were generally started at 100 micrograms three times daily subcutaneously, but were increased to 500 micrograms three times daily in some cases because of tolerance. Although it was thought that octreotide may have had a beneficial effect on the meningioma size in one case,[1] others found no evidence of tumour shrinkage.[2,3] A pilot study[4] examined the effects of octreotide in 16 patients with recurrent meningioma that overexpressed somatostatin receptors. There were 5 partial responses, 5 cases of stable disease, and 6 cases of progressive disease after the first 3 treatment cycles; progression-free survival at 6 months was 44% (7 patients).

THYMOMA. A patient with thymoma and pure red cell aplasia, in whom corticosteroids alone failed to control anaemia, had complete remission after treatment with octreotide and prednisone, and subsequently remained well on long-term maintenance therapy with octreotide 500 micrograms twice daily subcutaneously and prednisone 200 micrograms/kg daily.[1] In a study[2] that included 32 patients with thymoma and a positive octreotide scan, octreotide therapy alone (500 micrograms subcutaneously three times daily for up to 1 year) or with prednisone (600 micrograms/kg daily) had modest activity: there were 2 complete and 10 partial responses overall.

Nesidioblastosis. For reference to the use of octreotide in nesidioblastosis, see Hyperinsulinism, above.

Obesity. Hypothalamic obesity can be a complication of hypothalamic damage caused by insults such as head trauma, brain tumours, and cranial surgery or irradiation. Octreotide has improved body-weight, body-mass index, and regulation of insulin secretion in small studies of children with hypothalamic obesity.[1-3] Additionally octreotide has produced a small amount of weight loss in some obese adults with insulin hypersecretion.[4,5] Octreotide is also under investigation in the treatment of Prader-Willi syndrome (p. 2315.2).[6]

Pain. Octreotide 120 to 480 micrograms daily was given by continuous intrathecal infusion to 6 patients with cancer pain that had been poorly controlled by opioid analgesics.[1] All patients obtained good pain relief, 3 reporting pain to be totally absent. Sustained decrease in incapacitating bone pain has also been reported in a patient with skeletal metastasis of a gastrinoma who was given subcutaneous octreotide 100 micrograms three times daily.[2] The pain of hypertrophic pulmonary osteoarthropathy (a paraneoplastic syndrome of periostitis, arthropathy, and gynaecomastia seen particularly with squamous cell lung cancer) has also been reported to respond to octreotide.[3] However, a controlled study of octreotide in cancer pain found that it was no better than placebo in most patients.[4] (General guidelines for the management of cancer pain are discussed on p. 7.1.) Octreotide has also been reported to ease headache associated with meningioma (above), and pituitary adenoma (see Acromegaly, p. 1924.2, and Pituitary Adenoma, p. 1927.1).

The use of intrathecal octreotide has also been described[5] in 2 patients with severe intractable non-malignant pain. During 5 years of treatment, octreotide provided a beneficial degree of pain relief and allowed a reduction in opioid dosage. However, the dose of octreotide had to be gradually increased, suggesting tolerance to the analgesic effect; one patient was receiving a daily dose of 648 micrograms.

Pancreatic disorders. Octreotide has been tried in the treatment of acute pancreatitis, but was found to be ineffective.[1] Prophylactic octreotide has also been studied for the prevention of pancreatitis following endoscopic retrograde cholangiopancreatography with some positive results,[2,3] but a meta-analysis concluded that it was ineffective.[4] Others[5,6] have suggested that it might only be

effective at total doses of more than 500 micrograms, although the optimal route and timing are unclear.[5] For reference to the use of octreotide in the management of pancreatic endocrine tumours, see under Neuroendocrine Tumours (p. 716.3); for its use in pancreatic fistulae, see under Gastrointestinal Disorders, p. 1925.3.

Pituitary adenoma. Octreotide has a role in the management of pituitary adenomas that cause acromegaly (see p. 1924.2). It has also been used in the management of rare tumours such as thyrotropin-secreting pituitary adenomas, usually when surgery or radiotherapy have failed. Octreotide may reduce concentrations of thyrotropin and normalise thyroid hormones in most patients; tumour shrinkage also occurs in at least a third of cases.[1-4] Octreotide has also been tried in the management of other rare adenomas such as clinically nonfunctioning adenomas, but results have been mixed; in a few cases there has been relief of symptoms such as headache without any change in tumour volume.[5]

Polycystic kidney and liver diseases. Octreotide[1-3] and lanreotide[4] have been investigated in autosomal dominant polycystic kidney and liver diseases. Small studies, usually lasting 6 or 12 months, suggest that treatment may slow the rate of increase in kidney volume and may decrease liver volume.

Pretibial myxoedema. Pretibial myxoedema (deposition of glycosaminoglycans in the subcutaneous tissue of the shins) is associated with Graves' disease (see Hyperthyroidism, p. 2332.2). There are reports of apparent benefit from the use of octreotide for this condition. In one case,[1,2] octreotide given for 6 months after surgical removal of the myxoedematous tissue may have prevented its recurrence. In another,[3] octreotide injected intralesionally was reported to improve and control the condition. However, in other cases[4] subcutaneous octreotide has been ineffective.

3. Shinohara M, *et al.* Refractory pretibial myxoedema with response to intralesional insulin-like growth factor 1 antagonist (octreotide): downregulation of hyaluronic acid production by the lesional fibroblasts. *Br J Dermatol* 2000; 143: 1083–6.
4. Rotman-Pikielny P, *et al.* Lack of effect of long-term octreotide therapy in severe thyroid-associated dermopathy. *Thyroid* 2003; 13: 465–70.

Raised intracranial pressure. For reference to octreotide being tried in idiopathic intracranial hypertension, see p. 1271.3.

Sulfonylurea overdose. Octreotide has been used in the treatment of severe refractory cases of sulfonylurea-induced hypoglycaemia (see Treatment of Adverse Effects, p. 502.1).

Adverse Effects and Precautions

There may be a transient local reaction at the site of injection of octreotide. Systemic adverse effects are mainly gastrointestinal and may include anorexia, nausea, vomiting, diarrhoea and steatorrhoea, abdominal discomfort, and flatulence. Use between meals or at bedtime may reduce these gastrointestinal effects. Hypersensitivity reactions and hair loss have been reported rarely.

Gallstones may develop on long-term therapy; there have been isolated reports of hepatic dysfunction and of biliary colic associated with drug withdrawal. Checks should be made for gallstones before prolonged therapy and at 6- to 12-month intervals during treatment. There have also been isolated reports of pancreatitis and of hepatic dysfunction without cholestasis. Hypoglycaemia may occur, especially in patients with insulinomas, but there is also a risk of hyperglycaemia or impaired glucose tolerance. Thyroid function should be monitored during octreotide therapy because of the possibility of hypothyroidism. Pituitary tumours that secrete growth hormone can expand during treatment, causing serious complications; patients should be monitored for signs of tumour expansion, such as visual field defects. Cardiac rhythm should be monitored during intravenous use of octreotide. Doses may need to be adjusted in patients with liver cirrhosis or end-stage renal failure, in whom the clearance of octreotide is reduced.

In women with acromegaly, the normalisation of growth hormone and IGF-I concentrations by octreotide may restore fertility. Licensed product information for octreotide advises that contraception be used during treatment, but see also Pregnancy, below.

Effects on the biliary tract. Octreotide has an inhibitory effect on gallbladder motility and bile secretion, accounting for the development of gallstones and biliary colic.[1-6]

5. Moschetta A, *et al.* Severe impairment of postprandial cholecystokinin release and gall-bladder emptying and high risk of gallstone formation in acromegalic patients during Sandostatin LAR. *Aliment Pharmacol Ther* 2001; 15: 181–5.
6. Hofmann AF. Increased deoxycholic acid absorption and gall stones in acromegalic patients treated with octreotide: more evidence for a connection between slow transit constipation and gall stones. *Gut* 2005; 54: 575–8.

Effects on carbohydrate metabolism. Changes in glucose tolerance may occur in patients with acromegaly who are treated with somatostatin analogues. A meta-analysis of studies of the use of octreotide or lanreotide in acromegaly concluded that somatostatin analogues had a marginal impact on glucose homoeostasis. There was evidence for a decrease in fasting plasma-insulin, but without significant effect on fasting plasma-glucose or glycated haemoglobin ($HbA1_c$). Nevertheless, a significant adverse effect may occur in individual patients and glycaemic monitoring was recommended.[1]

There has been a report of deterioration in glucose tolerance leading to death from diabetic ketoacidosis when octreotide treatment was stopped in a patient with acromegaly and insulin-resistant diabetes mellitus.[2]

See also Diabetes Mellitus and Hyperinsulinism under Uses and Administration, p. 1925.1 and p. 1926.1.

2. Abrahamson MJ. Death from diabetic ketoacidosis after cessation of octreotide in acromegaly. *Lancet* 1990; 336: 318–19.

Effects on the hair. Diffuse loss of scalp hair has been reported in 4 of 7 women who received octreotide; after withdrawal of octreotide in 3 of the women there was a complete recovery of scalp hair.[1] Other similar cases have also been reported. In one case, diffuse alopecia in a male patient was completely reversed when octreotide was replaced with lanreotide.[2]

2. Lami M-C, *et al.* Hair loss in three patients with acromegaly treated with octreotide. *Br J Dermatol* 2003; 149: 655–6.

Effects on the liver. Hepatitis occurred in 2 acromegalic patients treated with octreotide 300 micrograms daily subcutaneously.[1,2] In both cases liver enzyme values returned to normal within 1 to 2 months of withdrawing octreotide, and recurred on rechallenge.

1. Arosio M, *et al.* Acute hepatitis after treatment of acromegaly with octreotide. *Lancet* 1988; ii: 1498.
2. González-Martín JA, *et al.* Acute liver injury and octreotide. *Am J Gastroenterol* 1996; 91: 2434–5.

Effects on mental function. A woman with acromegaly developed manic symptoms on 2 separate occasions 2 months after starting treatment with octreotide.[1]

1. Fernández-Real J-M, *et al.* Octreotide-induced manic episodes in a patient with acromegaly. *Ann Intern Med* 2006; 144: 704.

Effects on the pancreas. There have been reports of pancreatitis associated with octreotide[1-4] and lanreotide.[4] It has been suggested that octreotide-induced pancreatitis may result from spasm of the sphincter of Oddi, resulting in retention of activated pancreatic enzymes due to outflow obstruction.[3]

1. Predenrich A, *et al.* Acute pancreatitis after short-term octreotide. *Lancet* 1991; 338: 52–3.

4. Cannavò S, *et al.* Octreotide and lanreotide treatment in active acromegaly. *J Clin Endocrinol Metab* 1997; 82: 2376–7.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) and the Porphyria Centre Sweden, classifies octreotide as probably not porphyrinogenic; it may be used as a drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 24/10/11)

Pregnancy. There have been reports of women given lanreotide[1,2] or octreotide[2-7] during pregnancy. Most were being treated for acromegaly, although there is also a report[6] of octreotide use during pregnancy in a woman treated for nesidioblastosis. In most cases, the somatostatin analogue was stopped early in the pregnancy, but in some cases octreotide was continued to term. No maternal complications or congenital anomalies were described, although several cases[2] of babies born small for gestational age have been seen.

Interactions

Octreotide has been associated with alterations in nutrient absorption and there is a theoretical possibility that it may affect the oral absorption of other drugs. Patients receiving insulin or oral hypoglycaemics may require dose adjustments of these drugs if octreotide is also used. The bioavailability of bromocriptine is increased by octreotide. It has been suggested that dosage of beta blockers, calcium-channel blockers, or drugs to control fluid and electrolyte balance may also need to be adjusted.

Ciclosporin. For a reference to octreotide reducing serum concentrations of ciclosporin, see p. 1954.3.

Pharmacokinetics

Octreotide is rapidly absorbed after subcutaneous injection, with peak plasma concentrations reached about 25 to 40 minutes after a dose, and is distributed to body tissues. About 40 to 65% of the octreotide in the circulation is bound to plasma proteins. It is said to show non-linear pharmacokinetics, with reduced clearance at high doses. Octreotide has a plasma elimination half-life of about 1.5 hours; half-life is prolonged in elderly patients, renal impairment, and liver cirrhosis. About a third of a dose is excreted unchanged in the urine. Octreotide diffuses across the placenta.

Pasireotide *(USAN, rINN)*

Pasireotida; Pasiréotide; Pasireotidum; SOM-230; Пасиреотид.

Cyclo[(4*R*)-4-(2-aminoethylcarbamoyloxy)-L-prolyl-L-phenylglycyl-D-tryptophyl-L-lysyl-4-O-benzyl-L-tyrosyl-L-phenylalanyl-].

$C_{58}H_{66}N_{10}O_9$=1047.2

CAS — 396091-73-9 (pasireotide); 396091-76-2 (pasireotide acetate).

ATC — H01CB05.

ATC Vet — QH01CB05.

UNII — 98H1T17066.

Pasireotide Aspartate *(rINNM)*

Aspartato de pasireotida; Pasireotide L-aspartate; Pasiréotide, Aspartate de; Pasireotidi Aspartas; SOM-230B; Пасиреотида Аспартат.

$C_{58}H_{66}N_{10}O_9.C_4H_7NO_4$

CAS — 396091-77-3 (pasireotide x aspartate).

ATC — H01CB05.

ATC Vet — QH01CB05.

Uses and Administration

Pasireotide is a somatostatin analogue that binds to 4 of the 5 human somatostatin (hsst) receptors, especially hsst-5 which is expressed at high levels in corticotropin (ACTH)-producing adenomas. The resulting inhibition of ACTH secretion is used in the treatment of Cushing's disease (p. 2559.1), particularly when surgery is not an option or has failed.

It is given as the diaspartate ($C_{58}H_{66}N_{10}O_9.2C_4H_7NO_4$ = 1313.4) but doses are expressed in terms of the base; 125 micrograms of pasireotide diaspartate is equivalent to about 100 micrograms of pasireotide. An initial dose equivalent to 600 micrograms of pasireotide is given twice daily by subcutaneous injection. Clinical benefit should be assessed after two months and the dose may be increased to 900 micrograms twice daily if necessary, according to the reduction in urinary free cortisol. If no response is seen after two months, treatment discontinuation should be considered. Adverse effects may be managed by a temporary reduction in dose by decrements of 300 micrograms twice daily. For doses in hepatic impairment, see below.

Pasireotide is also under investigation in the treatment of acromegaly and carcinoid tumours.

Administration in hepatic impairment. Higher exposure to pasireotide has been seen in subjects with moderate and severe hepatic impairment.[1] Licensed product information suggests that dose adjustment is not required in mild hepatic impairment (Child-Pugh class A). For patients with moderate hepatic impairment (Child-Pugh class B) the initial dose of subcutaneous pasireotide should be 300 micrograms twice daily with a maximum dose of 600 micrograms twice daily. Pasireotide should not be used in severe hepatic impairment (Child-Pugh class C).

1. Horsmans Y, *et al.* Effect of hepatic impairment on the pharmacokinetics of pasireotide (SOM230): results from a multicenter phase I study. *J Clin Pharmacol* 2012; **52:** 552–8.

Adverse Effects, Treatment, and Precautions

As for Octreotide Acetate, p. 1927.1. Other common adverse effects include anaemia, headache, hypotension, myalgia and arthralgia, and fatigue.

Hyperglycaemia is very commonly reported in patients given pasireotide for the management of Cushing's disease. Glycated haemoglobin (HbA_{1c}) has been reported to increase significantly and stabilise during therapy, then decrease but not return to baseline values after stopping pasireotide. Fasting plasma glucose and HbA_{1c} should be assessed before starting pasireotide then monitored weekly for the first 2 to 3 months of therapy and periodically thereafter. Fasting plasma glucose should be measured 4 weeks, and HbA_{1c} at 3 months, after stopping treatment. If hyperglycaemia remains uncontrolled by antidiabetic therapy, the dose of pasireotide should be adjusted or it should be stopped.

Mild transient elevations of liver enzymes commonly occur in patients given pasireotide. Rare cases of more significant increases in liver enzymes and bilirubin have been reported, usually developing within 10 days of starting therapy, with full recovery after stopping pasireotide. Monitoring of liver function is recommended before using pasireotide, after 1, 2, 4, 8, and 12 weeks during treatment, and thereafter as clinically indicated.

Bradycardia and QT prolongation have been reported and it is recommended that ECG should be monitored before and 1 week after starting pasireotide treatment, and thereafter as clinically indicated. Hypokalaemia and/or hypomagnesaemia should be corrected before treatment and monitored periodically during therapy.

Pasireotide causes rapid suppression of corticotropin (ACTH) secretion in Cushings' disease, and complete or near-complete suppression can cause transient adrenocortical insufficiency. Dose reduction or withdrawal of pasireotide with glucocorticoid replacement therapy may be needed. Pasireotide may also inhibit other pituitary hormones, and monitoring of pituitary function is recommended.

Interactions

Pasireotide is a P-glycoprotein (PgP) substrate so there is potential for strong PgP inhibitors to increase the concentrations of pasireotide; however, the clinical implications are unknown. Pasireotide should be used with caution with other drugs that prolong the QT interval or have bradycardic effects. Dose adjustment of insulin and other antidiabetic medicines may be required in patients given pasireotide.

Pharmacokinetics

Pasireotide is rapidly absorbed after subcutaneous injection, with peak plasma concentrations reached about 15 to 30 minutes after a dose. Pasireotide is mostly distributed in the plasma and plasma protein binding is about 88%. Pasireotide is eliminated mainly by hepatic clearance and is mostly found, unchanged, in the faeces (48%) and urine (8%). The half-life in healthy subjects is about 12 hours and increases in hepatic impairment.

Preparations

Proprietary Preparations (details are given in Volume B)

Single-ingredient Preparations. *Denm.*: Signifor; *Fr.*: Signifor; *Neth.*: Signifor; *Norw.*: Signifor; *Switz.*: Signifor; *UK*: Signifor; *USA*: Signifor.

Pegvisomant *(BAN, USAN, rINN)*

B2036-PEG; Pegvisomanto; Pegvisomantti; Pegvisomantum; Pegwisomant; Пегвизомант.

18-L-Aspartic acid-21-L-asparagine-120-L-lysine-167-L-asparagine-168-L-alanine-171-L-serine-172-L-arginine-174-L-serine-179-L-threonine growth hormone (human), reaction product with polyethylene glycol.

CAS — 218620-50-9.

ATC — H01AX01.

ATC Vet — QH01AX01.

UNII — N824AOU5XV.

Uses and Administration

Pegvisomant is a protein of recombinant DNA origin to which several polyethylene glycol polymers are covalently bound. It is an analogue of human growth hormone that acts as an antagonist at growth hormone receptors, and is used in the treatment of acromegaly (below). A loading dose of 40 or 80 mg is given subcutaneously, followed by 10 mg daily. Further dose adjustments, in increments of 5 mg, are made according to serum concentrations of IGF-I, which should be measured every 4 to 6 weeks. The maintenance dose should not exceed 30 mg daily.

Reviews.

Administration in children. For administration of pegvisomant in children with pituitary gigantism, see below.

Acromegaly. Pegvisomant may be used in patients with acromegaly (p. 1918.1) who have not responded adequately to surgery, radiotherapy, or somatostatin analogues, or when these therapies are unsuitable or not tolerated. The combination of pegvisomant with a somatostatin analogue is also under investigation in patients whose response to a somatostatin analogue alone is inadequate. Pegvisomant has also been tried in a small number of younger patients with gigantism (see below).

Gigantism. Several case reports have described the use of pegvisomant in children and adolescents in the treatment of pituitary gigantism (p. 1918.1).[1-4] The condition had been previously uncontrolled by other treatments (surgery, octreotide, or dopamine agonists). Generally daily subcutaneous injections of pegvisomant 10 mg were given initially, and the youngest patient[3] was aged 5 years and 6 months.

Adverse Effects and Precautions

Adverse effects commonly reported with the use of pegvisomant include gastrointestinal disturbances, elevated liver function tests, flu-like symptoms, fatigue, injection site reactions, arthralgia, myalgia, peripheral oedema, headache, dizziness, somnolence, tremor, sweating, pruritus, rash, sleep disorders, hypercholesterolaemia, weight gain, hyperglycaemia, hunger, and hypertension.

Liver function should be tested before starting pegvisomant, then every 4 to 6 weeks for the first 6 months of therapy. US licensed product information recommends that further testing take place twice in the next 6 months and then twice in the following year.

Pegvisomant is structurally similar to growth hormone and may cause assays to overestimate growth hormone concentrations.

Breast feeding. The distribution of pegvisomant into breast milk has been examined (see Pregnancy, below).

Effects on the skin. Lipohypertrophy has been described in patients who have consistently injected pegvisomant into the same subcutaneous area.[1-3] Lipohypertrophy regressed on stopping the drug.[3] The efficacy of pegvisomant was also reduced in one case, but lipohypertrophy resolved and pegvisomant efficacy improved when the patient used the recommended technique of injection site rotation.[2] Licensed product information recommends that a different injection site is used daily to help prevent lipohypertrophy.

1. Maffei P, *et al.* Lipohypertrophy in acromegaly induced by the new growth hormone receptor antagonist pegvisomant. *Ann Intern Med* 2006; **145:** 310–12.

3. Bonert VS, *et al.* Lipodystrophy in patients with acromegaly receiving pegvisomant. *J Clin Endocrinol Metab* 2008; **93:** 3515–18.

Pregnancy. A women receiving pegvisomant for acromegaly continued therapy during pregnancy.[1] The dose of pegvisomant needed to be increased from 15 mg subcutaneously daily to 20 mg daily one month after conception, and to 25 mg daily at 3 months of gestation. Normal fetal growth milestones were achieved and a normal child was delivered at week 40 by caesarean section. The baby girl

was reported to be healthy and normal at 6 months of age. Transplacental passage of pegvisomant was considered to be either absent or minimal, based on samples of maternal and cord blood. There was also no evidence of substantial secretion into breast milk, and the authors suggested that any that might be ingested would be likely to undergo rapid gastric hydrolysis.

There is also a report of a woman who continued to receive pegvisomant during a single cycle of IVF and until a positive pregnancy test, with no apparent adverse effect on the fetus. The child was reported to be normal at 1 year of age.[2]

1. Brian SR, *et al.* Treatment of acromegaly with pegvisomant during pregnancy: maternal and fetal effects. *J Clin Endocrinol Metab* 2007; **92:** 3374–7.
2. Qureshi A, *et al.* IVF/ICSI in a woman with active acromegaly: successful outcome following treatment with pegvisomant. *J Assist Reprod Genet* 2006; **23:** 439–42.

Interactions

Pegvisomant may increase insulin sensitivity. In patients with diabetes, doses of insulin or oral hypoglycaemics may need to be decreased because of the increased risk of hypoglycaemia. Patients taking opioid analgesics may require higher serum concentrations of pegvisomant to achieve appropriate IGF-I suppression.

Pharmacokinetics

Pegvisomant is absorbed slowly after subcutaneous injection, and peak serum concentrations occur after about 33 to 77 hours. It is slowly eliminated from serum, with a half-life estimated to range from 74 to 172 hours. Renal clearance of pegvisomant is negligible.

CAS — 158861-67-7 (pralmorelin); 158827-34-0 (pralmorelin dihydrochloride).

UNII — R4AVR27MM8.

Profile

Pralmorelin is a small synthetic peptide that stimulates the release of growth hormone. It is used in the diagnosis of growth hormone deficiency; it has also been tried in the treatment of growth retardation (p. 1918.3).

CAS — 478166-15-3.

ATC — H01AC05.

ATC Vet — QH01AC05.

UNII — NZ8M50KKRG.

Uses and Administration

The somatomedins are a group of polypeptide hormones, some of which are involved in mediating the effects of growth hormone in the body. Insulin-like growth factor I (IGF-I) is believed to be responsible for many of the anabolic effects of growth hormone. It is secreted primarily by the liver, regulated principally by growth hormone and insulin secretion; IGF-I may also be secreted in other tissues, where it may exert local hormonal (paracrine) effects. In the circulation, IGF-I is almost completely protein bound; 6 binding proteins have been identified and production of some of these is also under the control of growth hormone. In addition to its anabolic effects IGF-I, which is structurally related to insulin, also has potent hypoglycaemic properties.

IGF-I is available as mecasermin, a product of recombinant DNA technology. It is used in the treatment of growth failure in children and adolescents with severe primary IGF-I deficiency or with growth hormone gene deletion who have developed neutralising antibodies to growth hormone (see Growth Retardation, below). However, it is not recommended for children less than 2 years of age because of a lack of data. The starting dose of mecasermin is 40 to 80 micrograms/kg twice daily by subcutaneous injection. After 1 week, if this dose is tolerated, it may be increased by 40 micrograms/kg per dose to a maximum of 120 micrograms/kg twice daily. Mecasermin should be given within 20 minutes before or after food, to minimise hypoglycaemia. The dose should be reduced if hypoglycaemia occurs with recommended doses despite adequate food intake. If the patient is unable to eat for any reason, the dose of mecasermin should be withheld.

Mecasermin rinfabate is a recombinant protein complex of IGF-I and its most abundant binding protein, insulin-like growth factor binding protein-3 (IGFBP-3). It has been investigated for the management of amyotrophic lateral sclerosis and myotonic muscular dystrophy. It is also under investigation in the prevention of complications in preterm neonates that may be associated with low endogenous concentrations of IGF-I, such as retinopathy of prematurity.

IGF-II (IGF-2) is thought to play an important role in fetal growth, although its function in adults is uncertain. It is closely related in structure to IGF-I, but is not under the control of growth hormone.

Administration in children. For details of mecasermin doses in children see Uses and Administration, above and Growth Retardation, below.

Diabetes mellitus. Patients with type 1 diabetes mellitus (p. 459.1) have low circulating levels of insulin-like growth factor I (IGF-I), and there has been considerable interest in the therapeutic potential of mecasermin in these patients.[1] Randomised studies[2,3] have found that mecasermin 40 micrograms/kg once or twice daily by subcutaneous injection improves metabolic control in the short term when added to insulin therapy. Insulin doses can also be reduced in some patients.[3] However, the role of IGF-I in the development of diabetic complications is unclear and there has been some concern about its proliferative effect in diabetic retinopathy.[1] Optic disc swelling and worsening of retinopathy have been reported with higher doses of mecasermin.[3] Mecasermin rinfabate has been tried in an attempt to limit adverse effects such as oedema, jaw pain, headache, Bells' palsy, and retinal oedema.[4]

Mecasermin has also been reported to improve insulin sensitivity and to lower concentrations of insulin, glucose, and C-peptide in patients with syndromes of severe insulin resistance or type 2 diabetes mellitus.[1]

Growth retardation. Mecasermin is used in the treatment of growth retardation (p. 1918.3) including Laron-type dwarfism (growth hormone resistance or insensitivity). It is given to children and adolescents with severe primary IGF-I deficiency, which includes patients with mutations in the growth hormone receptor or post-growth hormone receptor signalling pathway, and IGF-I gene defects. They have low concentrations of IGF-I and normal or elevated concentrations of growth hormone; they are not growth hormone deficient and cannot be expected to respond to growth hormone therapy. It is also used in children with growth hormone gene deletion who have developed neutralising antibodies to growth hormone. Mecasermin has stimulated linear growth and normalised biochemical abnormalities in these patients.[1] One study[2] found the effect on growth velocity in the first year to be dose dependent. The beneficial effect persisted during up to 8 years of treatment, but growth velocity gradually declined over this time. During long-term use, growth hormone and insulin are persistently suppressed, preventing hypoglycaemia and stabilising blood-glucose concentrations.[3] There is also an increase in the production of the insulin-like growth factor binding protein-3, which prolongs the half-life of mecasermin so that a progressive dose reduction is needed to avoid overdosage and adverse effects.[3]

Some children with idiopathic short stature have a low concentration of IGF-I of no apparent cause, which is less severe than IGF-I deficiency from genetic causes. It has been suggested that these patients, who have normal concentrations of growth hormone, might have a degree of growth hormone insensitivity, and a study[4] of IGF-I treatment reported improvements in height velocity, dependent on dose and age. However, this premise for IGF-I therapy has been criticised and a role for IGF-I treatment in idiopathic short stature requires further study.[5]

Motor neurone disease. Mecasermin has been investigated for the management of amyotrophic lateral sclerosis, a form of motor neurone disease (p. 2605.2). A review of 2 studies concluded that there was not enough evidence to assess the clinical efficacy of mecasermin.[1] A later study found no benefit from mecasermin.[2]

1. Mitchell JD, *et al.* Recombinant human insulin-like growth factor I (rhIGF-I) for amyotrophic lateral sclerosis/motor neuron disease. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2007 (accessed 21/08/08).

Adverse Effects and Precautions

Since the somatomedins are considered to be responsible for many of the actions of growth hormone similar adverse effects (see p. 1921.3) might be expected, and have been seen with mecasermin. Hypoglycaemia is common but symptoms can generally be avoided if mecasermin is given within 20 minutes of food. Tonsillar hypertrophy can develop; patients should be monitored for complications such as snoring, sleep apnoea, and chronic middle ear effusions. Thickening of the soft tissues of the face can also occur. Cardiomegaly and valvulopathy have been reported in a few patients. Although a relationship between cardiac changes and mecasermin therapy has not been confirmed, echocardiogram monitoring has been recommended. Injection site hypertrophy may occur, but can be avoided or resolved by proper rotation of injection sites. Cases of hypersensitivity, urticaria, pruritus, and erythema have also been reported.

Effects on the eyes. For concerns about an increased risk of retinopathy in diabetic patients receiving mecasermin, see under Diabetes Mellitus, p. 1929.2.

Intravenous administration. Syncope in the absence of hypoglycaemia has been reported in patients given mecasermin by intravenous bolus, accompanied in some cases by convulsions, asystole, bradycardia, hypotension, or dizziness.[1] Reports appear to have ceased since recommendations that mecasermin should not be given intravenously at rates greater than 24 micrograms/kg per hour. Arthralgia, nerve palsies, and hypophosphataemia and dyspnoea have been associated with high-dose intravenous bolus therapy.[2] Mecasermin is now given by subcutaneous injection (see Uses and Administration, p. 1929.2).

2. Usala A-L. Risks and benefits of insulin-like growth factor. *Ann Intern Med* 1994; 121: 550.

Pharmacokinetics

After subcutaneous injection, mecasermin has a bioavailability of almost 100% in healthy subjects. In the circulation it is bound to 6 binding proteins, with more than 80% bound to binding protein 3 (IGFBP-3). However, IGFBP-3 is greatly reduced in patients with severe primary IGF-I deficiency, such that there is an increase in the clearance of mecasermin. Mecasermin is metabolised in the liver and the kidney, and has a terminal half-life of about 6 hours in children with severe primary IGF-I deficiency.

After subcutaneous injection of mecasermin rinfabate in children with severe primary IGF-I deficiency, the half-life of free IGF-I is prolonged to about 13 hours and IGFBP-3 has a half-life of about 54 hours.

Uses and Administration

Somatorelin is a peptide, secreted by the hypothalamus, that promotes the release of growth hormone from the anterior pituitary. It exists as 44-, 40-, and 37-amino acid peptides; the 44-amino acid form may possibly be converted to the smaller forms but all are reported to be active, the activity residing in the first 29 amino acid residues. Sermorelin is a synthetic peptide corresponding to the 1–29 amino acid sequence of somatorelin.

Somatorelin acetate is used for the diagnosis of growth hormone deficiency. The usual dose is the equivalent of somatorelin 50 micrograms by intravenous injection, given after the patient has fasted. In highly overweight adults and in children, a dose of 1 microgram/kg is given. Plasma or serum concentrations of growth hormone are measured before the dose of somatorelin and usually 30 minutes after, but additional measurements may be taken at 15, 45, 60, and 90 minutes for a better assessment of growth hormone release. The test can distinguish between pituitary and hypothalamic disorders but is not suitable as a screening test for growth hormone deficiencies.

Sermorelin acetate has been used similarly for the diagnosis of growth hormone deficiency. It has also been used for the treatment of growth retardation in children with growth hormone deficiency (see below).

Sermorelin has also been tried as an adjunct to gonadotrophin therapy in the induction of ovulation and has been investigated in the treatment of HIV-associated wasting.

Diagnostic use. Somatorelin (in its 40- or 44-amino acid forms) has been used in the assessment of growth hormone deficiency.[1-3] It has usually been given as a single intravenous injection in doses of 1 microgram/kg or total doses of up to 200 micrograms. Subsequent normal or exaggerated increases in serum-growth hormone concentrations have occurred in healthy subjects,[1,2] and in patients with hypothalamic tumours[3] or acromegaly,[2] but not in patients with hypopituitarism.[2] A synthetic 29-amino-acid sequence of somatorelin, sermorelin acetate has also been used for the diagnosis of growth hormone deficiency. However, it has been suggested that the test is not useful for screening as it does not test the hypothalamic-pituitary axis, and that it should not be used in routine clinical practice.[4] The use of sermorelin with the synthetic hexapeptide growth-hormone-releasing peptide-6 has also been reported.[5,6]

Growth retardation. Sermorelin has been studied in children with growth hormone deficiency (p. 1918.3), usually in doses of 30 micrograms/kg subcutaneously daily. Although there have been reports of improved growth rates,[1-3] there are few direct comparisons with growth hormone. One large study[4] of sermorelin found that, compared with results generally reported for growth hormone therapy, fewer patients responded over a 12-month period and growth responses were poorer.

2. Lanes R, *et al.* Long term therapy with a single daily subcutaneous dose of growth hormone releasing hormone (1-29) in prepubertal growth hormone deficient children. *J Pediatr Endocrinol* 1994; 7: 303–8.
3. Ogilvy-Stuart AL, *et al.* Treatment of radiation-induced growth hormone deficiency with growth hormone-releasing hormone. *Clin Endocrinol (Oxf)* 1997; 46: 571–8.
4. Thorner M, *et al.* Once daily subcutaneous growth hormone-releasing hormone therapy accelerates growth in growth hormone-deficient children during the first year of therapy. *J Clin Endocrinol Metab* 1996; 81: 1189–96.

Lipodystrophy. In a placebo-controlled study[1] of 31 men with HIV-related lipodystrophy, insulin-like growth factor I (IGF-I) concentrations and body composition measures were improved in those given sermorelin 1 mg twice daily subcutaneously for 12 weeks.

1. Koutkia P, *et al.* Growth hormone-releasing hormone in HIV-infected men with lipodystrophy: a randomized controlled trial. *JAMA* 2004; 292: 210–18.

Adverse Effects and Precautions

Adverse effects of somatorelin acetate injection fo diagnostic use include a transient sense of warmth c flushing of the head, neck, and upper body. There may als be taste and smell disturbances. Similar effects have bee reported with sermorelin, as well as pain at the injectio site, headache, nausea and vomiting, and tightness in th chest. Antibodies to somatorelin often develop on repeate use of sermorelin.

Uncontrolled thyroid disorders, obesity, hyperglycaemia, or elevated plasma fatty acids may impair response t somatorelin or sermorelin. Sermorelin should also be use with care in patients with epilepsy. Sermorelin should nc be used to treat growth retardation in children whos growth hormone response to stimulation tests is inadequate. Treatment should cease once the epiphyses have closed.

Porphyria. The Drug Database for Acute Porphyria, compiled by the Norwegian Porphyria Centre (NAPOS) an the Porphyria Centre Sweden, classifies sermorelin fo diagnostic use as not porphyrinogenic; it may be used as drug of first choice and no precautions are needed.[1]

1. The Drug Database for Acute Porphyria. Available at: http://www.drugs-porphyria.org (accessed 24/10/11)

Interactions

Drugs that affect the secretion of growth hormone ma interfere with the diagnostic efficacy of somatorelin o sermorelin; these include growth hormone itself (whic should be stopped at least 1 week before testing, somatostatin and its analogues, insulin, corticosteroids, and cyclo-oxygenase inhibitors such as aspirin an indometacin. Growth hormone concentrations may b raised by clonidine and levodopa. The response t somatorelin or sermorelin may also be reduced b antimuscarinic drugs such as atropine, and by antithyroi drugs such as propylthiouracil.

Acetato de somatostatina; Somatostatiiniasetaatti; Somatostatin Asetat; Somatostatinacetat; Somatostatine, Acétate de Somatostatini Acetas; Соматостатина Ацетат.

ATC — H01CB01.

ATC Vet — QH01CB01.

Uses and Administration

Somatostatin is a polypeptide obtained from the hypothalamus or by synthesis. The naturally occurring form has cyclic structure. Although somatostatin derived from th hypothalamus is a 14-amino-acid peptide, a longer, 28-amino-acid form also exists in some tissues. Five differen receptors for somatostatin have been identified. Somatostatin inhibits the release of growth hormone (p. 1919.3) from the anterior pituitary. It also inhibits the release of thyrotrophin (p. 2346.1) and corticotropin (p. 1628.3) fror the pituitary, glucagon and insulin from the pancreas, an appears to have a role in the regulation of duodenal an

gastric secretions. In the CNS it appears to play a role in the perception of pain.

It has been tried in a variety of disorders such as upper gastrointestinal haemorrhage including variceal haemorrhage (see under Monoethanolamine, p. 2563.1), insulin resistance, and the management of hormone-secreting tumours and other hypersecretory disorders. However, it has a very short duration of action and several analogues of somatostatin have been produced in an attempt to prolong its activity as well as making its inhibitory effects more specific. Octreotide (p. 1924.1) and lanreotide (p. 1923.2) are such analogues.

Somatostatin is usually given as the acetate. In the treatment of gastrointestinal haemorrhage, such as acute bleeding from oesophageal varices, somatostatin acetate equivalent to somatostatin 250 micrograms has been given by intravenous bolus over 3 to 5 minutes, followed by a continuous infusion of 250 micrograms/hour (about 3.5 micrograms/kg per hour) until the bleeding has stopped, which is usually within 12 to 24 hours. The infusion may then be continued for a further 48 to 72 hours to prevent recurrent bleeding. In some cases, the infusion may be continued to a maximum of 120 hours.

Malignant neoplasms. Somatostatin given with melatonin, bromocriptine, and a solution of retinoids (the Di Bella regimen) was ineffective in the treatment of advanced malignancies (see Malignant Neoplasms, under Uses and Administration of Octreotide, p. 1926.2).

Adverse Effects and Precautions

Abdominal discomfort, flushing, nausea, and bradycardia have been associated with too rapid infusion. Because of the short half-life of somatostatin adverse effects are generally transitory on stopping or reducing the infusion. Giving with parenteral nutrition has been suggested because of the inhibitory effects of somatostatin on intestinal absorption; blood glucose should be monitored since somatostatin may interfere with the secretion of insulin and glucagon. Allergic reactions have also been reported.

Effects on the kidneys. Somatostatin has been reported to have an inhibitory effect on renal function[1,2] and severe water retention and hyponatraemia have been reported.[3]

Tesamorelin Acetate *(USAN, rINNM)*

Acetato de tesamorelina; Tésamoréline, Acétate de; Tesamorelini Acetas; TH-9507; Тезаморелина Ацетат.

(3*E*)-Hex-3-enoylsomatoliberin (human) acetate.

$C_{221}H_{366}N_{72}O_{67}S.xC_2H_4O_2$=5135.9 (tesamorelin).

CAS — 901758-09-6.

UNII — LGW5H38VE3.

Uses and Administration

Tesamorelin is a synthetic analogue of somatorelin (p. 1930.1) used for the reduction of excess abdominal fat in HIV-associated lipodystrophy. It is given subcutaneously as the acetate in a dose equivalent to 2 mg of tesamorelin daily.

6. Stanley TL, *et al.* Reduction in visceral adiposity is associated with an improved metabolic profile in HIV-infected patients receiving tesamorelin. *Clin Infect Dis* 2012; 54: 1642–51.

Adverse Effects and Precautions

Tesamorelin may cause hypersensitivity reactions such as rash and urticaria and adverse effects associated with released growth hormone such as arthralgia, extremity pain, peripheral oedema, hyperglycaemia, and carpal tunnel syndrome may occur. Additionally, injection site reactions can include erythema, pruritus, pain, urticaria, irritation, swelling, and haemorrhage.

Tesamorelin is contra-indicated in active malignancy and any pre-existing malignancy should be inactive and treatment complete before starting tesamorelin. It is also contra-indicated in patients with disruption of the hypothalamic-pituitary axis due to hypophysectomy, hypopituitarism, pituitary tumour or surgery, head irradiation, or head trauma. Tesamorelin is contra-indicated in pregnancy.

Insulin-like growth factor I should be monitored and tesamorelin stopped if the former becomes persistently elevated. Impaired glucose metabolism has been reported and therefore also requires monitoring. Stopping tesamorelin should be considered in the event of critical illness.

References.

1. Falutz J, *et al.* Long-term safety and effects of tesamorelin, a growth hormone-releasing factor analogue, in HIV patients with abdominal fat accumulation. *AIDS* 2008; 22: 1719–28.

Interactions

Since tesamorelin stimulates growth hormone production, they may have similar interactions (see p. 1923.1).

Pharmacokinetics

The absolute bioavailability of tesamorelin after a 2-mg subcutaneous dose was less than 4% in healthy adults. The mean elimination half-life of tesamorelin was 26 minutes in healthy subjects and 38 minutes in HIV-infected patients.

NOTE. The names Docrised, Octastatin, and Sanvar have been used as trade marks for vapreotide acetate.

Profile

Vapreotide is a somatostatin analogue similar to octreotide (p. 1924.1). It has been investigated in the management of various disorders, including bleeding oesophageal varices, gastrointestinal and pancreatic fistulas, acromegaly, carcinoid tumours, and for the prevention of postoperative complications after pancreatic surgery.

The compounds described in this chapter are used in diseases considered to have an auto-immune component, and in organ and tissue transplantation. Some other important drugs used for their immunosuppressant properties are described under Antineoplastics, p. 691.1 and Corticosteroids, p. 1597.1. The choice of an immunosuppressant is discussed below.

Choice of Immunosuppressant

Asthma

Immunosuppressant drugs do not play a role in the regular management of asthma (p. 1195.2). In individual patients requiring oral corticosteroids for chronic severe asthma immunosuppressants have however been investigated for their anti-inflammatory and corticosteroid-sparing properties.

Blood disorders

For the use of immunosuppressants in aplastic anaemia, see p. 1121.3.

Diabetes mellitus

For mention of the use of immunosuppressants in recent-onset type 1 diabetes, see Prevention of Diabetes Mellitus, p. 460.3. See also Pancreatic Transplantation, p. 1938.1.

Gastrointestinal disorders

Inflammatory bowel disease. A number of immunosuppressants have been tried in inflammatory bowel disease (p. 1808.3), with some success, but the mainstays of drug therapy remain the aminosalicylates and the corticosteroids. Immunosuppressants may be valuable in some circumstances for their corticosteroid-sparing effect and for chronic active disease refractory to other treatments.

Liver disorders

For a discussion of the role of immunosuppressants, and particularly azathioprine, in the management of chronic active hepatitis, see p. 1602.3. For the use of immunosuppressants in primary biliary cirrhosis see under Ursodeoxycholic Acid, p. 2638.3.

Lung disorders

Interstitial lung disease. Corticosteroids have been used with azathioprine (or occasionally cyclophosphamide), for the treatment of various forms of interstitial lung disease (p. 1607.1).

Neurological disorders

Multiple sclerosis. Immunosuppressants have been tried in the treatment of multiple sclerosis (p. 996.3), although in some studies the benefit obtained may have been outweighed by toxicity.

Myasthenia gravis. Patients with myasthenia gravis (p. 684.1) who require immunosuppression are usually treated with corticosteroids. Other immunosuppressants such as azathioprine, ciclosporin, mycophenolate mofetil, and tacrolimus have been tried mainly for their corticosteroid-sparing effect but may also be of use when corticosteroids are contra-indicated or when response to their use alone is insufficient.

Ocular disorders

Immunosuppressants have been used with some success in ocular disorders with inflammatory or immunological components. In *scleritis* and *uveitis* (see p. 1612.3 and p. 1615.1) corticosteroids, given topically, intra-ocularly, or systemically are widely used when treatment is needed, but in unresponsive disease, or in patients with unacceptable adverse effects, immunosuppressants such as azathioprine, ciclosporin, or mycophenolate mofetil, may be given. Daclizumab, leflunomide, sirolimus, and tacrolimus have also been tried in uveitis. Immunosuppressants may be valuable in the management of *Behçet's disease*, *rheumatoid arthritis*, or *Wegener's granulomatosis*, (see p. 1601.1, p. 13.2, and p. 1615.2, respectively), including their associated ocular lesions. Ciclosporin or azathioprine have been used with corticosteroids in the management of both ocular and vascular symptoms of *Cogan's syndrome* (p. 1603.2). Ciclosporin has also been used topically in corneal ulceration, see p. 1947.1.

Ciclosporin or methotrexate may be options in the treatment of *Graves' ophthalmopathy* (see under Hyperthyroidism, p. 2332.2).

Organ and tissue transplantation

Although surgical techniques suitable for the removal of organs and tissues from a donor, and their engraftment into a host, have existed for many years, such grafts would not normally survive for long. The host's CD4+ T-cells recognise foreign antigens from donor cells. A CD4+ cell is then activated by antigen-presenting cells to secrete interleukin-2 and induce T-cell proliferation. Activated T-cells mediate a rejection response, by increasing the activity and function of B-cells, cytotoxic CD8+ T-cells, and macrophages, either directly, or by cytokine release. Only from the 1960s with the development of drugs capable of attenuating or suppressing this response, did transplantation start to become a feasible mode of treatment.

The drugs available vary in their mechanisms of action, and are often combined for optimum effect. **Corticosteroids** (glucocorticoids) act at several points in the immune cascade, including antigen recognition and production of lymphokines. The **calcineurin inhibitors** ciclosporin and tacrolimus prevent formation of cytotoxic T-cells by inhibiting calcineurin activation, an important step in the release of interleukin-2 from helper T-cells, while polyclonal or monoclonal **antibodies** such as antilymphocyte immunoglobulins and muromonab-CD3 bind to and deplete T-cell populations. Basiliximab and daclizumab function as **interleukin-2 receptor antagonists**. **Antiproliferative drugs** such as azathioprine and mycophenolate mofetil act by preventing cell division of lymphocytes. Sirolimus and everolimus are **proliferation signal inhibitors** that inhibit the T-cell response to cytokines.

Immunosuppressant regimens may be divided into those aimed at:

- prevention of rejection in the early period after transplantation
- long-term maintenance prophylaxis
- treatment of acute episodes of rejection.

In haematopoietic stem cell transplantation, where an immunologically competent tissue is transplanted, it is the donor cells which attack host tissues (graft-versus-host disease), and immunosuppression is required for prophylaxis of this condition.

Because of the critical nature of the early stage, when the organ or tissue must recover normal function, and perhaps to permit better long-term tolerance, initial immunosuppressant regimens tend to use higher doses than maintenance therapy. Standard protocols are usually based around ciclosporin or tacrolimus, combined with corticosteroids and an anti-proliferative agent (triple therapy). Where appropriate, a course of monoclonal or polyclonal antibodies is added to the standard regimen for induction (quadruple therapy). This is usually only required in individuals at increased risk of acute rejection, such as children or patients with a previous transplant or pregnancy, multiple blood transfusions, or a poor HLA-matching. However, it also enables delayed introduction of ciclosporin or tacrolimus in patients at risk of nephrotoxicity, and the use of low-dose regimens, allowing for withdrawal of corticosteroids.

No one immunosuppressive regimen has been identified as being superior to others in pregnancy, and although there are known theoretical risks to mother and fetus, successful pregnancies are now common in transplant recipients. The incidence of structural malformation has not been noted to be increased compared with the general population, but newer regimens have yet to be evaluated.

Since immunosuppressant therapy must in most cases be given for the lifetime of the graft, in long-term maintenance the toxicity of the drugs used, and the risks of infection, neoplasia, post-transplant diabetes mellitus, gout, hyperlipidaemia, and osteoporosis, must be considered. Doses and numbers of drugs used tend to be reduced, and in particular there is a tendency to taper or even eliminate the doses of corticosteroids used in maintenance regimens because of the potential sequelae of prolonged corticosteroid use. Post-transplant cardiovascular disease is a leading cause of death and graft loss. The risk varies between types of transplant, and specific recommendations for prophylaxis may differ.

The use of less intensive maintenance regimens must be balanced against the risk of an acute rejection episode, and the likelihood of its responding to therapy. High-dose corticosteroids and polyclonal or monoclonal antibodies often play a role in the rescue therapy of patients with acute rejection episodes, although much depends upon the severity of the reaction, and whether such episodes have occurred previously.

The management of immunosuppression for the transplantation of particular organs is discussed in more detail below. With the use of suitable immunosuppressant regimens long-term graft survival can be obtained after transplantation. Ultimately, however, the complications of chronic rejection are likely to lead to loss of the graft: the induction of specific tolerance to the donor organ remains the goal of much research. In allogeneic haematopoietic stem cell transplantation, where the aim of immunosuppression is prevention of graft-versus-host disease rather than rejection, immunosuppressant therapy can often be tapered off and eventually withdrawn.

Much interest has been aroused by the possibility of organ transplants from *animals* genetically modified to reduce complement-mediated hyperacute rejection. It is not clear whether such xenotransplantation will require modified immunosuppressive regimens.

Corneal transplantation. For reference to the use of immunosuppressants to treat graft rejection after corneal transplant see Corneal Graft Rejection, p. 1603.3.

Haematopoietic stem cell transplantation. Haematopoietic stem cell transplantation (HSCT) is used in the treatment of a variety of malignancies, notably leukaemias and lymphomas; to permit the use of very high-dose chemotherapy in the management of some solid tumours (bone marrow rescue); and to treat some other serious disorders affecting the bone marrow, such as aplastic anaemia and the haemoglobinopathies.[1,2]

HSCT may be **autologous**, in which case the patient's own stem cells are harvested or **allogeneic**, where stem cells are harvested from a healthy donor matched as closely as possible for HLA type.[3,4] The haematopoietic stem cells themselves may be derived from:

- bone marrow (classical bone marrow transplantation, BMT)
- peripheral blood (peripheral blood stem cell transplantation, PBSCT)
- umbilical cord blood

PBSCT is convenient as collection does not require hospitalisation or general anaesthesia for the donor, and clinical studies have shown more rapid engraftment of neutrophils and platelets compared with BMT.[2,5-7] However, allogeneic PBSCT appears to increase the risk of graft-versus-host disease[1,2,6-10] (see below). Allogeneic PBSCT was associated with decreased relapse rates and improved disease-free survival but similar overall survival in adults, when compared with BMT.[6] However, in children, allogeneic PBSCT was associated with higher mortality and treatment failure than BMT although relapse rates were similar; advanced disease status and use of colony-stimulating factor were also associated with poorer outcome.[7] Use of umbilical cord blood is associated with slightly delayed engraftment,[2,11-13] and hence, perhaps, an increased risk of fatal infection,[2,11] but a lower risk[2,12,14] of graft-versus-host disease (see below). A meta-analysis[15] confirmed these findings, but found a similar relapse rate, and equivalent survival for cord blood transplantation compared with unrelated BMT. It has mainly been used for transplants in children, since the total number of stem cells in a donation often falls short of the levels deemed necessary for engraftment in an adult.[1,2,5,13] However, cord blood is increasingly used for transplants in adults.[16] Since cell dose correlated with outcome in most studies, strategies have been developed to increase progenitor cell numbers in the cord blood units; techniques include pooled or sequential cord blood transplantation, or expansion of the cord blood cells with cytokines. Combination cord blood and bone marrow transplants, and reduced intensity regimens are under investigation.[16-18]

With autologous HSCT problems of **compatibility** do not arise, but if abnormal cell clones are present in the marrow (as in leukaemia) or stem cells they may be transferred back into the patient and cause disease relapse.[1] Allogeneic HSCT requires immunosuppression for about 6 months[19] to prevent graft-versus-host disease (see below) until a new immunological balance is achieved.

The patient is normally prepared by **conditioning** with total body irradiation, or myeloablative chemotherapy with drugs such as cyclophosphamide or busulfan, or more often both, in order to destroy host bone marrow cells.[5,20] In autologous procedures, harvesting of bone marrow or peripheral blood must be carried out before conditioning. Bone marrow is aspirated from the donor, and infused into the recipient via an indwelling catheter or directly into a peripheral vein. Peripheral blood stem cells are collected by cell separation after mobilisation, which is best achieved by a combination of chemotherapy and granulocyte or granulocyte-macrophage colony-stimulating factor.[1,2,5] Infection is a major cause of morbidity and mortality after transplantation, so prophylactic cover with antimicrobials[2,21,22] and normal immunoglobulins has been recommended,[21] although the value of the latter has been questioned.[23] A subsequent systematic review[24] found no advantage for immunoglobulin prophylaxis in terms of survival or infection prevention; they increased the risk for veno-occlusive disease (VOD), but decreased the rate of interstitial pneumonitis. The authors concluded the evidence did not support the routine use of immunoglobulin prophylaxis for HSCT. Granulocyte colony-stimulating factors are sometimes used after allogeneic transplants to hasten haematopoietic recovery. While a meta-analysis found no evidence for an increase in risk for acute or chronic graft-versus-host disease,[25] a large study found delayed platelet engraftment, increased graft-versus-host disease, and increased mortality in those given growth factors after allogeneic bone marrow transplants; these effects were not seen in patients given allogeneic PBSCT.[26]

In addition to such supportive care, patients who have received allogeneic transplants require immunosuppressive therapy aimed at the prevention of **graft-versus-host disease** (GVHD). GVHD is usually characterised as *acute* or *chronic* depending on the manifestations, and the time of presentation[1,4,5,10,27-30] (by convention acute disease occurs within a hundred days of transplantation, and chronic disease after this time, although in practice there is considerable overlap).

The organ systems mainly affected are skin, liver, lung, and gastrointestinal tract. Both forms are marked by maculopapular rashes, which in severe disease may progress to bullous lesions and epidermal necrolysis. Liver disease may include cholestatic jaundice (usually in the acute form) and hepatitis; symptoms may need to be distinguished from the VOD which sometimes complicates bone marrow transplantation and is due to the pre-transplant conditioning regimen (VOD may respond to treatment with antithrombin III[31] or defibrotide[32,33]). Ursodeoxycholic acid has been found to be of benefit for the prophylaxis of hepatic complications.[34] The main symptom of gastrointestinal GVHD is diarrhoea, often severe and painful. In patients with chronic GVHD other manifestations may include arthritis, mucositis, lung disease (bronchiolitis *obliterans*), and scleroderma.

Most modern regimens for the *prophylaxis* of GVHD after allogeneic HSCT are based on ciclosporin. Although GVHD still occurs in many ciclosporin-treated patients, morbidity is much reduced and survival improved. Combination regimens have been tried for prophylaxis, particularly ciclosporin or tacrolimus with methotrexate, but also combinations with other drugs including antilymphocyte immunoglobulins, corticosteroids, mycophenolate mofetil, and sirolimus.[9,19,35] After allogeneic myeloablative HSCT, adding corticosteroids to the prophylactic regimen has been found to reduce the incidence of moderately severe acute GVHD, but no benefit has been noted for survival.[36] Monoclonal antibodies have been used to produce T-cell depletion or reduce the effects of circulating cytokines,[9,28] and it has been suggested that RNA interference may have a potential role.[37]

Acute GVHD is usually *treated* mainly by the addition of corticosteroids (usually methylprednisolone) to the existing regimen until symptoms are controlled, followed by gradual tapering of the dose. Mycophenolate mofetil, antilymphocyte immunoglobulins, interleukin-2 receptor antibodies, etanercept, and infliximab have also been tried.[2,9,19,38-40] PUVA therapy and extracorporeal photopheresis have been used[2,9,30] and infusion of mesenchymal stem cells is also under investigation.[9,30,41]

Chronic GVHD has no specific standard therapy; most centres use a combination of corticosteroids and a calcineurin inhibitor (ciclosporin or tacrolimus).[2,10,19,30,42,43] Drugs that have been tried for salvage therapy include mycophenolate mofetil, sirolimus, daclizumab, thalidomide, pentostatin, etanercept, infliximab, and rituximab.[10,19,39,42] PUVA therapy with extracorporeal photopheresis has also been used, with good response rates,[10,42] and recommendations for use have been published in the UK.[44] Mesenchymal stem cell infusion may be a potential therapy.[10] Octreotide is recommended for the symptomatic treatment of diarrhoea.[45]

Donor T-cells reactive to recipient minor histocompatibility antigens can inhibit the growth of abnormal cells, and may also target aberrantly expressed proteins, provoking a 'graft-versus-tumour' effect, which reduces relapse, both after allogeneic transplantation and among patients in whom GVHD develops.[1] Indeed, many leukaemia patients who relapse after allogeneic transplant can be reinduced into remission by an additional infusion of donor lymphocytes.[2] Consequently, too effective an immunosuppressant regimen may not always be desirable, and leukaemic patients given bone marrow transplants purged of T-cells, which virtually abolishes GVHD, do not have a better survival rate than those given conventional prophylaxis (engraftment too is reduced in the absence of all T-cells). Specific donor marrow T-cell depletion has been investigated as the sole form of GVHD prophylaxis.[46] In a multicentre randomised study, marrow T-cell depletion was found to reduce but not abolish the incidence of acute GVHD, accelerate neutrophil recovery and reduce toxicity compared with transplantation with T-cell replete marrow; however, disease-free survival at 3 years did not differ due to higher rates of relapse in some patients, and a higher incidence of serious infection in T-cell depleted marrow recipients.[47] The observation of graft-versus-malignancy effects has led to the development of low-dose non-myeloablative conditioning regimens (with or without donor lymphocyte infusions) for elderly or more sensitive patients who might have been unable to receive the standard aggressive therapy.[1-3,15,48-52] Fludarabine is commonly used in reduced-intensity conditioning regimens, often combined with other drugs such as busulfan or melphalan, or with low-dose total body irradiation.[53] Safety and efficacy of these reduced-intensity regimens has led to wider application;[1] however, the lower mortality rate may be offset by a higher relapse rate,[1] and poor engraftment.[2]

An uncommon complication of HSCT is **transplantation-associated thrombotic microangiopathy** which is a thrombotic thrombocytopenic purpura that presents as a microangiopathic haemolytic anaemia. Calcineurin inhibitors have been linked to its development, and initial treatment involves replacing ciclosporin or tacrolimus with alternative immunosuppressants. Improvement has been reported when daclizumab has replaced a calcineurin inhibitor; defibrotide and rituximab have also been used in small numbers of patients.[54]

The combination of irradiation, chemotherapy, and immunosuppression can cause the development of **secondary malignancies** in long-term survivors of HSCT.[1,55-58]

Intracoronary injection of haematopoietic stem cells into the heart is under investigation for cardiac disease,[59] **intramuscular** injection has also been investigated in peripheral vascular disease.[60] There is also interest in HSCT in some auto-immune disorders.[60]

Heart transplantation. Marked improvements have been seen in the outcome of heart transplantation since the introduction of ciclosporin, which has resulted in a reduced incidence and severity of rejection episodes.[1] The 1-year survival rate is about 80%.[1,2]

A common **immunosuppressive regimen** consists of triple therapy with ciclosporin or tacrolimus, azathioprine or mycophenolate, and corticosteroids.[3–6] Some centres also use induction therapy with antilymphocyte immunoglobulins (polyclonal antibodies) or muromonab-CD3.[4,7]

Induction therapy increases the risk of infection and lymphoproliferative disorders, but does delay the first rejection episode and allows transplantation in higher risk groups. It also enables calcineurin inhibitor use to be delayed in patients with initial poor renal function[7] and corticosteroids to be stopped as maintenance therapy in some groups of patients.[8] Muromonab-CD3 may be associated with a higher incidence of adverse reactions than polyclonal antibodies. Sensitisation to muromonab-CD3 is strongly associated with vascular rejection, and this and the dose-related propensity for lymphoproliferative disease with muromonab-CD3 have led to a decline in its use; some consider it should be abandoned in favour of polyclonal preparations.[7,9] The interleukin-2 receptor antibodies basiliximab and daclizumab have also been used for induction therapy.[2,7,10,11] However, daclizumab use has been associated with an increased risk of death due to infection, mostly in patients given additional immunosuppressive treatment with antilymphocyte drugs for early postoperative complications.[11] The interleukin-2 receptor antibodies have not as yet been associated with an additional risk of malignancies.[7] Alemtuzumab is under investigation for induction therapy in heart transplantation.[7,9]

There does not seem to be any great clinical benefit of tacrolimus over ciclosporin in heart transplant patients,[9,12,13] although some have reported reduced rates of histological rejection,[14,15] and there is evidence that patients of Afro-Caribbean origin in particular may be more prone to acute rejection with ciclosporin than with tacrolimus.[16] It has been suggested that tacrolimus be substituted for ciclosporin in those patients suffering persistent rejection, or adverse effects associated with ciclosporin,[17] or with hyperlipidaemia or hypertension.[18] Microemulsifying ciclosporin may be associated with less rejection than the oil-based formulation.[19]

The use of mycophenolate mofetil instead of azathioprine in triple therapy has been shown to reduce mortality and rejection in the first year after heart transplantation,[20] and a retrospective review[21] concluded that the advent of mycophenolate mofetil has contributed to improved survival in cardiac transplant recipients. Although lower mycophenolic acid (MPA) concentrations may be associated with an increased allograft rejection,[22] there appears to be no benefit in monitoring MPA concentrations beyond the first year in heart transplant recipients,[23] and MPA levels may be affected by concomitant immunosuppression, see Immunosuppressants under Interactions of Mycophenolate, p. 1964.2.

Many variations of regimens exist, and different drugs have been substituted or used adjunctively in order to decrease the doses, and thus alleviate the adverse effects associated with calcineurin inhibitors and/or corticosteroids. Substituting cyclophosphamide for azathioprine for 6 weeks after transplantation is reported to reduce the development of anti-muromonab-CD3 antibodies from induction therapy.[24] Substitution of mycophenolate mofetil with intravenous pulse cyclophosphamide for 4 months post-transplantation appeared to decrease the risk of rejection in a small, non-randomised study in sensitised allograft recipients.[25]

Alternative adjunctive therapies are the proliferation signal inhibitors, sirolimus and everolimus,[2,9] which allow for use of lower doses of calcineurin inhibitors, thus preserving renal function; however, long-term data are limited, and there is little experience with these drugs in paediatric patients. Use of sirolimus with ciclosporin and corticosteroids markedly reduced the incidence of acute rejection in a small open-label study.[26] However, the use of sirolimus with mycophenolate mofetil was associated with a higher than expected incidence of acute rejection in cardiac transplant patients switched from calcineurin inhibitors to this combination.[27]

It has been suggested that the high doses of corticosteroids used increase the risk of cardiac adverse events in the longer term, and protocols that wean patients from corticosteroids after 6 months postoperatively have been used,[28,29] without apparent increases in infection or rejection. Corticosteroid avoidance or early withdrawal regimens are feasible in many, if not most, paediatric heart transplant recipients.[9]

In the early post-transplant period, the most significant causes of **morbidity** are infection and rejection episodes.[8,9] Other complications post-transplant include right ventricular failure and cardiac arrhythmias.[30] Co-trimoxazole is used to protect against *Pneumocystis jirovecii* infection, and ganciclovir as prophylaxis against CMV.[3] Rejection is usually treated with corticosteroids, but other drugs have been used for corticosteroid-resistant cases,[8] including antilymphocyte immunoglobulins and muromonab-CD3.[4,29] In repetitive rejection, tacrolimus may be substituted for ciclosporin, and mycophenolate mofetil for azathioprine.[4,5] Adjunctive methotrexate, total lymphoid irradiation and photopheresis have all been tried.[8]

In the late post-transplant period, malignancy and coronary artery disease are the most significant problems.[3,7,8] About 5% of paediatric heart transplant recipients have been reported to develop post-transplant lymphoproliferative disease (PTLD).[2,31] The strongest risk factor for PTLD is the development of primary Epstein-Barr virus infection after transplantation although children who are seropositive for the virus are not necessarily protected from this complication.[2,9] Despite treatment with chemotherapy or a reduction in immunosuppression, PTLD is associated with significant morbidity and mortality; acute rejection may occur in those whose immunosuppression is reduced.[2] Rituximab and cellular immunotherapy are novel therapeutic approaches for PTLD.[9] Cardiac allograft vasculopathy (also termed coronary artery vasculopathy, or chronic rejection) is a major cause of death and prevention of its progression is a major therapeutic goal.[2,3,9,32,33] It is thought to be mainly an immunological response, but can be accelerated by recipient risk factors such as age, gender, obesity, hyperlipidaemia, hypertension, smoking, diabetes mellitus, pretransplant heart disease, postoperative CMV infection, and immunosuppression itself as well as donor risk factors such as age, gender, and hypertension.[3,6,8,34,35] Long-term use of calcineurin inhibitors is associated with renal dysfunction and also contributes to hypertension and hyperlipidaemia, all of which may exacerbate cardiac allograft vasculopathy.[33] Calcium-channel blockers have been used to decrease the incidence of coronary artery disease, but it has remained a difficult complication to treat.[34] HMG-CoA reductase inhibitors such as pravastatin and simvastatin are recommended[34,37] for the treatment of hyperlipidaemia: pravastatin or atorvastatin have been used in paediatric heart transplant patients.[2] There is evidence that statin therapy substantially improves survival.[38] Fibric acid derivatives may be considered in those patients with hypertriglyceridaemia not controlled by diet alone.[37] Supplementation with antioxidant vitamins such as C or E may reduce the progression of arteriosclerosis after transplantation,[39] and a small study[40] found that omega-3 fatty acids improved blood pressure control in hypertensive transplant recipients. There is some suggestion that sirolimus[26,41] and everolimus[42] may be of benefit in preventing cardiac allograft vasculopathy in adults; data are lacking in paediatric patients.[2,9] Retransplantation for graft failure due to cardiac allograft vasculopathy may be necessary.[33]

Improved surgical techniques and the use of ciclosporin have also made possible successful combined *heart-lung* transplants, although these may require enhanced or modified immunosuppression to prevent obliterative bronchiolitis, a possible manifestation of chronic rejection.[43] Early rejection after transplantation is the most important risk factor for the development of bronchiolitis obliterans syndrome although pathogenesis is unclear.[44] Lung infection,[43] or oxidative stress and lack of glutathione[44] may be factors in the aggravation or onset of bronchiolitis obliterans syndrome.

Donor-specific tolerance, whereby the patient permanently accepts their graft without the need for long-term immunosuppression, while remaining immunocompetent, remains the ultimate goal in cardiac transplantation.[6,9]
